

**Acerca de este libro**

Esta es una copia digital de un libro que, durante generaciones, se ha conservado en las estanterías de una biblioteca, hasta que Google ha decidido escanearlo como parte de un proyecto que pretende que sea posible descubrir en línea libros de todo el mundo.

Ha sobrevivido tantos años como para que los derechos de autor hayan expirado y el libro pase a ser de dominio público. El que un libro sea de dominio público significa que nunca ha estado protegido por derechos de autor, o bien que el período legal de estos derechos ya ha expirado. Es posible que una misma obra sea de dominio público en unos países y, sin embargo, no lo sea en otros. Los libros de dominio público son nuestras puertas hacia el pasado, suponen un patrimonio histórico, cultural y de conocimientos que, a menudo, resulta difícil de descubrir.

Todas las anotaciones, marcas y otras señales en los márgenes que estén presentes en el volumen original aparecerán también en este archivo como testimonio del largo viaje que el libro ha recorrido desde el editor hasta la biblioteca y, finalmente, hasta usted.

**Normas de uso**

Google se enorgullece de poder colaborar con distintas bibliotecas para digitalizar los materiales de dominio público a fin de hacerlos accesibles a todo el mundo. Los libros de dominio público son patrimonio de todos, nosotros somos sus humildes guardianes. No obstante, se trata de un trabajo caro. Por este motivo, y para poder ofrecer este recurso, hemos tomado medidas para evitar que se produzca un abuso por parte de terceros con fines comerciales, y hemos incluido restricciones técnicas sobre las solicitudes automatizadas.

Asimismo, le pedimos que:

+ *Haga un uso exclusivamente no comercial de estos archivos* Hemos diseñado la Búsqueda de libros de Google para el uso de particulares; como tal, le pedimos que utilice estos archivos con fines personales, y no comerciales.

+ *No envíe solicitudes automatizadas* Por favor, no envíe solicitudes automatizadas de ningún tipo al sistema de Google. Si está llevando a cabo una investigación sobre traducción automática, reconocimiento óptico de caracteres u otros campos para los que resulte útil disfrutar de acceso a una gran cantidad de texto, por favor, envíenos un mensaje. Fomentamos el uso de materiales de dominio público con estos propósitos y seguro que podremos ayudarle.

+ *Conserve la atribución* La filigrana de Google que verá en todos los archivos es fundamental para informar a los usuarios sobre este proyecto y ayudarles a encontrar materiales adicionales en la Búsqueda de libros de Google. Por favor, no la elimine.

+ *Manténgase siempre dentro de la legalidad* Sea cual sea el uso que haga de estos materiales, recuerde que es responsable de asegurarse de que todo lo que hace es legal. No dé por sentado que, por el hecho de que una obra se considere de dominio público para los usuarios de los Estados Unidos, lo será también para los usuarios de otros países. La legislación sobre derechos de autor varía de un país a otro, y no podemos facilitar información sobre si está permitido un uso específico de algún libro. Por favor, no suponga que la aparición de un libro en nuestro programa significa que se puede utilizar de igual manera en todo el mundo. La responsabilidad ante la infracción de los derechos de autor puede ser muy grave.

**Acerca de la Búsqueda de libros de Google**

El objetivo de Google consiste en organizar información procedente de todo el mundo y hacerla accesible y útil de forma universal. El programa de Búsqueda de libros de Google ayuda a los lectores a descubrir los libros de todo el mundo a la vez que ayuda a autores y editores a llegar a nuevas audiencias. Podrá realizar búsquedas en el texto completo de este libro en la web, en la página `http://books.google.com`

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

**Usage guidelines**

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

**About Google Book Search**

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

# GENERAL INDEX

** References to Notes in "Among Our Contemporaries" are distinguished by a star preceding the page number.*

## A

Agriculture, Electricity in..... *19
Aluminum electrical conductors..... 77
——History, manufacture and use of.... 194
——in printing, Use of..... 416
——railway feeders..... 339
——soldering ..... 572
——wire for fire-alarm purposes..... 565
Alternating-current arc..... *336
——Calculation of..... 139
——circuits, Drop in..... 119
——distribution, single-phase..... 328
——distribution, two-phase current in N. Y. City..... 328
——fan motors, Operation of, at different frequencies, P. M. Heldt..... 351
——generation and distribution, changes contemplated in Atlanta..... 333
——motors, Synchronous and induction, Ernst J. Berg.....17, 63
——Lessons in..... 90
——regulation, New departure in..... 525
——switchboard connections..... 509
Amalgamating zinc plates for batteries ...*172
Ammeter (Electrical Catechism)..... 41
——without commutator, Direct-current integrating ..... *412
Amyl acetate lamp, Prof. Wilbur M. Stine 208
Anesthetics, dental, The electrical application of..... 523
Annunciator mechanism, Star Electric Company ..... 585
Annunciators, Star Electric Company..... 443
Arc, Hissing..... *220
——lamp, Belden enclosed..... 493
——coupling ..... *655
——factory testing room, Standard Thermometer and Electric Co..... 45
——hanger, Insulated, Ohio Brass Co..... 196
——The Morris..... 245
——"Petite" alternating..... 400
——Small, Safford Arc Lamp Manufacturing Co..... 49
——Toerring, long burning..... 441
Arc lamps, Hand-feed, Baker & Fox..... 100
——on incandescent circuits..... *219
——Starting device for (patent)..... 520
Arc light, enclosed, Loss of light in..... *414
——systems, A comparison in the economy of two..... 324
Arc lighting, carbons for..... 295
——plant for Fire Department use..... 565
Arc lights from alternating generators.... 280
Arc line trouble, Peculiar, Hervey Scofield ..... 352
Arc line trouble, Peculiar, Geo. M. Ockford ..... 575
Arc system, Series alternating current, in Hartford.....323, 489
Arcs and non-arcing metals, Geo. T. Hanchett ..... 16
Armature, How to balance an..... *221
——reaction in alternating dynamos..... 179
Armatures, Simple method of testing..... 417
——Testing of, Thomas Barnard..... 352
Arnold Electric Power Station Company, The history and present status of.. 489
——system ..... 451
Asbestos, Insulating paper and board from, Asbestos Insulating Co..... 101
Auburn Station of the Central California Electric Co..... 405
Aultman chains for power transmission and conveying purposes..... 365
Automobile carrying its own generating station ..... 223
——Combined gasoline and electric, Munson Co. ..... 362
——Combined hydrocarbon and electric motor ..... *468
Automobiles, Comparison of..... *169
——controlling apparatus of (patent)..... 176
——in Germany..... *337
——Relation of, to central stations..... 75

## B

Babbitt metal, Effect of heat on..... 531
Barber shop, An electrical..... *20
Battery (see Storage).
——gauge, Pocket, Standard Electric Time Co..... 99
——New primary, for power purposes....*170
——Pullen ..... 582
——Regenerative primary..... *336
Batteries, Bunsen cells, modified..... *114
Bell, Monitor electric, Rousseau's Electrical Works..... 244
Bell wiring, Novel system of, F. M. Swalm ..... 532
Binding post, Improved (patent)..... 470
Blast furnace gases, Electrical energy from ..... *217
Bleaching solutions, Electrolytic production of..... *114
Blow pipe, Electric..... *21
Boiler cleaner, Water-tube, Union Boiler Tube Cleaner Company..... 151
——cleaners of the blow-off type..... 530
——compounds, Sight-feed device for, Hall Compound Feeder Co..... 499
——feeding apparatus..... 40
——feed waters, Scientific treatment of impure, J. H. Parsons..... 435
——plant with small repair account, Hazelton ..... 443
——tube cleaning, A difficult case of, Chicago Boiler Tube Cleaner Co..... 47
Boilers, Aultman & Taylor (Cahall)..... 44
——Methods of keeping clean..... 525
Books, New:
—Alternating-Current Wiring and Distribution, W. L. R. Emmet..... 103
—American Electrical Cases, W. W. Morrill ..... 310
—Columbia Engineer, The..... 586
—Commercial and Business Aspects of Municipal Electricity Supply, Alfred H. Gibbings..... 366
—Construction and Repair of Commutators, L. C. Sharp..... 541
—Diagrams and Handbook for Telegraph Engineers, W. H. Jones..... 403
—Electricity in the Diagnosis and Treatment of the Diseases of the Nose, Throat and Ear, W. Scheppergrell, A. M., M. D..... 104
—Electricity in Town and Country Houses, Percy E. Scrutton..... 248
—Electrodynamics, Prof. C. A. Carus-Wilson ..... 103
—Elements of Physics, The..... 444
—Hand-Book of the Corliss Steam Engines, F. W. Shillitto ..... 103
—Indicator Handbook, The, Chas. N. Pickworth ..... 403
—Internal Wiring of Buildings, The, H. M. Leaf..... 499
—Lighting by Acetylene, Wm. E. Hibbs, M. C..... 53
—Liquid Air and the Liquefaction of Gases, T. O. Sloane..... 310
—Magnets and Electric Currents. J. A. Fleming ..... 104
—Matter, Energy, Force and Work. Prof. S. W. Holman..... 104
—Mechanical Movements. Gardner D. Hiscox ..... 499
—Petroleum Motor Cars. Louis Lockert. 53
—Pocket Dictionary of Electrical Words, Terms and Phrases. Edwin J. Houston, Ph. D..... 103
—Practical Electricity. J. C. Lincoln.... 444
—Premiers Principes d'Electricite Industrielle. Paul Janet..... 366
—Shop and Road Testing of Dynamos and Motors. Eugene C. Parham and John C. Shedd..... 53
—Slide Rule, The. Chas. N. Pickworth... 403
—Slide Valve, The. W. J. Tenant..... 499
—Steam Engine Indicator. F. R. Low.... 310
—Twentieth Century Magic..... 103
—Twentieth Century Sketch Book for Schools, Colleges and Practical Men. M. A. Avery..... 103
Booster, Storage battery. Bullock..... 441
Boring machine, Electricians'. G. & E. Electric Co..... 48
——Machine, Roberts..... 441
——tool, American Electric Company.... 364
Boston Electric Light Company, central station of..... 265
Bradford, Pa., A gas engine central station at..... 407
Bradstreet Company, electricity used in printing ..... 105
Brake, Novel electro-magnet..... *515
——Sterling safety..... 248
Brush resistance in measuring the efficiency of dynamos..... *274
——The use of a third..... *277
Brush holder, improved..... 539
——Reaction type (patent)..... 563
Brushes, carbon, Contact resistance of....*415
——made of alloys..... *219
Bullock Electric Mfg. Co., A modern plant for the manufacture of dynamos and motors ..... 360
Bunsen Flame, Temperature of..... *338
Buoy, life, Electrically lighted..... *379

## C

Cable head and distributing box, Moon Mfg. Co..... 495
——ship, The first U. S. Government..... 278
——supporting clip, Barron & Co..... 442
——testing outfit, Portable, Queen & Co. 307
Calcium carbide, Energy required for the production of..... *335
——manufacture of..... *19
Canal towage..... *117
Carbolite, A substitute for calcium carbide ..... *171
Carbon, Biography of arc lamp..... 96
Carbons ..... 295
Catechism, Electrical, 41, 93, 144, 191, 236, 293, 353, 394, 431, 494, 538 576
Central California Electric Company at Auburn ..... 405
Central station accident, An English..... 84
——Boston Electric Light Company..... 265
——Chicago Edison Company, Homer E. Niesz ..... 445
——Design ..... 74
——440 volt, in England..... *273
——A gas engine, at Bradford, Pa..... 407
——Imperial, St. Louis. H. H. Humphrey 553
——Louisville Electric Light Co. George Wilbur Hubley..... 367
——Merrill Railway & Lighting Company, F. E. Woodford..... 551
——Peculiar accident to..... 522
——practice worthy of imitation, Features of English..... 281
——Private ..... 203
——records, Card system of..... 146
——Wilmington City Electric Light Co., Wilmington, Del..... 43
Central stations, English..... 249
——Gas driven..... *21
——limited. Alton D. Adams..... 263
Cigar lighter, An electric. Stanley & Patterson ..... 101
Circuit breaker, Automatic. Fisher Electrical Mfg. Co..... 365
——for electric cars..... *414
——New "I. T. E."..... 363
——Relay, Ward Leonard Electric Co.... 243
Circuit breakers for flat rate customers.. 281
——time-element attachment for..... 563
Cling-surface, Tests of..... 242
Clocks, tower, Electrically illuminated. Edward Rowe..... 431
Club, A live electrical..... 458
Clutch, Dynamo and engine..... *414
Coal, Electricity direct from..... *118
Coal-handling equipment. Jas. F. Hobart. 428
——equipment of the Louisville Electric Light Company. Geo. Wilbur Hubley ..... 368
——machinery, Link Belt Engineering Co..... 50
Coal mining, Electrical installations in. Harry N. Gardner..... 373
——Electricity in..... 299
Coherer construction, Improvement in. Geo. T. Hanchett..... 393
——experiment, Interesting..... *171
Commutator design and construction. Alton D. Adams..... 568
——tools, Construction of. Alton D. Adams ..... 476
Commutators, their care and repair. Jos. H. Smith..... 138
Compensator, Mershon ..... 434
Compressed Air and liquid air..... 213
Condenser discharges, Measuring of ..... *170
Condensers, pumps and cooling towers of Imperial plant ..... 556
Conductors for the three-wire system. W. H. Donner ..... 27
——Weights of ..... *337
Conduit joints, Improved system of..... 514
Conduits for interior wiring. Charles E. Knox ..... 423
——Vitrified clay, for underground electric wires ..... 537
Consolidated Traction Co., Pittsburgh, Boiler equipment of new power station of ..... 398
Controllers, Cutler-Hammer ..... 308
Convention, Northwestern electrical ..... 73
Conveying machinery ..... 556
Cooking, Electric ..... 88
Copper, Electricity and the supply of.... 71
Corrosion of the leading-in wires of incandescent lamps. E. C. Meilloret... 431

Digitized by Google

Couplers, Van Dorn automatic..... 305
Crossing of an arc and alternating circuit. W. H. Coleman..... 292
Culm, Accumulations of, and utilization for power purposes. Harry N. Gardner ..... 163

D

Damper regulator, Hydraulic, Patterson Damper Regulator Co..... 200
Die sinker's engine. S. S. White Dental Co..... 248
Draft, Mechanical..... 147
——in Imperial plant..... 555
Drexel Institute course of electrical engineering ..... 471
Dynamo, alternating, Construction of fly-wheel (patent)..... 521
——"Ideal." F. A. LaRoche & Co..... 98
——Inductor. Royal Electric Co..... 199
——Unitooth ..... 335
——arc, Brush multi-circuit..... 436
——direct-connected, 100-kw., C. & C. Electric Co..... 51
——multipolar, E. G. Bernard Co..... 307
——Eight-pole and engine, B. F. Sturtevant Co..... 48
——field connections. J. C. Brown..... 91
——fields, Westinghouse..... 243
——for use with gas engines, E. G. Bernard Co..... 494
——High-tension, General Electric Co... 364
——How to design a..... 37
——inductor, An odd..... *467
——new Jantz and Leist..... 196
——Laminated pole (patent)..... 563
——Lundell direct-coupled..... 302
——Lundell split-pole..... 584
——marine, Bullock..... 583
——Model, Eldridge Electrical Mfg. Co.. 52
——multipolar, Marine type of, E. G. Bernard Co..... 52
——New type of, Louis D. Bliss..... 191
——Ringing, actuated by batteries, Eureka Electric Co..... 361
——testing, to find the turns in the shunt or series coil of a compound dynamo, L. E. Carpenter..... 575
——Tests of an induction..... 109
——Triumph Electric Co..... 101
Dynamos, alternating, Armature reaction in..... 179
——compensated for inductive loads..... 535
——Effect of capacity upon. J. A. Thunen..... 352
——Means of paralleling..... *561
——Paralleling of..... *277
——and motors, Mayer..... 248
——and motors, Multipolar..... 398
——and motors, Spherical, Roth Bros. & Co..... 309
——Brush resistance in measuring the efficiency of..... *274
——Double-current, Chicago Edison plant. Homer E. Niesz..... 445
——for Edison stations..... 474
——Field windings of. Prof. Arthur L. Rice..... 12
——Friction losses in..... *515
——Jenney four-pole..... 46
——Railway, Bullock..... 494
——testing, Simple method of..... *274
Dynamometer, cradle, Construction of. Prof. A. F. McKissick..... 409

E

Economics for small manufacturers. Lyman C. Reed..... 216
Edison Illuminating Company of N. Y., Annual report of..... 174
Education, Engineering..... 127
Electric Appliance Company, Supply house ..... 359
Electric Storage Battery Co., Annual report of..... 359
Electro-dynamometer, Siemens ..... 93
Electrolier, Automatic..... 309
Electromagnets, Power and pull of..... 76
——on cranes..... * 21
Electromagnetic stress..... 75
Engine cylinders, Effects of high-pressure steam on. F. W. Roller..... 165
Engines (see Steam Engines or Gas Engines).
——multiple expansion, Economy of. W. S. Aldrich..... 210-259
English central stations, Some..... 249
Ether waves..... 124
Exhaust steam heating..... 418
——Distribution of, American District Steam Co..... 304
——head, Sturtevant..... 498
Exhibition, The electrical..... 211
Exposition, National Export..... 542
Extractors, Oil and grease..... 573

F

Fan, exhaust, The Triumph..... 197
——Magneto battery, Ohio Electric Works..... 245
——motors, Alternating-current. P. M. Heldt..... 351
——1899 models..... 155
——Peerless, Victor Telephone Co..... 102
——Sturtevant ventilating..... 246
——suspended, Electric, B. F. Sturtevant Co..... 102
Feeders and mains. Chas. E. Knox..... 220
Feed-water heaters and purifiers, Hoppes Mfg. Co..... 540
——"Cookson"..... 201
——Otis..... 306
Feed-water heaters, return coil, Robertson Mfg. Co..... 48
——Value of. J. C. Jones..... 393
——vs. Economizers..... 385
Field connection, New (patent)..... 376
Filament of carbide of silicon..... *220
Firepot, Clayton & Lambert Mfg. Co..... 151
Floor outlets in large offices..... 474
Floor outlets in large offices. A. S. Howard..... 532
Forge blowers, Emerson Elec. Mfg. Co... 152
Foucault current losses, Separating, from others in dynamos..... *275
Frequencies..... * 71
Frequency changer (patent)..... 176
Fuel economizers..... 555
Furnace, The electric. Lieut. F. Jarvis Patten..... 6
——The experimental electric. Prof. Samuel A. Tucker..... 408
Furnaces, Three-phase..... *379
Fuse, High-tension..... * 72
——holder, Removable, Zimdars & Hunt 150
——Noark enclosed..... 366
——switch, Shunted, D. & W. Fuse Co.. 361
Fuses and other safety devices. W. L. R. Emmet..... 331
Fusible cut-outs, Design of. Benj. H. Glover..... 560
Fusing the neutral of a three-wire system *412

G

Galvanometer, D'Arsonval ..... 93
Galvanometers, Insulation and cable testing, Willyoung & Co..... 245
Gas burner, New ..... 341
Gas engine, driving, for small electric plants ..... *21
——central station at Bradford, Pa.... 407
——Columbus Machine Co..... 497
——Cornell ..... 498
——igniters, Induction coil for, Varley Duplex Magnet Co..... 196
——Largest ..... 522
——Standard Automatic ..... 578
——Westinghouse ..... 490
Gas Engines (see also oil engines).
——as power for railway plants..... 206
——in railway power plants ..... 224
Gaskets for packing purposes, U. S. Mineral Wool Co..... 402
Gas lighter, John Y. Parke..... 306
Gas works, Use of electricity in..... 573
General Electric Co., Annual report..... 221
General Electric Co.'s new iron foundry.. 195
Generators (see dynamos).
Gibraltar, Electric lighting of..... *115
Glass, Application of electricity to the manufacture of ..... *338
Governor, steam engine, Monarch Governor & Machine Co..... 50
Graphite, Artificial ..... 141
——The manufacture of..... 322
Ground detector, Electrostatic..... 192
——for three-wire systems, A. P. Kennedy ..... 483
Grounding device, Automatic, for secondary circuits (patent)..... 470
Gutta Percha, The exhaustion of..... *72

H

Hartford Electric Light Co., A simple two-phase system of secondary mains ..... 473
——The series alternating-current arc system in ..... 323
Heaters, bracket electric, Girard Electric Co. ..... 47
——High resistance materials for..... *172
Heating and ventilating system of a large telephone exchange..... 536
High-tension lines, Discharges from, Robert Fairbanks ..... 575
Hospitals, Electrical equipment of Polhemus Memorial Clinic ..... 57
Hot-wire instruments, Hartman-Braun... *513
Hunting of rotary converters, A cure for (patent) ..... 376
Huntington railroad power plant..... 206
Hydraulic and electric engineering in the West Indies. Henry E. Raymond.... 317
——power ..... 547
——station at Auburn, California..... 405
Hysteresis meter, A... ... . ..... *69

I

Illumination in San Francisco. Clarence L. Cory ..... 506
——Interior ..... *219
——Simple way of measuring..... *218
Incandescent lamp filament of carbide of silicon ..... *220
——of highly refractory material (patent) ..... 470
——High efficiency ..... *337
——Largest ever made..... 340
——"New Lynn" ..... 196
——Remodeled, Orient ..... 197
——socket, Bryant Electric Co. ..... 364
——250-volt installation ..... *336
Incandescent lamps, A detailed description of their manufacture..... 241
——Advantages of long filaments in.... 507
——Device for removing and cleaning, Electric Light Manipulator Co..... 244
——High-pressure low candle-power..... *561
——Miniature, H. E. Plass Elec. Supply Co. ..... 539
Indicator, "Standard," The Lippincott Steam Specialty Co..... 52
Inductance, A method of measuring..... *170
Induction coil interrupter for alternating current ..... *218
Induction of one steady current by another. . *171
Injector, National Automatic..... 198
Induction motor (see Motor, Induction).
Insulators, Locke ..... 199, 582
——Porcelain and clay ..... 399
Insurance of electrical machinery..... 358
Interrupter, Electrolytic ..... *115
——liquid, Nikola Tesla on..... 174
——New liquid ..... 279
——Wehnelt, The, Chas. T. Child and Geo. T. Hanchett..... 165
——Wehnelt, The ..... *217, *277, *515
Isolated plant, Monocyclic ..... 203
——plant of a wholesale grocer's establishment ..... 451

J

Jones electric light station of Portsmouth, N. H. ..... 203
Junction boxes and distribution panels, Johnson & Morton ..... 303

K

Kingston, Jamaica, Railway system of. Henry E. Raymond ..... 317

L

Lafayette Telephone Company, Independent exchange of ..... 410
Lessons in practical electricity, 37, 90, 139, 190, 235
Lighting plant of the steamship "Oceanic" ..... 501
Lightning and lightning arresters. Henry E. Raymond ..... 214, 262
Lightning arresters, American types of. H. E. Raymond..... 15, 66
——Line discharger, Simple form of, Stanley Elec. Mfg. Co..... 400
——Railway power house, A. E. Kennelly 572
Line losses of polyphase transmission, Geo. T. Hanchett ..... 517
Liquid air and compressed air..... 213
Liverpool, Power house of the street railway system of ..... 153
Locomotive, Electric for mines..... 512
Louisville Electric Light Company, Central station of. Geo. Wilbur Rubley 367
Lubrication of high-pressure steam engines. F. W. Roller..... 165

M

Madison, N. J., Municipal light and water plant ..... 257
Magnet coils, Manufacture of..... 579
——windings, A handy rule for, Geo. H. Gibson ..... 144
Magnets, Lifting, in steel mills..... 457
——Permanent ..... 76
Mail despatch tube in London, Electrically operated ..... 471
Mains, Underground concentric..... *466
Manhattan Refrigerating Co..... 1
Marconi system in this country..... 565
Marine plant of the steamship "Oceanic". 501
——plants, Use of hull as return for..... 525
Measuring instrument, Electrostatic, in vacuo (patent) ..... 469
Medical battery, Knapp Electric & Novelty Co. ..... 441
——clinic, Polhemus, Electrical equipment of ..... 37
Merrill Railway and Lighting Co., Power plant of. F. E. Woodford..... 551
Metal working, Electric..... *21
Meter, Combined maximum demand and integrating ..... 305
——Hoyt discount ..... 400
——induction, Improvement in design of. 495
——motor, Direct-current with mercury commutation (patent) ..... 377
——Three-phase (patent) ..... 521
——Multiple rate ..... *379
——practice, General, Lyman C. Reed. 33, 84
——protection (patent) ..... 564
——rates, Systems of..... 74
——testing and handling, James E. Judd 120
——Two-rate charging from the consumers' standpoint, Lyman C. Reed. 140
——Watt-hour, Stanley ..... 355
——Wright demand ..... 192
Meters, Prepayment electricity, Long-Schattner ..... 46
Michigan Electric Company's supply house ..... 397
Mines, coal, Electrical installation in, Harry N. Gardner..... 373
Mining coal, Electricity in..... 299

## ELECTRICITY IN REFRIGERATION.

### ELECTRICAL EQUIPMENT OF A MODERN REFRIGERATING PLANT.

IN the commercial development of electrical energy for light and power purposes, no factor has been more potent than its adaptability to special applications. Of the many peculiar environments where the successful installation and operation of electrical apparatus would seem to be beset with almost insurmountable difficulties, the placing of an electrical distributing system in a building where moisture or even water and mechanical injury are the predominating factors to be combated, may be considered as one of the most severe cases.

When wires are installed in ordinary buildings every precaution is observed to eliminate the very elements with which the electric current must, in the instances above referred to, work in harmonious relation. Ordinary methods, therefore, need revising, and appliances which serve successfully in combating either one of these disturbing elements require careful combining so that the completed installation will possess the advantages of the highly insulated open work, so far as electrical isolation and reasonable freedom from any serious moisture is concerned, and at the same time be secure against disturbance.

Electric plants have been installed in many instances where such conditions of more or less severity were met and successfully overcome. Amongst such installations may be mentioned breweries, dye houses and refrigerating plants. When it, therefore, became necessary to install electrical apparatus for lighting and power purposes in the large new refrigerating, storage and distributing plant of the Manhattan Refrigerating Company in New York City, several already tried methods were available. The conditions to be met and the service desired by the owners were, however, of such a character as to warrant a decided departure from the ordinary path in such cases.

A short description of the refrigerating plant and its function will serve to illustrate the desirability of such changes. The main building occupies a ground area of 80 ft. x 100 ft., and has six floors and basement. This is supplemented by another structure, the lower part of which serves as the power house. Aside from the space reserved for offices, all other available floor space throughout the main building and the upper part of the power house are given up to cold storage rooms in which the temperature ranges from almost zero to simply a chilling point.

Every conceivable form of perishable food product is here stored, and, as is quite obvious, the utilization of every available cubic foot in these rooms is an economic necessity. The refrigerating service is, however, not limited to the demands within the building, but is also extended by means of heat-insulated underground pipes to the various stalls at the adjacent Gansevoort Market, the average distance of service at present being about 2800 ft. The system of distribution is such that no insulation against heat is required on the distributing mains, as no refrigeration is produced on the way, frost appearing only in the boxes of the customers.

The lighting, ventilating, elevating, power and partial pumping service for this storage building is entirely electrical. The power plant, located in the ground floor of the wing building, already mentioned, includes three 150-h.p. horizontal return tubular boilers, worked at 80 lbs., made by the Struthers & Wells Co., Warren, Pa. Aside

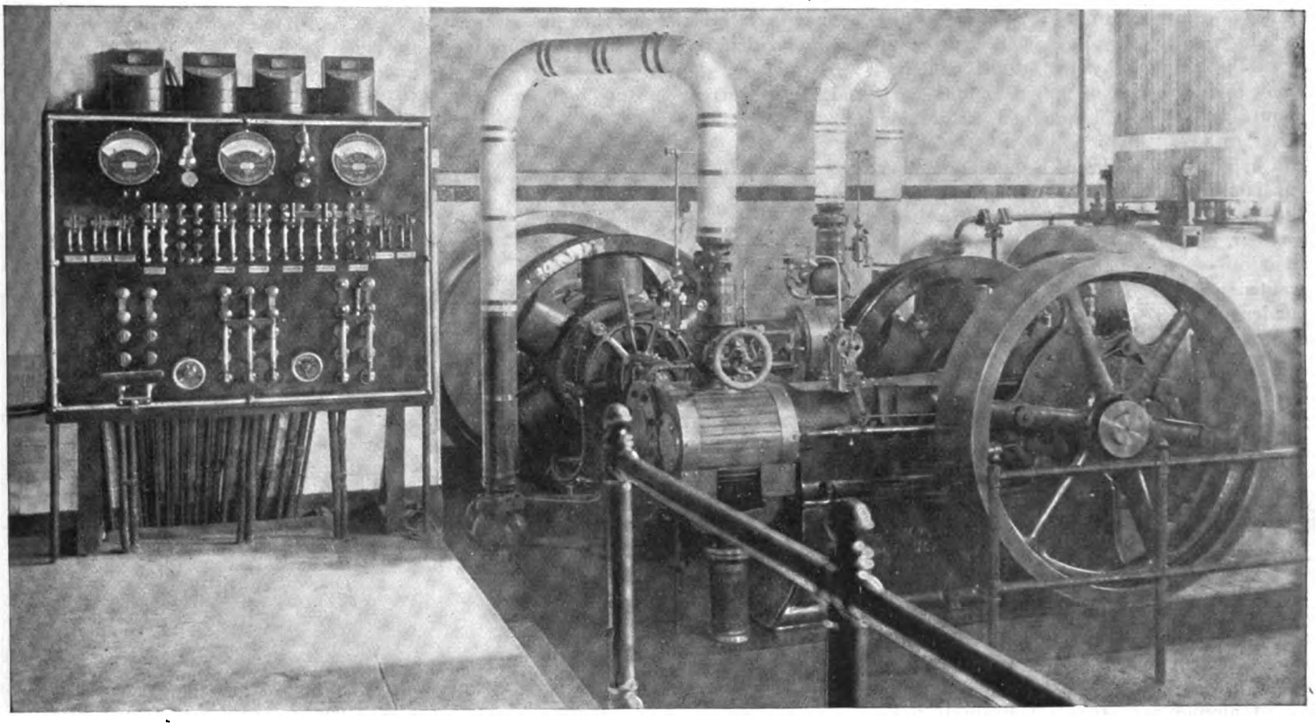

FIG. 1.—GENERATING PLANT AND SWITCHBOARD.

Digitized by Google

from the use of steam for heating in the ammonia apparatus, as described later on, its use for power purposes is confined to the dynamo driving engines and the ammonia pumps, where for certain reasons steam instead of electric pumps were found desirable.

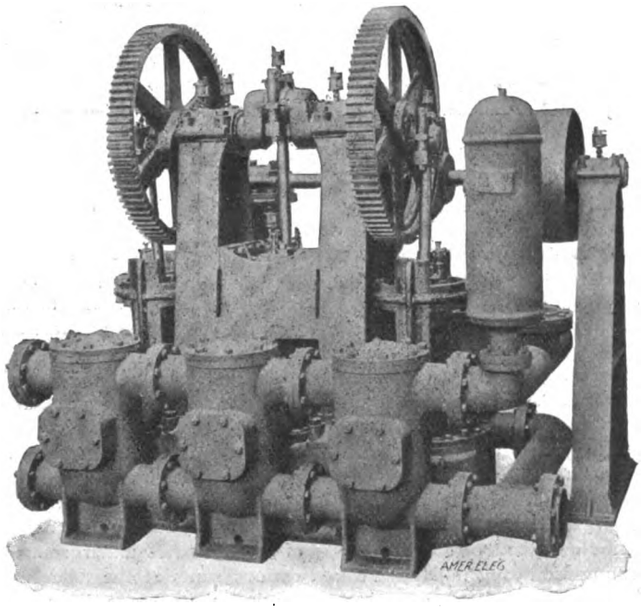

FIG. 2.—ONE OF THE BRINE PUMPS.

The refrigerating machinery is of the ammonia absorbtion type, using as a cooling agent ordinary liquid or aqua ammonia. At the present time two complete refrigerating machines (Fig. 4) are installed, although two more will eventually be placed. The capacity of each of the present machines is equivalent to 125 tons of ice melting in twenty-four hours. The process from the ammonia water to the cooling effect of the expanding liquid ammonia is about as follows: Ammonia saturated water, or aqua ammonia, is first heated in a still by means of steam coils, and ammonia gas is thereby driven off. From the still the hot gas passes through a so-called rectifier, which is a type of separator whose function is to free the gas from any entrained water. Next the gas passes to a condenser, where it is cooled by water flowing over the containing pipes, the reduction of the temperature and consequent pressure liquefying the now anhydrous ammonia, which then passes to the receiver. The actually utilized refrigerating effect is now produced by forcing the liquid ammonia through so-called expansion coils, by means of which heat is absorbed from the environment as the ammonia expands.

For nearly all service within the building the refrigerating medium consists of brine, which, after being thus reduced in temperature, is circulated by means of a proper piping system to the various rooms. For the central station service to the market the liquid ammonia is supplied through the underground pipes to the expansion coils, and acts directly on the surrounding air. The expanded ammonia, after thus performing its function, flows back to an "absorber," where the previously used water reabsorbs the gaseous ammonia and is then repassed to the still and used over again.

While the pumps for manipulating the ammonia are steam operated, the brine and water pumps are driven by electric power. For this purpose there are four triplex Goulds pumps (Fig. 2), having 8-in. stroke and 7½-in. cylinders. Each pair of pumps is operated by a 20-h.p. belted multipolar G. E. motor. In connection with this part of the installation it is particularly noteworthy that the room in which the motors are located is far from dry, yet one has been in constant operation for six months at nearly full load, and has in no way shown any bad results from this severe service.

Electric current is supplied from two generating units (Fig. 1), composed of Harrisburg Ideal simple horizontal engines, each directly connected to a G. E. multipolar compound 250-volt generator. The dynamos are of 50 and 75 kw. capacity, and operate at 280 and 260 r.p.m. Owing to the peculiar arrangement of the power house floors it was essential to provide a foundation for these units which is somewhat unique, as will appear from the illustration, Fig. 3. Pillars carry pairs of I beams, the transverse ones being supported at the other end by the wall. The space between these beams is floored by Z beams resting on the lower flanges. On these is placed a layer of beach sand, over which is laid concrete, the latter being covered with brick tiling, the engine bed resting on the latter. The peculiar feature of this foundation is the fact that the concrete bed at no point touched the framework of the building, being isolated therefrom by the beach sand filling on which it practically floats.

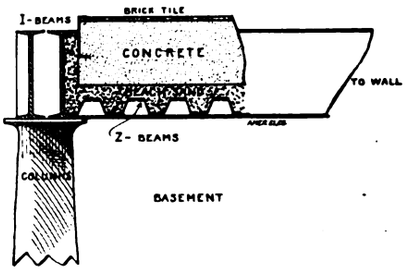

FIG. 3.—DETAILS OF FOUNDATION.

The main switchboard, shown in Fig. 1, is adjacent to the generating units, and is equipped with a separate light and power bus. The main dynamo switches are arranged to connect one machine to the light and the other to the power bus, and a three-pole switch is used to throw these two busses together and connect the equalizer from the dynamos for parallel running. Excepting under heavy power load the busses are run together. All switches and contacts on this board are silver plated to prevent any chemical action from the ammonia gas or the salt laden moisture, and together with the switchboard were furnished by the Crouse-Hinds Company, of Syracuse, N. Y.

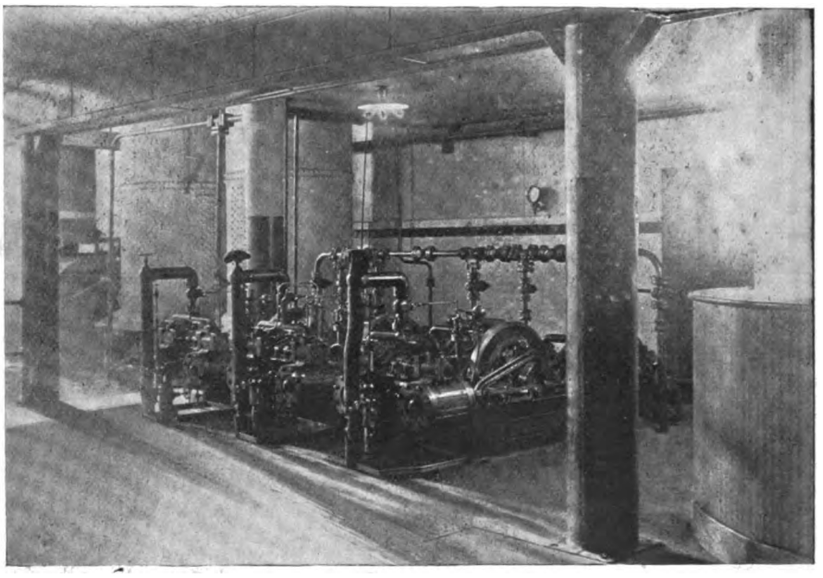

FIG. 4.—REFRIGERATING MACHINES.

Digitized by Google

Since it was desired to operate both light and power circuits from the same generating units, it was decided to use 230 to 235-volt two-wire distribution throughout. With this comparatively high voltage a successful working under the conditions met with throughout the storage rooms would seem exceedingly difficult. In many places, particularly in the freezing rooms, the walls and ceilings are covered by a frozen film, and snow-covered pipes abound. The use of open wires on insulators was discarded, as this type of con-

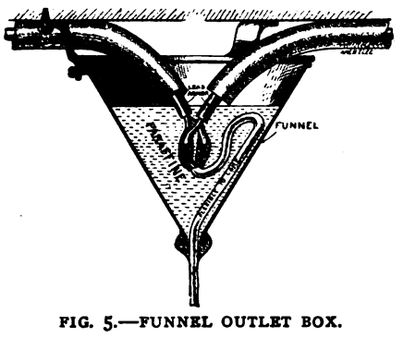

FIG. 5.—FUNNEL OUTLET BOX.

struction would be in no measure protected from mechanical injury in filling the rooms to their maximum capacity. It was necessary to encase the conductors and not only guard against mechanical disturbance, but to ward off all moisture from the current conducting wires and appliances.

The manner in which this has been accomplished is not only a decidedly striking departure from methods adopted in similar instances, but is also unique in the fact that the wire covering alone is used for electrical insulation.

Throughout "Safety Insulated" rubber-covered lead-armored twin wires run in "Loricated" steel pipe, and all the wires are sealed at the various outlets. The wire sizes range from 16 to 4 B. & S. As far as the actual conducting system is concerned, a rusted iron pipe enclosing an electrical conductor is but a minor matter, and

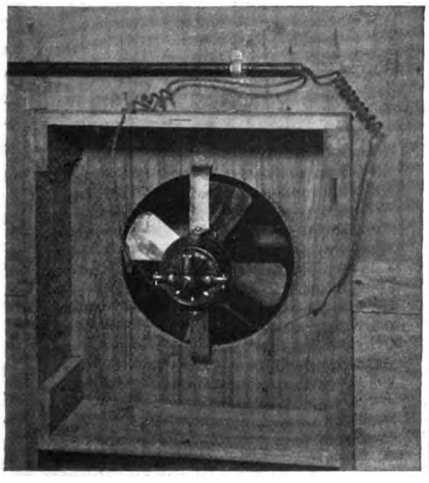

FIG. 7.—12-INCH AIR CIRCULATING FAN.

scarcely worthy of note. The real difficulties encountered were not in the pipe, but at the outlets. The piping throughout being thoroughly leaded and painted at the joints, serves as an excellent injury-proof jacket. For the cold storage rooms the feed circuits are run from the switchboard, and panels have been used on some of these at points exterior to the storage space, from whence the branches extend. Within the storage rooms exposed contacts are, however, entirely eliminated.

Up to the present time the paraffine-filled iron outlet box, shown in Fig. 10, has been used at most of the light outlets. This box is of the ordinary iron round type, and the paraffine was injected by means of an ordinary bicycle pump through the small hole shown. Difficulties experienced with this type of sealed outlet box have resulted in the placing of a number of very unique substitutes, shown in Fig. 5.

An ordinary agate ware funnel about 6 ins. in diameter at its flaring end is held downwardly projecting by means of a tripod supporting ring. The small end of the funnel through which the wire to the lamp passes is sealed, and slack wire sufficient for lowering is allowed inside. After the tap is made the funnel is filled with paraffine, and while the latter is still liquid the funnel is snapped onto its holding base, sealing up the ends of the lead armored

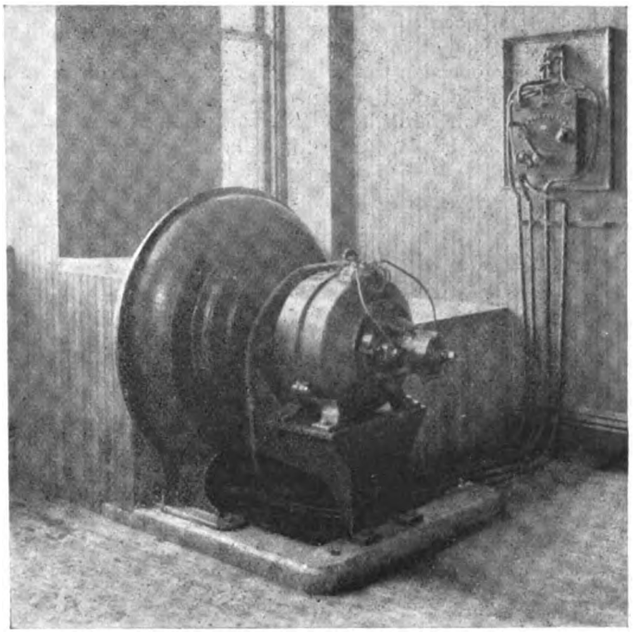

FIG. 6.—VENTILATING BLOWER.

wire outlets and the entire tap. It is intended to substitute this arrangement for the other type of outlet boxes. All lamp sockets are of the porcelain waterproof type, and are, in most instances, hung from these outlet boxes by means of twisted flexible rubber cable.

The necessity of a large number of local switching appliances introduced another difficulty. The cold storage space on each floor is divided into a number of separate rooms, arranged on each side of a central passageway which at its ends is entered through double doors. It was necessary to provide

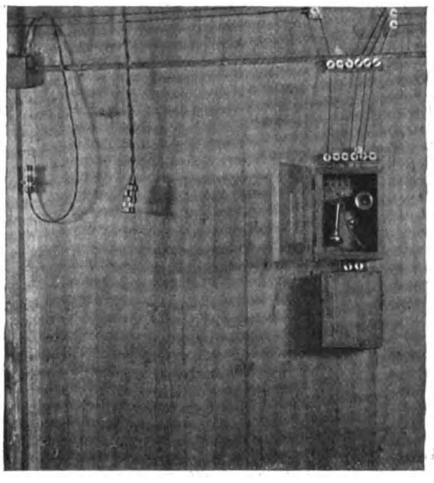

FIG. 8.—SEALED SWITCHES AND TELEPHONE STATION.

FIG. 9.—PASSAGEWAY, SHOWING ELECTRIC CONDUIT AND BRINE PIPES.

switches in this passageway for each storeroom, so that the lights and ventilating motors within could be operated from the exterior, and switches to similarly operate

Digitized by Google

the lights in the central passage were needed at each entrance.

At first long-break, single and double-pole exposed contact, knife switches were installed, but moisture soon played havoc with these. Not only were leaks and partial short circuits constantly occurring, but, owing to the complete film of moisture covering the switch, the operator had to exercise particular care in order to prevent getting a taste of the current through his bare and frequently moist hands. As a

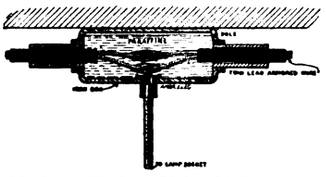

FIG. 10.—SEALED IRON OUTLET BOX.

consequence, the men employed in the warehouse would use somewhat severe means for closing and opening the switches. Hats, bars of wood, or anything else that came to hand would be used to knock the switches in and out. Certainly such usage alone warranted some substitute, but even with the greatest care the exposed contact knife switches soon showed the effects of the deteriorating environment. There are altogether about 300 16-c.p. incandescent lights and 50 motors throughout the cold storage rooms, which are controlled by about 65 local switches; single-pole for controlling the individual room and aisle lights which range from 2 to 6 on one switch, and double-pole for the various motors.

Since the matter of local switches was a most important element, a novel type of mercury contact switch was devised, having all conducting parts entirely sealed, and which could, therefore, be handled with perfect impunity. The two forms of this sealed switch are shown in Fig. 12.

The arrangement is exceedingly simple, consisting merely of a glass tube, corked and sealed at each end, and hung by a suitable cable from a paraffine filled outlet box. Terminal wires project through one of the corks into the interior. These terminal contacts are ordinary iron nails, and a small quantity of mercury, when this end of the switch is hung downward, connects across. The operation of the switch simply involves hanging the tube so that the mercury is at one end or the other. Iron instead of brass or copper terminals were adopted so as to obviate the rapid deterioration of the contacts. Double-pole switches are arranged by simply duplicating the tube. The arrangement of the three-point switches used at the entrances to the aisles so that the lights may be turned on or off from either end are particularly ingenious.

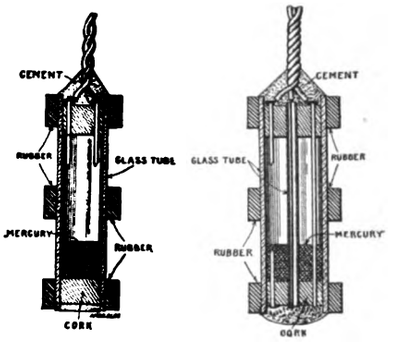

FIG. 12.—DETAILS OF SEALED SINGLE-POLE AND THREE-POINT SWITCH.

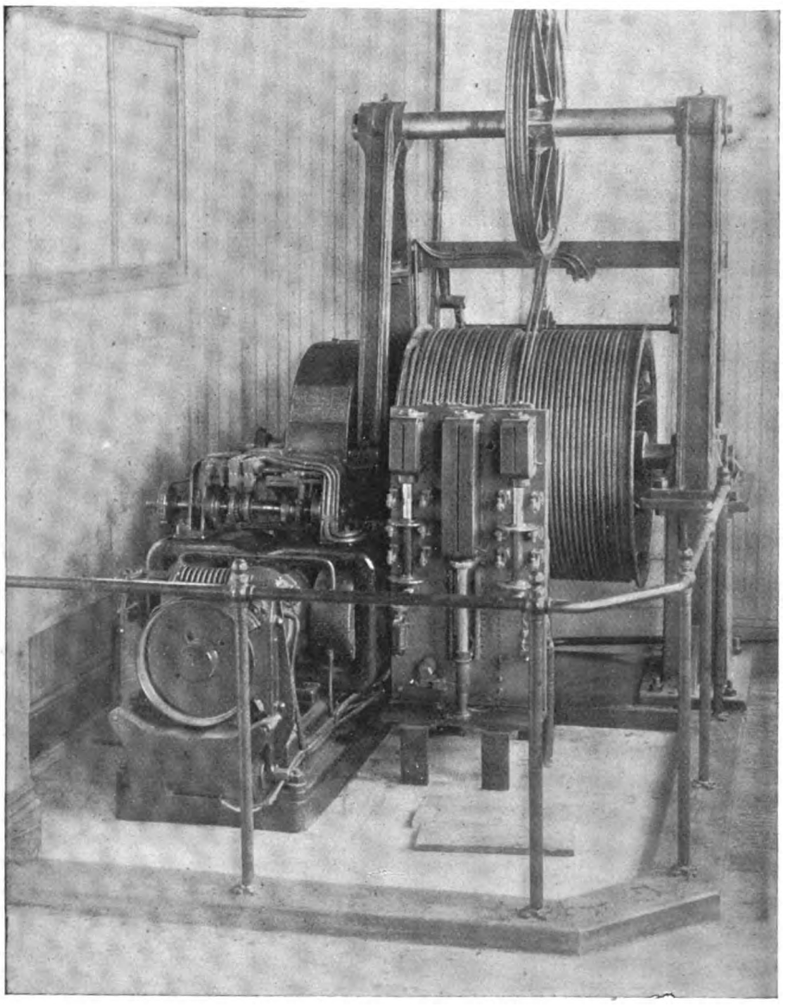

FIG. 11.—FREIGHT ELEVATOR.

An important item in the maintenance and care of storerooms filled with produce is at all times to keep the air in circulation and thus maintain an even temperature all over the room. In this work the electric motor has found a most fertile field. A large centrifugal blower, operated by a 5-h.p. motor, is used to clear the various passages and aisles. In the meat freezing room a fan, operated by a 1-h.p. motor, drives fresh air through the refrigerating coils at one end of the room and circulates it to the other.

Probably the most interesting application of motors for ventilating is the use of about forty small 12-in. Lundel fan motors, set in the partitions between the actual storage spaces and the coils, as shown in the diagram, Fig. 13, and in Fig. 7. The motor forces the air from the room through the coils and sends it through the openings in the false ceiling, thus keeping the temperature even throughout. Rooms in which fruit, eggs, etc., are stored, and which need but a chilling, but even, temperature and an air circulation to prevent mold, are thus equipped. Usually two motors are placed in each room. They are connected to the circuit by the sealed double-pole switches, exterior to the rooms, and their speed is controlled by rheostats placed on the inside wall. The drip pump in the boiler room is also electrically operated, and a G. E. 5-h.p. motor is used to drive the tools for pipe working in the machine shop.

In addition to the motor equipment, already mentioned, two large electric freight elevators have been installed, one on each street front of the building. These are Sprague drum-winding, worm-gear machines, and are provided with electric switch control, not only from the car, but also at each floor landing. The peculiar advantages of electrically operated elevators for establishments of this nature is most strikingly illustrated by the smoothness and facility of operation, but particularly by the absolute safety from interference in operation, a feature inherent in the peculiar control system here installed. This is so arranged that if the car is being loaded or unloaded at any floor the switches on all the other floors can be made inoperative

Digitized by Google

by locking any one of them. The advantage of this arrangement where, as here, it is frequently necessary to bring the car to any floor from another, and where anybody is permitted to operate it, is obvious. Each of these elevators has a capacity of 6000 lbs. at 80 ft. per minute. They are counterbalanced for part of the load carried, and their operation on a circuit also carrying lights has proven most satisfactory.

In addition to the light and power equipment of this up-to-date refrigerating plant, a Schmidt & Bruckner interior telephone system has been installed, centering in a small station located in the main office. As with everything else electrical, various provisions had to be made against moisture. Many of the stations are in the aisles on each floor, and the manner of placing the apparatus and

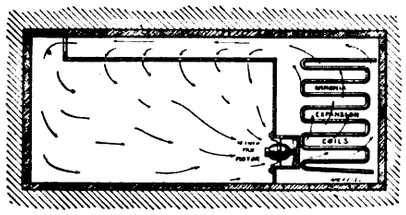

FIG. 13.—AIR CIRCULATION IN COOLING ROOMS.

local battery in paraffine-soaked wooden boxes, separated from the wall by porcelain insulators, is shown in Fig. 8. The boxing of the instruments was necessary owing to the possibility of mechanical injury, and extension call bells were, therefore, used. The ordinary box bell arrangement was, however, found unsatisfactory, resulting in the design of a novel hanging waterproof magneto bell, shown in Fig. 14. All telephone wires are run on porcelain knobs.

Up to the present time the installation seems to have met all expectations. Changes and modifications have, it is true, been necessary, but there seems to be every reason to believe that any additional obstacles can be as well overcome as those already met with. The designer of the complete electrical installation, Mr. Chas. H. Warner, has given this type of construction work a good deal of attention,

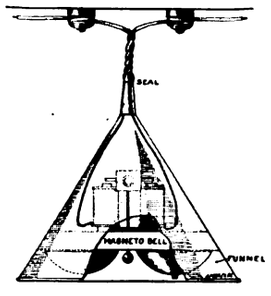

FIG. 14.—WATER-PROOF MAGNETO BELL.

and his many departures from the beaten track will probably pioneer other similar installations. The actual installation work was done by the Starr Engineering Co., who also installed the complete refrigerating plant and street pipe line.

In conclusion a word may be said in another direction which, although perhaps not of any direct bearing on the plant described, has yet a certain relationship which should not be overlooked. It would appear that refrigeration might in many cases be profitably coupled with the production of electrical energy. Electric central stations might well consider this opportunity for employing energy when it can well be spared. Refrigeration would, in fact, furnish an ideal day load.

## COUNTER E. M. F. OF MOTORS.

BY PROF. A. F. MCKISSICK.

The following experiments have been found to give students a clear conception of the nature of the counter e.m.f. of motors. The first one is found in Nichol's Laboratory Manual, Vol. II., and was devised by Prof. G. S. Moler, of Cornell University. The second one, very closely resembling the first, originated in the electrical laboratory of the Alabama Polytechnic Institute.

The connections for the first mentioned method are shown in Fig. 1. A is a small series generator without regulator; B is the shunt motor to be experimented with; C, a shunt dynamo used for exciting the fields of B; e is an ammeter and d a voltmeter, both of which will read right and left, thus show-

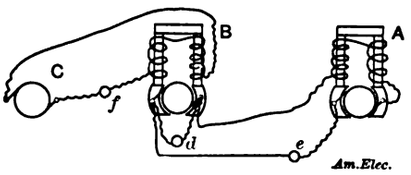

FIG. 1.—DIAGRAM OF CONNECTIONS.

ing direction and values of currents; f is an ammeter indicating the field current of B. With the field of B excited by C, A on being started up will furnish current to the armature of B, and cause it to make a few revolutions in one direction and then reverse. The instruments d and e will also show reversals. By supplying sufficient friction to the pulley with the hand, the armature can be made to rotate continuously in one direction. An increase in the strength of the field of B reduces the number of revolutions before reversing takes place, and a decrease in the field causes the reverse.

The explanation of this is that the counter e.m.f. of armature B overpowers the impressed e.m.f. of A, causing a reversal of the current in A, and therefore a reversal of the direction of rotation of B. By means of friction, the armature of B is not allowed to reach that speed necessary for reversal, hence its continuous rotation in one direction. Increasing the field strength of B increases the counter e.m.f. of B, necessitating therefore a lower speed for reversal. Decreasing the field strength decreases the counter e.m.f. of B, therefore requiring a higher speed for reversal.

Taking up the second experiment, C is a shunt dynamo, used for exciting the fields of B, which is a shunt motor with armature and field windings separated. A is a Thomson-Houston arc dynamo with regulating apparatus as shown; a and b, ammeter and voltmeter respectively, of the type used in experiment I. With the fields of B excited, on furnishing current from A to the armature of B the latter will rotate continuously in one direction, inasmuch as A is self-regulating and does not allow the counter e.m.f. of B to overpower its impressed e.m.f. On closing the switch c, thereby

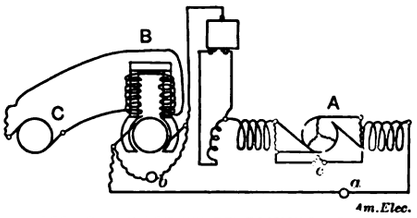

FIG. 2.—DIAGRAM OF CONNECTIONS.

stopping the generation of current by A, B being up to a high speed begins to act as a dynamo, and what before was the counter e.m.f. of motor B now becomes the impressed e.m.f. of dynamo B. This impressed e.m.f. of B sets up a current through the fields of A, reversing the polarity of the same. By opening the switch c again, we make A generate current, but now reversed, and therefore the armature of B will rotate in opposite direction. The instruments a and b also will indicate these reversals.

## THERMODYNAMICS DEFIED.

In a circular letter of recent date, with a New York address, the attention of steam users is called to a "steam regenerator" of marvellous properties, which, it is claimed, makes the steam engine a "perfect thermodynamic machine;" converts all the exhaust steam into live steam, and, besides, is a condenser that does not require condensing water and a feed-water heater that heats all the feed to 300 degrees! The invention consists in taking "the waste product known as exhaust steam after it leaves the engine or feed-water heater, and, by a system of compression, re-evaporation, sub-heating and mixing with live steam, brings its temperature and pressure up to that of the steam in the boiler, to return this exhaust, now revitalized, into the main steam pipe to engine—not to boiler. It will be seen that this makes a closed system of an engine and boiler, and, while adding more machinery to the combination, practically returns all heat not used in work to reservoir, to be used over again. It will also be seen that this machine is also an auxiliary generator, doing part of the work of the boiler." It is claimed that the use of such a device means a revolution in steam-engine practice, but the direct statement to this effect is somewhat ambiguous, and astonishingly conservative in view of the claim that the system returns to be used over again practically all the heat otherwise wasted; for it merely says: "If, by any system of working exhaust steam, we can raise this (10 per cent efficiency) to 20 per cent efficiency, we have something that no steam user can afford to be without."

## THE ELECTRIC FURNACE.

BY LIEUT. F. JARVIS PATTEN.

It may be stated in general terms that the electric furnace, even in its comparatively extensive applications, to-day consists of little else than an arrangement of devices and parts, the operation of which make the exceedingly high temperature of the electric arc available for commercial use. Strictly speaking, this temperature should be very close to that required to volatilize carbon, but, in speaking of the temperature of the electric furnace, its value cannot be stated in such definite terms, because there are several widely different temperatures at work.

M. Violle, by means of extensive research in this field, established the temperature of the positive electrode at a maximum of 7000 deg. F., and that of the negative pole at about 5600 deg., whereas the arc itself between poles may be as high as 8600 deg. F., this temperature, according to the determinations of this eminent authority, being independent of the size or thickness of

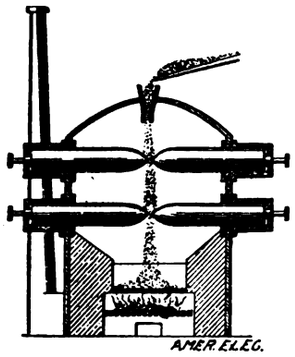

FIG. 1.—PICHON FURNACE.

the arc, as well as the strength of the current.

It is this high temperature, the highest applied in industrial processes, that opens such a broad field for the electric furnace, and brings into play a new set of chemical affinities heretofore accepted as fixed and definitely controlling the union or dissociation of certain elements, doing so, however, only within certain limits of temperature, which limit being exceeded, the affinities change and the elements combine in a way to make entirely different combinations.

This alteration of chemical affinities finds excellent illustration in the production of calcium carbide ($CaC_2$) from the union of calcium and carbon when subjected to the temperature of the electric arc. At the lower temperature the calcium is firmly bound to the oxygen required to form the oxide CaO, common lime. This, when finely divided and mixed with powdered coke (carbon), the latter unites with both the elements forming lime, making with one $CaC_2$, or calcium carbide, and with the other carbon monoxide, or CO, according to the following reaction: CaO (lime) + 3 C (carbon) = Ca $C_2$ (calcium carbide) + CO (carbon monoxide). Such is the simple chemical change by which calcium carbide is formed by subjecting lime and coke, which contains its elementary constituents, to a very high degree of heat.

At ordinary temperatures, however, the resulting carbide is comparatively unstable, being chemically disintegrated by mere contact with cold water, the carbon attacking the hydrogen of the latter with great avidity to form acetylene gas ($C_2 H_2$), while the calcium unites with its oxygen to form lime.

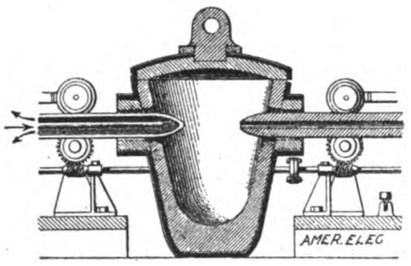

FIG. 2.—SIEMENS FURNACE.

The first electric furnaces mentioned were built with the expectation that they would offer improved methods of smelting ores, and doubtless a chief reason why they received little or no practical development is because they antedated our present methods of generating and controlling the electric current. They are therefore only interesting as the earliest examples of the art.

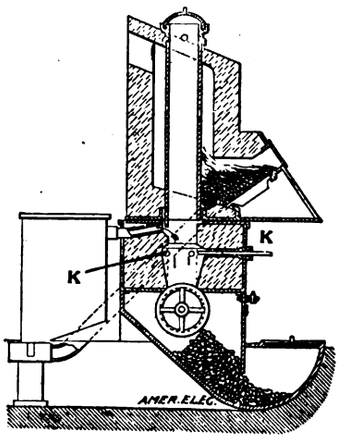

FIG. 3.—FAURE FURNACE.

Such a one is the Pichon furnace, Fig. 1, which dates back to 1853, and which is the evident precurser of several later types. The mineral to be operated upon is allowed to fall through arcs maintained between separate pairs of electrodes, placed one set vertically over the other. Another of the same year and of English origin is strikingly suggestive of the Cowles furnace of 1887. These examples suffice to show that the art is older than the modern dynamo, and that, notwithstanding the fact that Siemens in 1879 was the first to reduce the electric furnace to something like a practical form, he was by no means the first to formulate or invent some kind of an electric furnace.

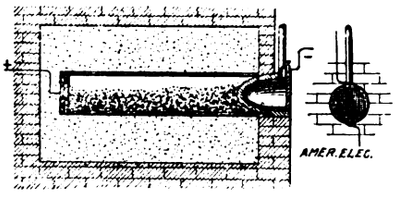

FIG. 4.—EARLY COWLES FURNACE.

The essential features of the Siemens furnace—strictly speaking, an electrically heated crucible—are given in Fig. 2, taken from the English patent, a type of which was exhibited in operation at the Paris Exposition of 1881. In this device the crucible was made of carbon, as well as the electrodes, A, and a carbon cover closed the vessel; there was also provision for keeping the carbons relatively cool outside the furnace by means of a continuously circulating stream of water. Siemens presented about this time several different forms which, taken as a class, present all the more important elements found in the electric furnace of to-day, and for this reason he may be regarded as the founder of the art. Between the work of Siemens in this field and that of Cowles, who was first to use the electric furnace on a true commercial scale in the later eighties, we find the name of Camille Faure, whose work in this direction is evidenced by an English patent of 1882, describing an electric furnace for smelting iron ore by using a system of multiple arcs between a series of horizontally radiating carbons, K, Fig. 3.

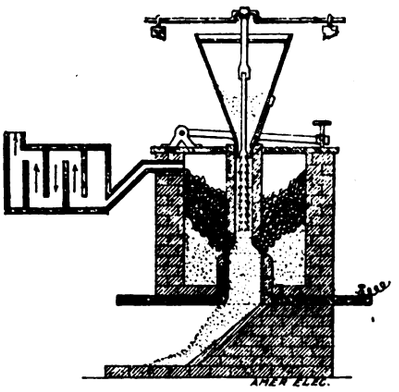

FIG. 5.—COWLES HOPPER FURNACE.

In the early eighties the Cowles brothers patented and operated successfully in England quite a variety of electric furnaces, which were used chiefly for reducing metallic oxides. The earlier forms built by them were for zinc ores, but later the oxides of barium, magnesium and aluminum were treated in a similar way. An early type of these is shown in Fig. 4. It consists of an interior cylinder of silica or similar non-conducting refractory substance.

This cylinder, which contained the material to be operated on, is embedded in powdered wood charcoal to retain the heat. A carbon slab closing the cylinder at one end forms the positive electrode, and a graphite crucible closing the other end of the cylinder is the negative electrode. A charge consisting of a mixture of ore and coke is brought to incandescence in the cylinder by the passage of the current.

A number of furnaces were designed and operated by the Cowles brothers for several years that differed from each other only in

Digitized by Google

the arrangement and construction of the electrodes and the system of charging or of feeding the material to the furnace. One designed for continuous operation is shown in Fig. 5. One electrode is a vertical carbon tube secured to the lower extremity of the feeding hopper. The lower electrode is a somewhat larger tube carried by the furnace floor. The whole arrangement is inclosed by walls of refractory brick. A mixture of powdered carbon and lime completely surrounds the lower electrode, serving to confine the heat to the zone between the electrodes. The charge is forced down by a screw feed working in the upper tubular electrode, while the escaping gases incident to the reaction are led off to a condensing or collecting apparatus shown at the left.

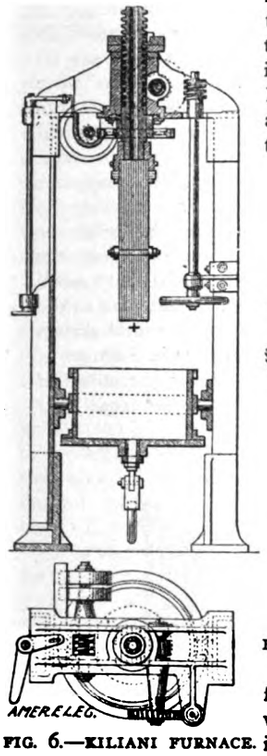

FIG. 6.—KILIANI FURNACE.

Early in the use of the electric furnace, and particularly in the production of carbides, it became evident that the arc between electrodes confined itself almost entirely to the path offered by the first carbide formed, this material being a much better conductor of the electric current than the carbide and lime charge at first attacked by the arc. As soon as the charge began to be worked effectively, therefore, energy was lost by the tendency of the current to follow the new low-resistance path. This difficulty gave rise to numerous furnace systems, in which it was attempted to keep the arc moving about from point to point, so as to get at new material and not waste the current by keeping that which had been formed in a state of incandescence. Most of these attempts were mere mechanical devices for moving one electrode about while the other remained fixed.

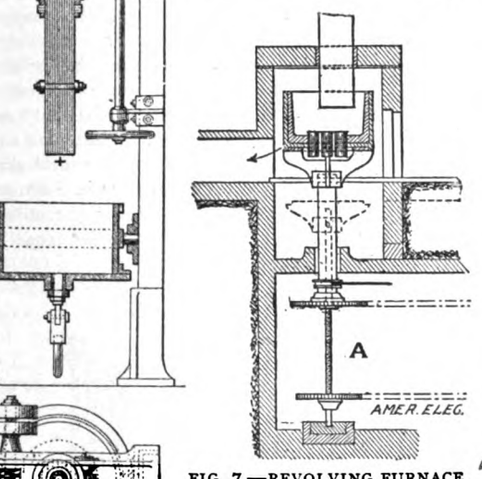

FIG. 7.—REVOLVING FURNACE.

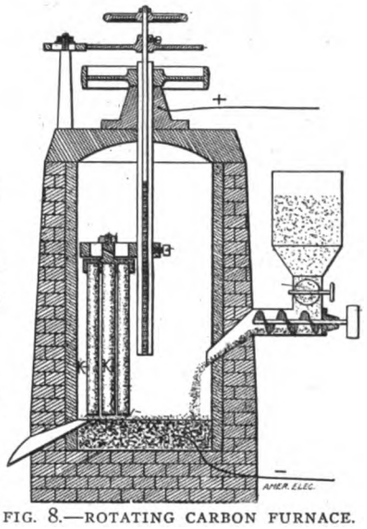

FIG. 8.—ROTATING CARBON FURNACE.

The Kiliani furnace, Fig. 6, is one of the first of this type. The upper electrode is swung in such a way that it can be given motion in two horizontal directions, and therefore by a combination of these two motions the electrode can be rotated. A recently patented French furnace having the same objective in view is shown in Fig. 7. Here the lower electrode, formed of a group of carbons, forms the central base of a crucible or pot, the purpose of which is to hold the charge. This pot turns upon a central vertical axis, A, being driven slowly by machinery. The upper electrode, arranged vertically, is fixed in position, but its axis is placed eccentrically to that of the crucible, from which it results that as the pot turns fresh material is continually brought beneath the arc.

Another device, the illustration of which, Fig. 8, is taken from a recent American patent, has a rotating vertical carbon, K, the end of which is thus made to traverse over the surface of a fixed horizontal table forming the lower electrode.

Two English inventors, Rogerson and Slatter, however, as early as 1888, were the first to show what may be fairly styled a distinct and novel type of furnace, in which the chief object was to control the position of the arc between electrodes by placing it in a magnetic field. In view of this attempt, made public so many years ago, and indicating a simple method of moving the arc without mechanism, it is surprising to see so many recent methods of accomplishing the same result by apparently clumsy and mechanical methods.

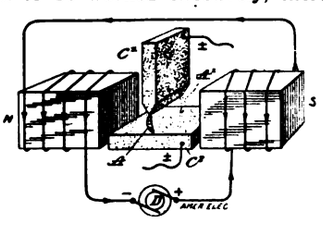

FIG. 10.—MAGNETIC CONTROL OF ARC.

In the furnace mentioned, Fig. 9, the arc between electrodes is placed in a strong magnetic field which will deflect the arc upward or downward, according to the direction of the lines of force of the field, and by reversing the field the arc can evidently be directed upward or downward at will. In view of this evident hint, it is strange that the principle shown should not have received broader application—to that, for instance, of keeping the arc continuously in motion in either a reciprocating or a rotary manner.

Several solutions of this problem were worked out by the writer, giving a system of furnaces with arcs which are not only moved over quite large working surfaces, but were made to move automatically and without the use of any auxiliary mechanism whatever and while both electrodes remained fixed in position. In one form the arc is made to traverse to and fro at right angles to the direction of the current, and in another it is made to rotate in a plane at right angles to one of the electrodes.

The first of these is illustrated in Figs. 10 and 11, the first indicating the application of the principle used, and the second giving a cross-sectional view of a traversing multiple arc furnace. Referring to Fig. 10, $C_1$ and $C_2$ are carbon slabs given the shape of rectangular blocks and placed at right angles to each other at arcing distance. The arcing space is placed in the field of the magnet N S, and this, by well-known principles, will hold the arc in the position $A_1$, its tendency being to go out of the magnetic field in a direction at right angles to the lines of force.

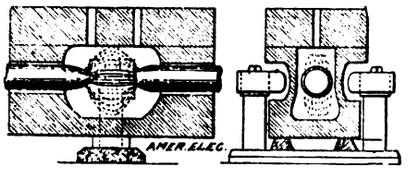

FIG. 9.—READMAN FURNACE.

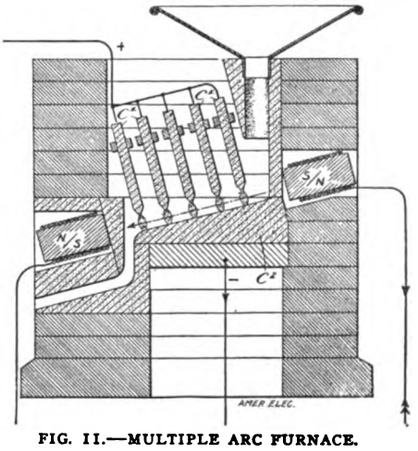
If, however, the magnet is turned through 180 deg., so that the relative positions of the N and S poles are reversed, the arc will then go over to the position $A_2$ at the other side of the magnetic field. Evidently, then, if the magnet N S could be revolved or spun around the vertical middle line of the carbon slab $C_1$, then the arc would, in order to get out of the changing magnetic field, move to and fro across the lower edge of the vertical carbon, and thus be kept reciprocating as the magnet revolved.



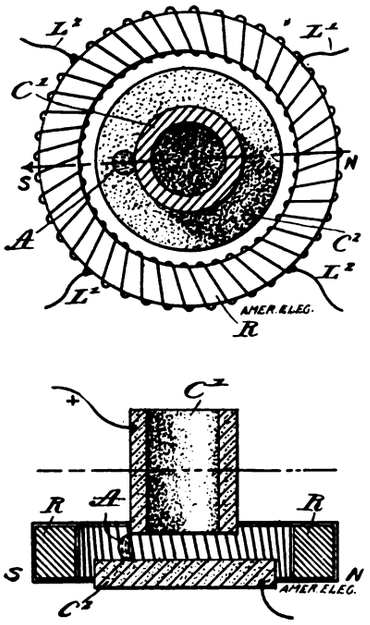


FIG. 11.—MULTIPLE ARC FURNACE.

It is evidently not necessary, however, to revolve the magnet, as described to get this result, for it would do just as well to let the magnet remain fixed in position and

Digitized by Google

reverse the magnetism periodically. And, again, there are clearly two ways of accomplishing the same result without moving any part. Thus, it matters not whether we put a direct current between electrodes and reverse the field magnetism periodically, or let the magnetism remain constant and periodically reverse the direction of the current betwen the electrodes. Thus, if we use an alternating current for the furnace work, an ordinary electro magnet of unchanging polarity embracing the arcing space in its field will cause the arc to recip-

FIGS. 12 AND 13.—ARC IN ROTARY FIELD.

rocate from side to side with each reversal of the current direction.

Fig. 11 indicates a multiple arc furnace involving this principle. A number of carbon slabs, $C_1$, are arranged parallel to each other at right angles to another, $C_2$, that forms at the same time the inclined base of the furnace and an opposite electrode to all the others. The magnet N S is built into the furnace walls in such a position as to embrace all the arcs in its magnetic field. If direct current is used between electrodes to do the smelting, then the magnetism of the surface magnet is slowly reversed, causing the arcs to all move to and fro across the furnace floors.

An evident and interesting variation is to connect the upper or vertical electrodes in series in such a way that the current flows up in one and, at the same time, down in the next, and so on throughout the series. Under these conditions one arc will be going from right to left across the furnace base while the other is going in the opposite direction from left to right.

The several types of furnace in which the arc is made to take up a rotary motion around the vertical electrode are all exemplified in principle by Figs. 12 and 13, which represent horizontal and vertical sections, respectively. The vertical electrode, $C_1$, is made preferably in the form of a tube, which at the same time serves as a passage through which to feed the material to the arc. A circular or ring magnet, R, surrounds the arcing space, and within the peripheral space of the ring a rotating magnetic field, A, is maintained by exciting its winding with slowly reversing multiphase currents, $L_1$, $L_2$. Under these circum-

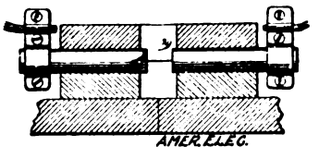

FIG. 14.—BORCHERS FURNACE.

stances, the arc between the upper tubular carbon electrode and the lower slab, also the base of the furnace, will be made to rotate around the lower end of the tubular electrode in its continuous effort to get out of a rotating magnetic field.

One other furnace system deserves mention for the reason that it represents a distinct type, and, though it is to be found among the earlier forms, it has not come into extensive use, although copied in several recent forms. Reference is made to the Borchers furnace, first made by the eminent German chemist and electro-metallurgist of that name, and may be described as a furnace of the incandescent type in contradistinction to those previously described which, for sake of distinction, may be considered as of the arc type.

In the Borchers furnace, Fig. 14, two large carbon electrodes take a heavy current inside the furnace, where these carbons, instead of being placed at arcing distance from each other, and an arc sprung between them, they are joined to each other by a comparatively small pencil of carbon, which, in fact, is made too small in cross section to carry the current brought in by the large carbons without fusion. The re-

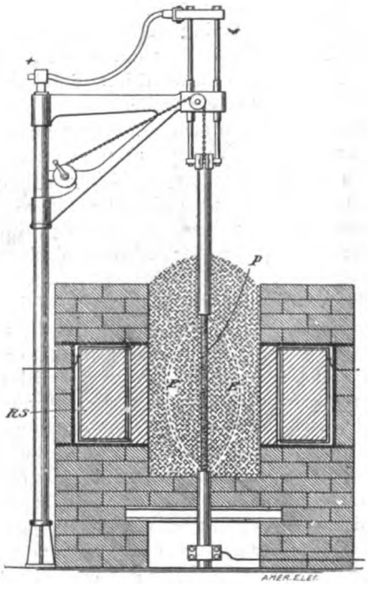

FIG. 15.—KING-WYATT FURNACE.

sult is the carbon pencil is soon brought to a state of high incandescence and finally fused. At this stage the heat is sufficient to fuse some of the mixture of carbon and lime immediately surrounding the pencil. When this is accomplished, the fact being indicated by a rapid increase in the rate of current flow, the carbon termini now connected only by fused material are gradually drawn further apart, thus bringing more unfused material under treatment. In fact, from this stage on, that is to say after a mass of fused material has been formed between electrodes, the operation of the furnace differs in no essential particular from that of a furnace of the arc type. The difference of the two methods appears to reside only in the manner of starting the operation. There is no essential difference in the construction or operation of the earlier furnace of Borchers and that known as the King-Wyatt, Fig. 15, patented in the United States years after the same system had been reduced to practice in Europe.

A slight variation, however, the object of which is to greatly increase the capacity of

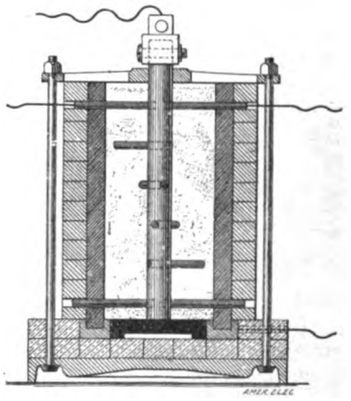

FIG. 16.—MULTIPLE CARBON FURNACE.

the furnace at one charging, is shown in Fig. 16. In this arrangement a large number of carbon pencils are introduced as radiating branches from a central main electrode at the middle of the furnace, and the circular wall thereof, also built up of carbon blocks and forming the other main electrode. The small radiating pencils may be a dozen or more in number, and may be either operated singly in rotation or, if current enough is available, the entire lot may be operated simultaneously in multiple arc. In either case there will be a number of nuggets made at one charging corresponding to the number of pencils operated, and thus save the heat lost recharging and in the cooling of the entire furnace at each formation of a single nugget.

In this way it is possible to approximate, in some degree at least, to what is generally termed a continuous process, by which is meant one in which material is continually fed into the furnace at one point and removed by a process of flow from a nozzle or tuyere in the shape of fused carbide.

Many advocates of different furnace systems claim to have such a continuous method of operation, but none that has ever come under the writer's observation has proved to be so in fact.

Most furnaces in use at present in the United States are of the single arc type, with two vertical carbon electrodes, the upper one being movable vertically and the

Digitized by Google

lower one fixed, the two being separated by raising the upper one as the material between them passes to the fused or new chemical state. This is continued until a nugget three or four feet long is formed, generally circular in cross section and tapering toward the ends to the size of the electrodes.

The more recent forms differ only in the manner of feeding the material, arrangements for withdrawing and recharging, and the additional feature that many of the modern furnaces for making carbide of calcium are multiple arc, or multiple electrode furnaces all worked simultaneously, thus giving half a dozen nuggets at one operation.

The more recent of these furnaces are about 30 ft. high, having five or six arcs each simultaneously in operation, and turning out 1500 to 1800 lbs. at a single operation lasting about four hours.

The carbons in these furnaces are built up of slabs of carbon bound together so as to produce an electrode having a cross section about 6 ins. x 9 ins. Evidently the current carrying capacity of these electrodes is quite considerable.

As to the voltage used, practice has thus far seemed to indicate that a voltage of sixty-five to seventy gives the best results, it being attempted to maintain this factor as nearly as possible constant, and vary the current in proportion to the quantity of material under action of the current from time to time. This voltage at, say, 400 amps. of current, corresponds to from 30 to 40 h.p. per electrode. Several of the recent forms of furnace, however, take much more current—nearer 1000 amps., and using from 75 to 100 h.p. per stack.

The output of carbide on an average is 0.4 lb. per electrical hour, or about 200 h.p. hours per day of twenty-four hours per ton.

It is evident from all this that the cost of carbide at the furnace is altogether dependent upon the cost of power at the furnace, and that made from cheap water power that is not too far from commercial centers will always be very much cheaper than that which can be produced from any other source of energy.

As to the origin of the carbide process now worked, there has been considerable controversy that has failed to lead to any very definite result. All German authorities credit their very eminent physicist, Dr. Borchers, with having first made carbides of the alkaline earths by use of the electric furnace, and there is little doubt that he was actually the first to get some results of this description. The French are equally enthusiastic in support of the claims of M. Moisson in this field, and, while admitting that Dr. Borchers made the earlier attempts in this direction, he did not obtain pure carbides, whereas, Moisson, at a later, did obtain such results by more advanced methods of the same general description. M. Moisson's researches have at all events been most thorough and far-reaching in their exposition of the wide possibilities of the electric furnace.

Between these claimants and the evidence brought by their respective advocates, the claim of Wilson, an American inventor, to have first discovered carbide, accidentally, as a by-product of the production of aluminum by the electric furnace process, seems to lack real foundation. Although this inventor may have independently discovered calcium carbide, his date was too recent to admit of any claim to being the first discoverer of the material or process.

# Three-Phase Electric Railway.

## A SWISS THREE-PHASE MOUNTAIN ELECTRIC RAILWAY.

Since the installation of the first alternating current railway in 1896 at Lugano, and doubtless owing to the very satisfactory results obtained in the operation of this plant, a number of new roads in Europe have been equipped on the polyphase system. One of the latest of these is a three-phase line from Stansstadt to Engelberg in Switzerland, which road has an additional interest from the fact that part of it climbs a 25 per cent grade.

Referring to the profile of the railway in Fig. 3, the track for a distance of 11.2 miles is of the ordinary type, traction being accomplished by adhesion; then for a distance of a little short of a mile the roadbed is furnished with a rack-rail, the grade on

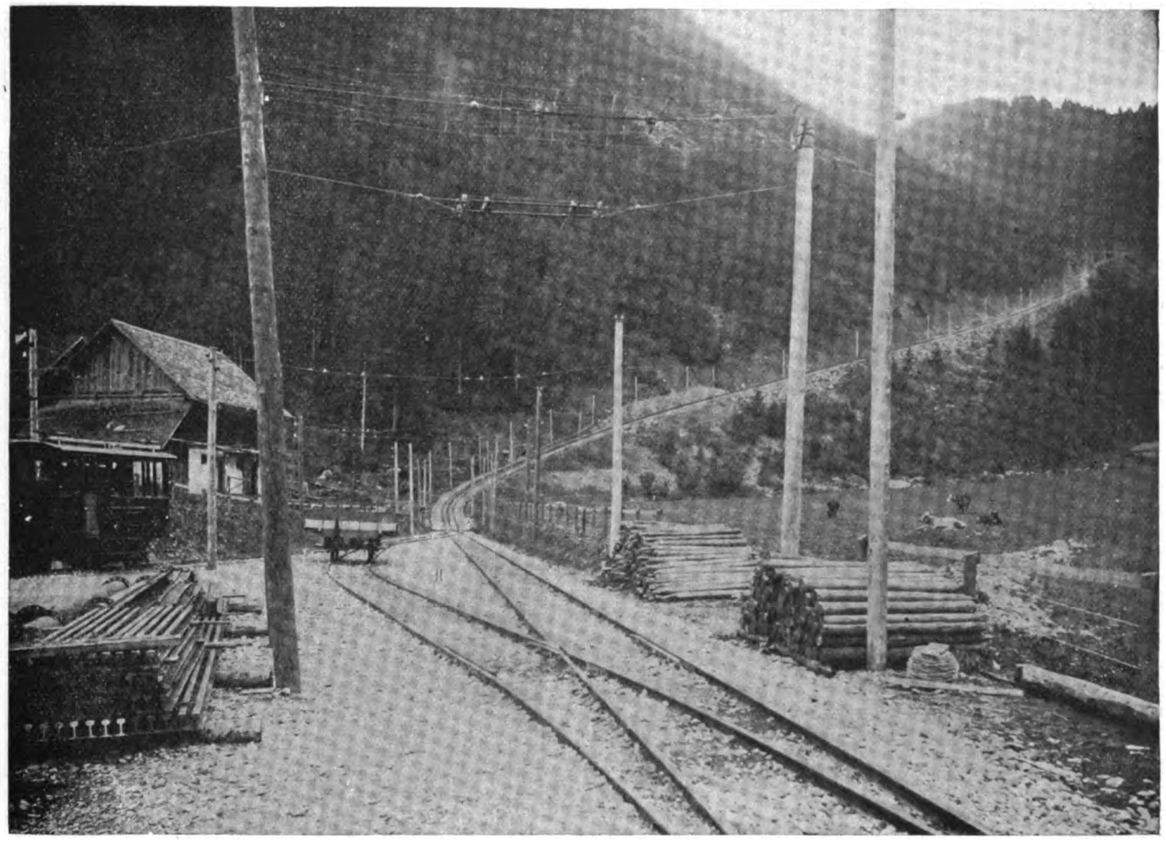

FIG. I.—POWER HOUSE, AND FOOT OF INCLINE.

Digitized by Google

this section being an average of 25 per cent.

The first-mentioned section of track is operated by single motor cars which are

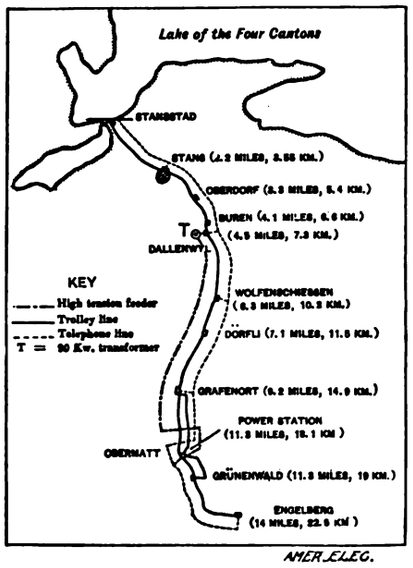

FIG. 2.—MAP OF LOCATION AND TROLLEY LINE.

designed to be capable of drawing one trail car. At the foot of the steep incline an electric locomotive is run up behind the motor car, and without coupling the train proceeds up the grade under the power of the locomotive alone. On arriving at the upper point, the motorman of the car turns current into the motors and the car proceeds to the end of the line under its own power without being obliged to uncouple from the locomotive. A view of a train going up the incline is shown in Fig. 6.

To descend, the car runs on the rack section and the locomotive is coupled. When they arrive at the bottom of the incline the motor car proceeds independently after about two minutes' delay for uncoupling.

The speed of the cars is absolutely constant, being at the rate of twelve miles over the long portion of the road, and three miles going up the incline. While operating under constant speed may have disadvantages under some circumstances, it has the advantage that the motorman is not able to waste current by lack of judgment or take liberties with the running schedule, while the manipulation is confined to closing a switch and slowly cutting out a starting resistance.

The power house (Fig. 1) is located at

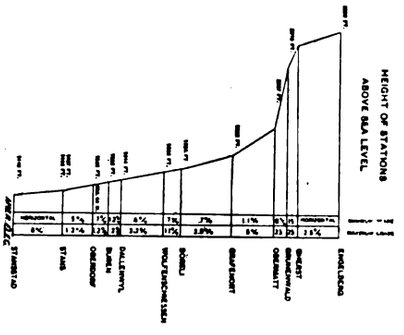

FIG. 3.—PROFILE OF ROAD.

the bottom of the rack incline, and contains two three-phase generators (Fig. 5) of 200-h.p. each, driven by turbines at 65 r.p.m., and excited by two 10-h.p. direct current machines, each driven by a small turbine. The current is generated at 750 volts and 35 periods, and is conducted directly to the trolley wire supplying the section immediately adjoining the station. In addition, feeders are run to the extremities of the sections having the highest grades, at Grafenort and Grunewald. Fig. 2 shows the distribution of current. To feed distant sections the voltage is stepped up to 5000 and then lowered to 750; there is a 90-kw. transformer for this purpose at the power house, the lowering transformer of the same capacity being 6.9 miles distant.

In Fig. 7 are represented the generating and distributing circuits. G is a 750-volt three-phase generator; E a 110-volt direct-current exciter; R. a regulating rheostat, and T a 750-5000-volt transformer.

There are two trolley wires of a size somewhat larger than No. 1, B. & S. gauge (75 mm.), the ground return serving for the third conductor of the three-phase system.

The rolling stock is composed of two electric locomotives, five motor cars and four freight cars. The locomotives (Fig. 10), which have a weight of 16.5 tons, draw the cars on the rackrail section, as well as handle the freight trains. These locomotives are mounted on two axles, and are equipped with two motors of 75 h.p. each, and drive the rack gear wheel by a double reduction gearing as shown in Fig. 4. The motors operate at a speed of 650 r.p.m., and the speed on the rackrail is 3 miles per

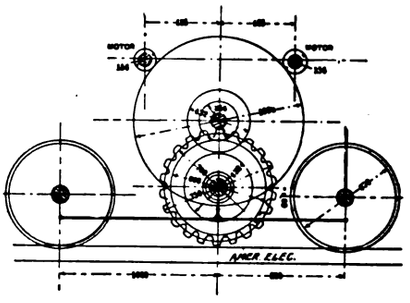

FIG. 4.—RACK DRIVING GEAR.

hour. In addition, the locomotives are so built that the rack gear can be disconnected, and they can operate on the ordinary sections at a speed of 8 miles per hour.

The duties of the motorman are very simple. He closes first the main switch and slowly cuts out the resistance which is in the circuit of the motors. The motors operate then in synchronism with the generators of the power station and at a constant speed, independent of the load drawn. When ascending a grade of 25 per cent and pushing a motor car completely loaded, the locomotives absorb an average of from 95 to 100 amps. at 750 volts. In descending and with the same conditions of load, the motors furnish a current from 60 to 65 amps., going up to a maximum of 75 amps. The current is taken from the overhead wires by means of two sliding bow con-

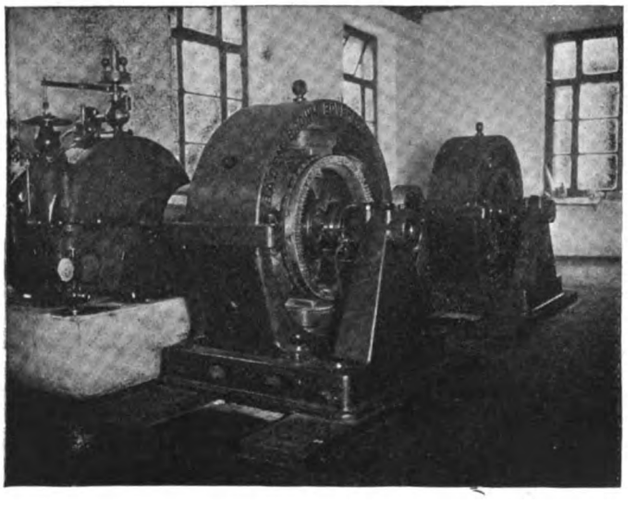

FIG. 5.—THE GENERATORS.

FIG. 6.—TRAIN ON INCLINE.

Digitized by Google

tacts, which are composed of two long cylinders of aluminum separated from each other by a piece of wood soaked in paraffine. The bow system of contact has been adopted in order to avoid the difficulties of construction with overhead frogs, which were not considered desirable with two

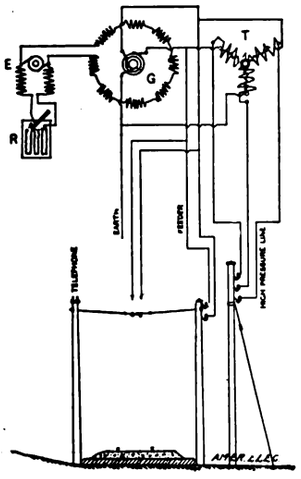

FIG. 7.—DIAGRAM OF GENERATING AND DISTRIBUTING CIRCUITS.

trolleys. The bows have given up to the present excellent satisfaction.

The locomotives are fitted with the following braking apparatus: first, ordinary brake shoes that operate on the four wheels; second, the motors working as generators when the current is reversed, the speed of the motors being constant whether they work as motors or generators; third, an emergency brake, operating simultaneously on the two grooved pulleys

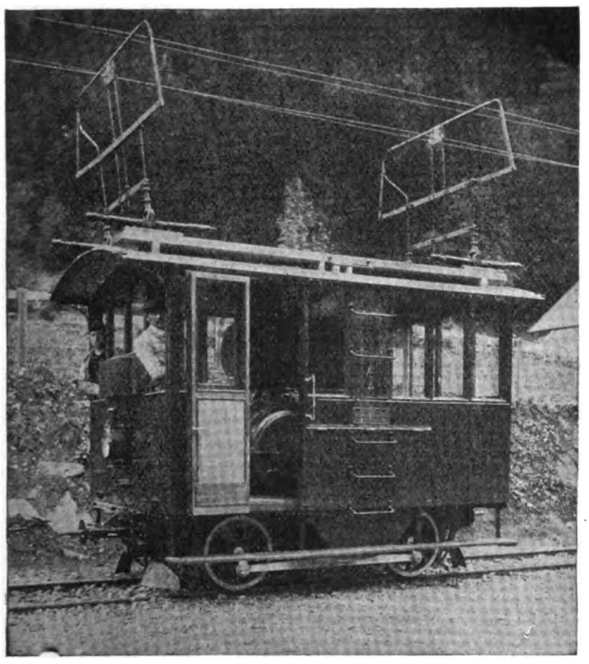

FIG. 10.—ONE OF THE LOCOMOTIVES.

or drums, of which one is mounted on the shaft of the motor and the other on the counter-shaft placed between the motors and the axles. These two brakes are connected mechanically together in such a way that the pressure divides itself uniformly on the two axles. When the eight brake shoes are applied a pressure is brought to bear against the grooved pulleys at the same time. The rack brake is operated in two different ways, by hand and automatically. To secure this a speed governor is used, which puts the brake in operation when the speed exceeds the normal. Moreover,

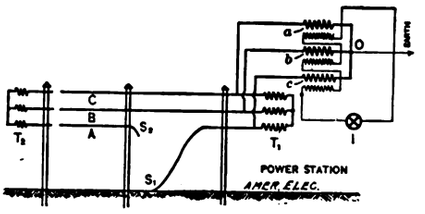

FIG. 8.—DEVICE TO DETECT BREAKAGE OF A LINE WIRE.

when the main switch is opened the brakes are automatically set.

The motor cars at present are five in number, and have a length of 46 ft. They are mounted on two trucks and divided into six compartments, not counting the compartment for baggage placed at the end of the car. The number of seats varies from 44 to 48. The two platforms are inclosed by a vestibule, the windows of which can be lowered at pleasure. The forward platform is reserved for the motorman, who has at hand the following apparatus for controlling the speed: a switch, a lever for throwing in the resistance of the diverter, and a hand brake. The approach of the car is signaled by means of a horn, and the car carries a small, primary battery, so that the conductor, who is on the rear platform, can signal to the motorman on the front platform.

The two motors are carried on the two axles of the same truck; they are 35 h.p. each with six poles, revolve at 480 r.p.m., and drive the axle by gearing. The free swivel truck is furnished on one axle with a toothed gear emerging in the rack and arranged to be braked by means of an emergency brake carried on the rear platform of the car. The efficiency of the motors at full load is 80 per cent, including the gears.

The regulating resistance, which is thrown in the induced circuit of the motors, is carried on the roof of the car, and inclosed in a water-tight case. The electric equipment of the cars is completed by fusible plugs and lightning arresters, as well as lamps for the general lighting of the interior of the car, and two signal lamps carried regularly on the head.

An interesting feature of this installation is the method of braking. When a train descends the grade of 25 per cent the motors are connected to the line as generators and send power into the line. This power is utilized in part by the other cars on the section, but as the amount of power produced in descending this steep grade is generally greater than the consumption of the other trains, the surplus has to be absorbed in some other way. Consequently at the central station there has been installed a water rheostat (Fig. 9) consisting of three rails laid in the discharge canal from the turbines. The distance between these rails and their length has been so adjusted as to permit their absorption of from 140 to 240 h.p. When a train starts to descend the steep grade the central station is advised of the fact by telephone, and the engineer at the central station throws in the water rheostat by means of two special switches. The system, although somewhat primitive, has given excellent results so far.

Another interesting feature is the device intended to prevent accidents from the breakage of the wires of the 5000-volt circuit. Referring to Fig. 8, the primary coils, a, b and c, of the three small transformers, are connected to three wires of the high-tension circuit at the points where

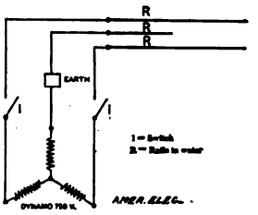

FIG. 9.—WATER RHEOSTAT.

they leave the station, and possess a common point O, which is led to earth. The secondary currents of these three transformers are connected in series to a single circuit, in which also is connected the apparatus which will produce the interruption of the primary circuit at the moment designed. The secondary e.m.f. of these transformers is 50 volts. The automatic circuit breaker in the circuit at I is an arc lamp.

When there is nothing abnormal in the circuit—that is to say, when there is no broken wire, there is an equilibrium of the entire system, and the secondary coils of the three transformers are not traversed by any current. When, on the other hand, any one of the three wires is broken, the equilibrium is interrupted. The unbalancing causes the secondary coils to be excited, and the current circulates so that the moment the carbons light they interrupt the exciting circuit of the generators. The tests made with this apparatus have consisted in letting a wire of the transmission circuit fall to the ground, and have shown that the interruption of the exciting circuit of the generators is produced in a length of time varying from four to seven seconds. The effect is then not absolutely instantaneous, but it would not be difficult to increase sensibly the rapidity of its operation, for example, by substituting for the arc lamp a circuit breaker which would open the circuit almost instantaneously.

## FIELD WINDINGS OF DYNAMOS.

BY PROF. ARTHUR L. RICE.

The ordinary method of generating voltage in a dynamo is by moving a series of wires, which are wound on the armature core and connected in series, in a strong magnetic field. In order to denote the condition of the space in which there exists a magnetic field and to be able to discuss different intensities, the convention has been adopted of considering that such space is filled with magnetic lines or lines of magnetic force, and the intensity of the field is represented by the number of such lines which are supposed to exist per square inch. The magnetic field (or the lines) may be confined to an iron circuit in something the same way that a current is confined to an electric circuit; also the iron offers some opposition to the establishment of a magnetic field as does a conductor to an electric current. The great difference comes in the fact that all substances except iron and steel oppose very strongly the setting up of magnetism through them, but do not entirely prevent it; while all metals and some liquids are more or less good conductors, but substances such as mica, wood, rubber, cotton, porcelain and glass, known as insulators, will entirely prevent flow of current through them.

The non-magnetic materials when present in a magnetic circuit have the same

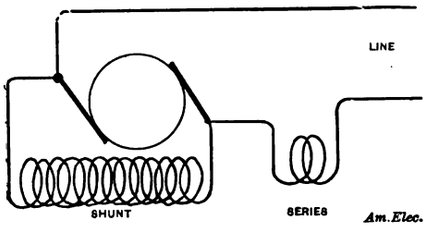

FIG. 1.—SHORT SHUNT CONNECTION.

relation to it that high resistance conductors have to an electric circuit; that is, they require a large force to establish magnetism through them, but do not prevent its establishment.

In the magnetic circuit of a dynamo there are included the cores of the field spools, the yoke joining them, the core of the armature and the air space, called the "gap," between the armature core and the pole faces. All parts are of iron or steel except the gaps, and hence require a comparatively small magneto-motive force to set up magnetism through them. The amount of magneto-motive force required in the iron parts depends on the strength of the magnetism which it is desired to set up; at high densities, such as are often used in the teeth of a toothed armature core, this may become considerable, but will seldom compare with the force needed to set up magnetism of the same density through an equal length of air.

The use of the field winding is to establish through the magnetic circuit of the dynamo, and especially through that portion in which the armature conductors revolve, the strong field needed for the generation of e.m.f. The magneto-motive force needed to set up this field is usually expressed in ampere turns; that is, in the turns of wire times the current flowing. The m.m.f. needed may be gotten by using many turns of wire and small current, or fewer turns and larger current. The more turns the greater will be the cost for copper; the greater the current, the larger will be the heat loss, and a limit to choice in this direction is set by the allowable heating of the field coils. This will confine the shunt current to not over 5 per cent of the line current, the value generally being much lower than this, depending on the per cent of loss allowed in the field winding. When the number of ampere turns has been determined and the space allowable for the coil decided upon, so that the average length of a turn on the coil is known, the size of wire is determined by the following considerations:

The current in amperes through the coil will, by Ohm's law, be equal to the e.m.f. on the field coils divided by the resistance of the coils;

$$\text{amp.} = \frac{\text{E.M.F.}}{\text{Res. of field}};$$

the resistance of the fields = the resistance per 1000 ft. × the length in thousands; R field = R per 1000 ft. ×

$$\frac{\text{length in ft.}}{1000.};$$

the length in ft. = the length of one turn × the number of turns. Combining these expressions,

$$\text{amp.} = \frac{\text{E. M. F.}}{\text{R per 1000 ft.} \times \frac{\text{length of 1 turn} \times \text{turns}}{1000}}$$

or the Res. per 1000 ft. =

$$\frac{\text{E.M.F.} \times 1000}{\text{amp. turns} \times \text{length one turn in ft.}}$$

The e.m.f. used should be about 25 per cent less than that of the machine to allow for regulation by the rheostat. From the resistance per 1000 ft. the size of wire may be determined from a wire table.

To decide whether the proposed winding is allowable, it is necessary to test if the rise in temperature which will follow its use is safe for the insulation. The rise usually considered safe is 80 degrees F., and there will be a rise of 99 degs. for each watt loss in heating of the field coils, which has to be radiated from a square in. of surface; that is, watts per sq. in × 99 = rise in temp. in degs. F. The watts allowable per sq. in. will then be,

$$\frac{80}{99} = 0.81$$

and the coil must be tested for this value. For good economy the resistance of the shunt must never be less than 300, and is better made 1000 times the armature resistance.

In determining the shunt winding, the flux to be established is that needed to establish the e.m.f. when there is no load on the machine. When current is flowing through the armature there is a tendency to demagnetize the fields, and also the e.m.f. at the machine terminals is less because of the drop in the armature due to its resistance. Both these effects increase as the line current increases, and therefore may be counterbalanced by the use of the line current carried around the field coils a number of times so that the back m.m.f. of the armature current is overcome and the magnetic field strengthened sufficiently to cause the e.m.f to rise as much as it will be cut down by the drop in the armature. By increasing the number of turns in the coil which carries line current,—which is in series with the line and is the "series" or "compound" coil,—the e.m.f. at the terminals of the machine may be made to rise as the current flowing in the line increases, and thus the dynamo may be over-compounded for the drop in the line or the feeders. It is difficult to compute accurately before the machine is wound exactly the number of series turns needed for any given compounding; in order to avoid rewinding, it is customary to put on a considerable number more turns than would probably be needed and to shunt part of the current by a piece of german silver or iron across the terminals of the series coil. The resistance of this shunt can be adjusted to give any desired value of compounding. The process of computation of the ampere turns needed for the shunt and series coils is being given in "Practical Lessons in Electricity," so need not be taken up here.

If it is desired to compound a dynamo after it is built, the number of series turns needed can be gotten as follows. Run the machine at no load and measure the cur-

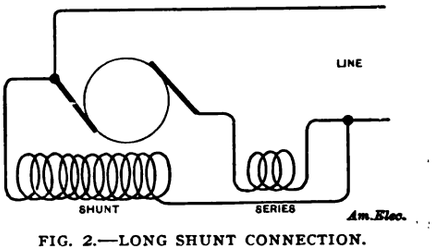

FIG. 2.—LONG SHUNT CONNECTION.

rent needed in the fields to bring it up to and adjust the field regulator until the voltage is at the required value. (If the machine is to be even compounded, this will be the same as the e.m.f. at no load; if overcompounded, it will be larger by the amount of the overcompounding.) Measure the field current again. The difference in these two readings of field current times the number of turns on the field coils will give the ampere turns needed in the compound coil; this value divided by the current in the series coil will give the number of turns needed. In the "short shunt" connection, Fig. 1, the shunt coil is connected directly to the brushes so that the shunt current does not go through the series coil; the "long shunt," Fig. 2, has the shunt connected across both armature and series coil, and the series coil does carry the shunt current. The former method requires a few more turns in the series coil to make up for the less amount of current. The size of wire to be used on the series coil is determined by the amount of heating permissible. In general its resistance should not be more than the resistance of the armature, and it is better kept below

Digitized by Google

two-thirds of this value. This is a matter of efficiency of the machine, and any size of wire larger than that thus indicated may be used, but will increase the weight of copper on the machine and therefore the cost.

The shunt winding is generally made of a single cotton covered wire wound on the end of the spool next the yoke; it has a great many turns, high resistance, and uses only a small current. Leads of flexible cable are joined to the wire and brought out to make connections from spool to spool and to terminals.

If the shunt current of a 10-kw. machine which runs at 125 volts is to be 2.5 per cent. of the total current, it will be

$$\frac{10000 \times .025}{125} = 2 \text{ amperes.}$$

The resistance would then be, allowing 25 per cent of the voltage for regulation,

$$\frac{125 \times .75}{2} = 47 \text{ ohms.}$$

By the same process, the resistance for the shunt of a 50-kw. machine would be 9.4 ohms, but as the output increases the field loss allowed generally decreases, so that at 50 kw. it would be about 1.5 per cent and the resistance would be about 15.6 ohms. For some examples of two-pole commercial machines the resistances are, for the 10-kw., 53.8 ohms, and for the 50-kw., 12.4 ohms.

The series coil is wound up of copper strip, flexible cable or large wire, depending on the size of the machine. It is generally put on the end of the spool next the armature so that it will have as great an effect as possible on the magnetism in the air gap. The terminals are brought out as bars or as heavy flexible cable. Usually all the shunt coils on a dynamo are joined in series, and the compound coils are all joined in series. This is more likely to give the same degree of magnetization in all the poles than any other method of connection.

For the series coils of the previously considered machines, the resistances at two-thirds of the armature resistance would be .0284 ohms for the 10-kw. and .006 ohms for the 50-kw. The actual resistance of the compound coils on the machines cited are .015 ohms for the 10-kw. and .0014 ohms for the 50-kw. The total field loss in watts for the 10-kw. would be about 260, or 2.6 per cent of the output; for the 50-kw. the loss would be 932 watts, or about 1.9 per cent of the output. The resistances and field loss will be about the same for all well-designed machines of the same output regardless of the type. The resistances of the fields will increase in direct proportion to the square of the voltage; then the field loss which equals

$$\frac{E^2}{R}$$

will, if the voltage be doubled, be

$$\frac{(2E)^2}{4R} = \frac{4E^2}{4R} = \frac{E^2}{R}$$

the same as before. There will be twice as many turns of wire with half as large cross-section.

The relation between the ampere-turns on the shunt and series fields is not very exact, but may be averaged roughly as about 2 to 1. The accompanying table gives the resistances and losses of 125-volt direct-current dynamos, values being taken from the average of a number of tests and being about what would be found in any of the medium speed machines on the market.

The large per cent loss in the shunt field of the 50-kw. machine is due to the considerable rheostat resistance needed to hold the voltage down; the heat generated in the rheostat is wasted. The values agree fairly well with the table above given by D. C. Jackson in his "Text Book of Electro-Magnetism" for average losses of a dynamo:

TABLE II. PERCENTAGE LOSSES.

| OUTPUT. K. W. | Total Field Loss, Per Cent | Armature Loss, Per Cent. |

# Improvement of the Steam Engine.

## IMPROVEMENT IN THE ECOMONY OF THE STEAM ENGINE.

BY PROF. W. F. DURAND.

The aim of those concerned with the improvement of the steam engine as a prime mover is to decrease the cost of operation per unit of delivered power. This cost first and last is dependent on many conditions, chief among which are: (1) The cost of coal. (2) The efficiency of the boiler or the cost of steam in pounds of coal. (3) The thermal efficiency of the engine or the cost of the indicated horse power in terms of the steam, or, more properly, in terms of the heat of which the steam is simply the carrier. (4) The mechanical efficiency, or the fraction of the indicated power which can be delivered to a driven machine, such, for example, as an electric generator. With 1 and 2 we are not at present concerned. They relate fundamentally to the boiler part of the power plant. We are here concerned with the economy of the steam engine alone, and this depends simply on 3 and 4, the thermal and mechanical efficiencies of the engine.

Regarding the latter, it may be said in brief that advance in this direction must come in improved methods of mechanical design and construction. Much in this way has been accomplished in the past few years. The total loss due to mechanical inefficiency and absorbed by frictional resistances is probably not over 8 to 10 per cent in good practice at the present time. With further advances toward ideal mechanical perfection, it becomes more and more difficult to make additional steps, and it is probable that with present types of engines, but little more can be gained in mechanical efficiency.

Turning now to 3, the subject proper of the present article, we shall discuss the various conditions upon which depend the thermal efficiency of the steam engine.

A discussion of the fundamental principles relating to the efficiency of the steam engine will be found in the AMERICAN ELECTRICIAN for August, 1896, page 117. To sum up briefly these fundamental points, it appears from the science of thermodynamics that the ideal efficiency of any heat engine is expressed by the difference in the temperatures between which the engine works, divided by the higher temperature measured from the absolute zero. In symbols this becomes:

$$e = \frac{t_2 - t_1}{460.7 + t_2}$$

where $e$ is efficiency and $t_2$ and $t_1$ are the higher and lower temperatures between which the engine works. The conditions to be fulfilled in order that this efficiency may be attained are as follows: (1) The absorption of heat by the working substance must all take place at the constant upper temperature, $t_2$. (2) The rejection of heat must all take place at the constant lower temperature, $t_1$. (3) The passage of the working substance from the higher temperature, $t_2$, to the lower temperature, $t_1$,

Digitized by Google

must be by means of an expansion in which no heat is either absorbed or rejected. (4) The passage from the lower temperature, $t_1$, to the higher temperature, $t_2$, must be by means of a compression in which no heat is either absorbed or rejected. Such a series of operations constitutes the so-called *Carnot* cycle, and stands as the highest ideal toward which the actual engine cycle should be made to approach as closely as possible. In practice no one of these conditions is actually fulfilled, and the efficiency attained is hence only a fraction of the ideal. This fraction or relative efficiency may vary from about 75 per cent downward as the conditions for the ideal cycle are more and more widely departed from.

It will be plain now that improvement in the steam engine may proceed along two lines. (1) An attempt to raise the ideal efficiency, expecting that the actual efficiency will follow upward in proportionate degree. (2) An attempt to approach more nearly to the ideal conditions and thus to realize a larger fraction of the ideal efficiency as fixed by the given temperature limits. All methods for the improvement of the steam engine may be grouped under one or the other, or both of these headings. Let us examine in order the more important.

Reference to the value of $e$ above shows that improvement in the ideal efficiency may be realized by relatively increasing the numerator of the fraction. This may be brought about by either lowering the lower temperature, $t_1$, or raising the higher, $t_2$, or both, thus in any case increasing the temperature range. Practically the lower temperature cannot be much lowered. In a condensing engine it is the temperature of the condenser, and it is not practicable to reduce this much below 100 to 120 F. It only remains then to raise $t_2$, the upper temperature, or the temperature of the steam as it enters the cylinder. This may be done by using higher steam pressure or by superheating, or both. In the former the pressure is raised, but without attempting to superheat, so that pressure and temperature increase together according to the law for saturated steam. In the latter the steam is heated out of immediate contact with water, and thus becomes superheated. In such case the increase of pressure relative to temperature is less rapid than for saturated steam, so that the temperature is higher than for saturated steam having the same pressure or the pressure is lower than for saturated steam having the same temperature.

Both of these methods of increasing efficiency are attracting present attention from those concerned with these problems. It may be noted, however, that with superheated steam, unless the degree of superheat is considerable, it will all disappear on the entrance of the steam into the cylinder, due to the absorption of the heat by the relatively cold walls, as discussed further at a later point. It will result in such case that the actual temperature range will not be increased, though a saving will be effected as will be seen later under another head.

Let us now turn to the means available for improving the process by means of which the heat of the steam is transformed into mechanical work. We must first note the more important ways in which the actual process departs from the ideal as already described. It will be remembered that in the ideal cycle the elevation of temperature is obtained wholly by a compression without loss or gain of heat, and that all heat received is taken in at constant temperature during the next stage of the process. In the actual process the water is fed into the boiler at a relatively low temperature, which is gradually raised by the addition of heat until the temperature of boiling is reached. Then during transformation into vapor the heat is added at constant temperature. Again, in the ideal process the expansion should be without loss or receipt of heat from without. This is not fulfilled, because the walls of the cylinder absorb heat from the steam during admission, and then give it back to a greater or less extent during expansion.

Again, in the ideal process the heat is all given up at the constant lower temperature of the cycle. This is not fulfilled in the actual process, for expansion is rarely down to the back pressure, and the heat is therefore given up at a range of temperature extending from that at the end of expansion down to the final exhaust temperature. The compression is furthermore usually incomplete, and in any event it does not deal with the actual working substance which is rejected from the cylinder and sent to the boiler as feed water.

In addition to the losses due to these various irregularities of the cycle there is a constant loss of heat by radiation from the outer surface of the cylinder and piston rod, and by conduction through the frame, bed-plate, etc.

Then again, parallel with the cycle through which the steam passes, there is also a cycle through which the metal of the cylinder passes, resulting in a transfer of heat from the boiler to the condenser without doing useful work. This operation is as follows: At the instant the steam valve opens the steam rushes in, to find itself in contact with surfaces which have but recently been exposed to the influence of the condenser or the external air. They are therefore at a lower temperature than the steam, and hence absorb heat from it, resulting in its partial condensation.

This absorption of heat has been already referred to above in speaking of the irregularities of the cycle, and, as there stated, a part of the heat so absorbed will be given back during expansion. As noted, this results in a loss by itself, but by far the greater part of this heat is not returned until the exhaust period. This means that it is carried by the exhaust steam to the condenser without doing useful work. It thus appears that this action of the walls of the cylinder is equivalent to a means whereby a part of the heat short circuits past the work producing cycle in the cylinder, and thus escapes. The heat, which thus avoids the regular cycle, appears as an expense, but with no corresponding useful result.

We may here quote from an earlier communication by the author on this same subject.*

"This action of the walls of a steam cylinder depends on their capacity, when at a lower temperature, for absorbing heat from the steam during admission and for giving it up when at a higher temperature, as during exhaust. The amount of such action depends therefore on the range of temperature between admission and exhaust, and on the particular readiness with which the walls absorb and reject heat according as they are cooler or hotter than their surroundings. There are, therefore, two distinct features to be considered—the range of temperature and the characteristic readiness of absorption and emission. Now it seems to be the case that once the walls of the cylinder become wetted or covered with a film of moisture, the absorption and emission of heat into and from the metal proceed with much greater readiness than when they are dry. In other words, the passage of heat between metal with a moistened surface and moist steam is much more rapid than between the same metal with a dry surface and dry or superheated steam. In the ordinary steam engine we have, therefore, an action of the walls due to the range of temperature employed, and to the natural capacity of cast iron to absorb and emit heat from and to steam, greatly augmented by the presence of a more or less complete film or layer of water over the surface, arising from the condensation of the first entering saturated steam."

This action of the walls producing what is termed *initial condensation* is one of the most serious causes of loss in efficiency, and one which has long attracted the attention of those concerned with the improvement of steam engine economy. Improvement may be sought in two directions. (1) In the use of a material for cylinders which shall reduce the fundamental action of the walls as above described. (2) By preventing the formation of the initial layer of moisture on the inner walls and thus avoiding the multiplied amount of action which seems to accompany such formation.

For reducing the fundamental action of the walls several methods have been attempted. A material is required which shall be slow to absorb heat and equally slow to give it out. Various ways of treating the inner surfaces of cylinders so that they should less readily absorb and emit heat have been proposed, and some have been tried in practice. The results, however, have been comparatively small in amount, and while the engineer should always hold this in mind as a possible means of increasing economy, there has not, as yet, been found a practicable and efficient mode of carrying it out.

In the following number we shall discuss the more important methods available for decreasing the amount of water formed on the cylinder wall during the cycle. This will bring us to the questions which are more particularly attracting present attention from those interested in the economy of the steam engine.

## TYPES OF AMERICAN LIGHTNING ARRESTERS.

BY H. E. RAYMOND.

Among lightning arresters depending upon a movable mechanism for arc destroying devices, the Garton type occupies a prominent position. This arrester, the station form of which is shown in Fig. 1 and the cross-sectional view in Fig. 2, is designed for operation on both direct and alternating currents of any frequency and voltage. Standard sizes include those for use on circuits of from 52 to 2000 volts.

FIGS. 1 AND 2.—GARTON STATION ARRESTER.

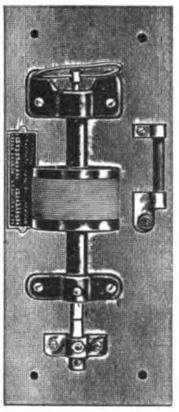

FIG. 3.—GARTON RAILWAY STATION ARRESTER.

FIG. 5.—GARTON CAR ARRESTER.

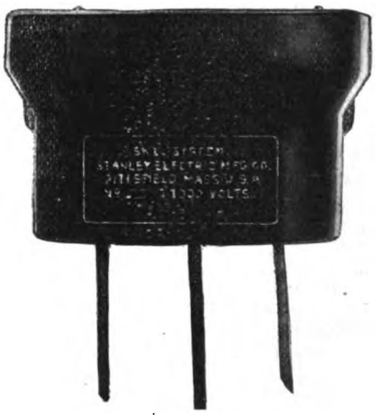

FIG. 7.—S. K. C. ARRESTER FOR LINE USE.

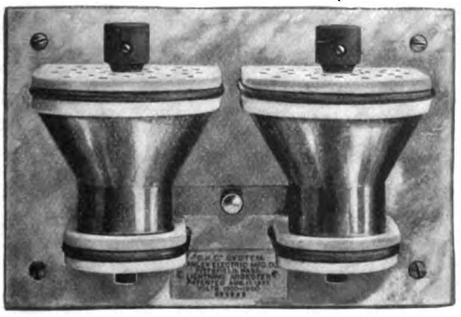

FIG. 6.—S. K. C. STATION ARRESTER.

FIG. 8.—PARTS OF S. K. C. ARRESTER.

In Fig. 3 is shown the street railway station form, which differs from the ordinary station arrester in the resistance of the graphite, and in the fact that the coil is normally rests on the top of the upper discharger, is drawn up by the magnetism of the solenoid, and the arc broken in the tube in which it forms.

The action of the arrester is such that a discharge coming from the line enters the arrester at the lower end of the graphite in shunt with part of the resistance only. The pole arrester, Fig. 4, is of similar type, inclosed in a weather-proof box of wood or iron. The car arrester, Fig. 5, is also similar, and is placed in a case provided with flanges, in such a manner that the lower end may project below the car

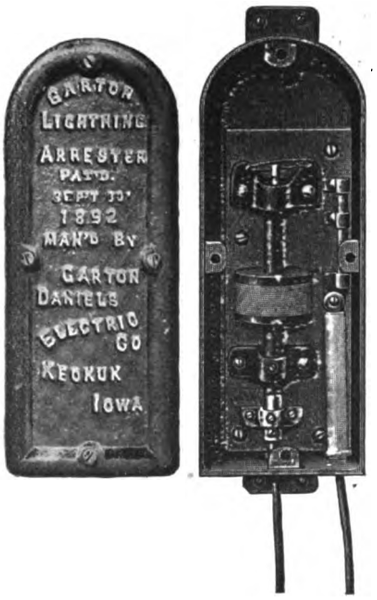

FIG. 4.—GARTON POLE ARRESTER.

floor and reduce the space required. The Garton-Daniels Company recommend the use of one arrester on each wire where it enters the building. They also employ choke coils made up in a convenient form.

The S. K. C. arrester, the open form of which, Fig. 6, is designed for station use, is intended to be used on alternating current circuits only. The inclosed or outdoor form, Fig. 7, is identical with the station type except that it is placed in an iron box. The arrester consists of two nests of tunnel-shaped concentric brass castings surrounding a central cylinder. The diverging portions are placed at the top, and at both top and bottom are porcelain plates grooved to fit the brasses, or cylinders, and hold them in certain relative position. To the innermost cylinders the line is electrically connected. The outer cylinders of each pair are joined by a metal strip, to which in the double pole form the ground wires are connected. These dischargers are held by the grooves in the porcelain, Fig. 8, in such relative positions that the parallel portions shall be 1-16 in. apart. The upper cone-shaped or flaring portions are made so that the angle of divergence from the perpendicular increases toward the outer discharger. By

Digitized by Google

this means it is claimed a natural sparking distance is obtained, and should the arc form, it would travel upward to where the terminals are further apart. This increased distance, together with the greater surface and the upward currents of air, will tend to break the arc.

There are three gaps for every 1000 volts, each gap being 1-16 in. long. One-half a double pole arrester contains 3-16 in. gap. This distance requires, at commercial frequencies, 5000 volts to jump it, but it is

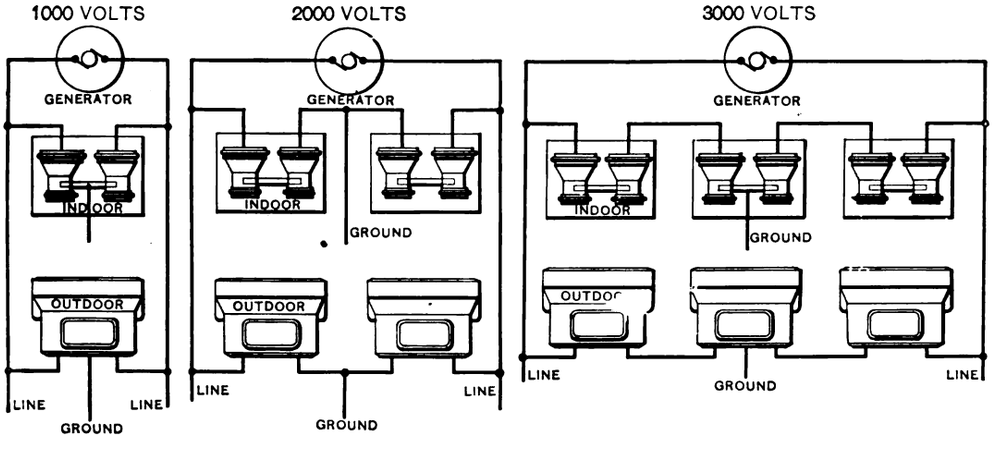

FIG. 9.—CONNECTIONS, S. K. C. ARRESTER, ON SINGLE PHASE.

claimed that at the frequency of lightning less than one-half will bridge the gap. This very considerable air space is considered an advantage on account of this very surprising phenomenon, for the space allowed would naturally permit of a certain rupture of the arc and yet at high static charge frequencies be of low discharging potential. The composition of the dischargers

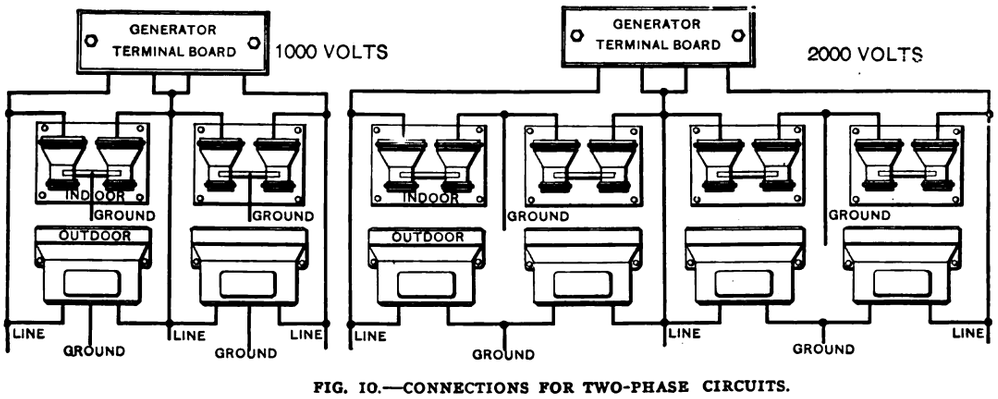

FIG. 10.—CONNECTIONS FOR TWO-PHASE CIRCUITS.

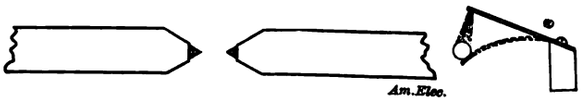
is not stated, but is presumably of some form of cast brass.



The arrester is made in one form only, the out-door type being identical with the station type, and simply placed in a weather-proof box. The standard unit is called 1000 volts double pole. For voltages higher than this they are used in combinations of single and double pole, so arranged that there will be three gaps for each 1000 volts. Fig. 9 illustrates the connections for single phase work to 3000 volts, and Fig. 10, the method of installing on two-phase three-wire, three-phase, etc.

## ARCS AND NON-ARCING METALS.

BY GEORGE T. HANCHETT.

If we place two pieces of metal in intimate contact with each other and pass through the joint an electric current, we shall find that on separating the joint an arc occurs, the magnitude of which seems to depend upon a number of causes. The higher the voltage and the greater the volume of current, the more intense is the arc. If the voltage is the predominant feature, the arc will be considerably attenuated, but if, on the other hand, the current is the large quantity and the voltage is small, the arc will also be very small.

It is further a fact that if the circuit is broken quickly, the arc will be less intense and elongated than if it is broken slowly. Another feature which may not be unfamiliar to many is, that if the terminals of the circuit are separated from point contact, such as is shown in Fig. 1, the arc or

FIGS. 1 AND 2.—TYPES OF CONTACTS.

spark is very much less than is the case of wipe contact, such as is shown in Fig. 2. The first method of breaking circuit is familiar in telegraph relays. The second appears in pendant gas burners, and it will at once be remembered that the facts just cited obtain, although the first thought would seem to be that a wipe spring contact would break so much more rapidly than a point contact that the arc or spark would be correspondingly reduced. It is also a fact that two terminals connected to a circuit which will maintain a very long and intense arc may be approached to within a few one-hundredths of an inch, and, unless contact is made, no arc will be formed.

These phenomena which have just been cited, most of which are familiar to everyone, if carefully considered seem to furnish a reasonable basis for some most interesting conclusions which it is the purpose of this article to set forth

If we are to determine the exact method by which an arc starts, we must consider the condition of the two surfaces between which it is formed at the moment of their separation. The fact that two surfaces of widely different potentials can be approached within a minute distance without forming an arc, shows conclusively that with the ordinary conditions which obtain on commercial circuits there is no static or jumping effect which is measurable.

Two surfaces are pressed together into close contact, and as they are separated the elasticity of the materials comes into play and the area of contact grows less and less, in precisely the same way as if two rubber spheres were pressed together and separated. Presently the narrow isthmus of metal through which the current flows becomes so small that it is heated red hot. It becomes smaller still and is vaporized, bridging the gap with vapors of moderately high resistance. If the resistance of these vapors is the largest part of the total resistance of the circuit there will be practically no arc, for as the area of contact diminishes the current diminishes also; but if, on the other hand, it is a comparatively small part of the resistance of circuit, and a well sustained voltage is at hand to keep up the magnitude of the current, the over heating just described will occur and an arc will follow, for current will be forced through the comparatively high resistance formed by the vaporized metals. The $C^2R$ loss will be very great and appear in heat at that point, which will vaporize more of the terminals and assist in the formation of the arc. If the surfaces are rapidly separated, the resistance of the arc will become so great that the current will fail to maintain its value and the arc will break. With arc machines the voltage is sufficient to overcome the resistance of a very long train of vaporized metal.

If this is true, and the writer believes that it is the generally accepted theory, it follows that if a metal of zero restivity could be provided it would be a non-arcing metal, for the reason that no matter how attenuated its contact might be the resistance thereof would be zero, and hence the final point of contact would not be heated at all and the arc would not start.

Digitized by Google

It also follows that if a metal was provided that is absolutely non-elastic, and if two surfaces of this metal were prepared, absolutely plane, and pressed together into intimate contact, and then separated in a line at exactly right angles to the contact surface, that no arc would follow, no matter what the current or voltage, for the reason that there would be only two resistances in the joint during the operation, namely, the resistance of the joint pressed together, and the practically infinite resistance of the short air gap. The isthmus effect, if such it can be called, upon which the arc depends for its formation, would not occur. Of course, the conditions must be such that the voltage cannot produce an electrostatic jumping. This theory offers an explanation of the point contact phenomena already referred to.

A non-arcing metal should, of course, have as high a melting point as possible, for in this way, even though an attenuated contact may become gradually overheated, the amount that is volatilized will not afford as good a nucleus for the formation of an arc as will be the case with the larger volume of conducting vapor that the same heat would form from a more fusible metal.

From the foregoing we can lay down the following specifications for a non-arcing metal. First, its refractory character should be very high. If it were absolutely infusible there would be no arc. Second, its resistivity must be very low. If it had no resistance there would be no arc. It would seem, therefore, that it is advisable to experiment with a highly infusible metal, such as platinum or iridium, and endeavor to make an alloy of low resistivity and at the same time retaining the refractory properties of the initial components.

Carbon, which is the least fusible of all conducting substances, unfortunately cannot be prepared in surfaces which will make intimate contact with each other. The contact is always granular and the little particles between the contact surfaces always become volatilized and form an arc. Moreover, its resistance is very high. In spite of these defects, carbon is one of the best non-arcing substances that we have, due to its very high refractory powers, and as such is used for auxiliary contacts or whenever a circuit is to be broken repeatedly.

Metal which, when vaporized, forms an exceedingly high resistance, will also be non-arcing, and the many metals have been made claiming to possess the non-arcing property, if they have possessed any characteristic at all that would logically conduce to this result, depend upon this principle.

The technical press has been rife with discussions as to whether there was any such thing as cooling effect; that is to say, whether the presence of a large volume of metal in the immediate proximity of an arc tended to reduce its intensity and cool it out, as it were. It seems to the writer that the arc occurring between large terminals would be less than that occurring between small ones carrying the same current at the same voltage, for the reason that under the given conditions it would be impossible to volatilize so large a volume of metal in the case of the large terminals as in that of small ones. It is evident that with large terminals the "isthmus" of metal between the two separating surfaces would be very much smaller before the vaporizing point was reached, because the heat would be more rapidly conducted away. As to the possibility of cooling out a well established arc, the writer's experience has seemed to show that the size of the terminals is immaterial.

Methods of avoiding arcs are numerous and ingenious, and all of them are based directly upon the principle of the formation of the arc, although the writer is not aware that they were applied with a predetermined notion, or for any other reason than that they were found to be effective. The simplest of these is to blow out the arc, either by means of an air blast or a magnet. The air blast blows away the conducting vapor and breaks the circuit. The magnet repels the current carrying conductor, which is, of course, the vapor, and produces practically the same result.

Another popular way to avoid the arc is to break it up into many parts by a number of simultaneous breaks in series. This practically multiplies the rapidity with which the circuit is broken by the number of breaks, and in addition subdivides the heating energy superinduced by the breaking of the circuit into many small portions, all of which are collectively unable to volatilize as much metal as if they were concentrated at a single point. In this way one large arc is exchanged for a number of smaller ones, each of which is moderately harmless.

Still another way to avoid arcs is to shunt the point where the circuit is broken by means of a high resistance. This is effective only in cases of circuits where the sparking current is due to an inductive discharge. If applied to an ordinary non-inductive break it would simply reduce the arc in proportion to the current that it deflected from the main switch jaws. If the resistance that is placed in multiple with the arc be low, it will deflect considerable current from the main switch jaws and largely reduce the arc occurring there, but in such cases it will be usually necessary to break the auxiliary circuit also.

This principle is adapted to main circuits in which the copper contacts are reinforced by carbon. The copper contacts are supposed to carry the current, the carbon to take the arc. In order that the arcs shall come for the most part to the carbon circuit, its resistance must be extremely low.

Another method of transferring the arc applies in cases where the resistance of the contact is not material, and main switch and auxiliary break are arranged in series. In this combination the carbon contacts must open first in order to take the arc, whereas in parallel combination they are opened last.

# Alternating Current Motors.

## ALTERNATING CURRENT SYNCHRONOUS AND INDUCTION MOTORS.

BY ERNST JULIUS BERG.

Although during recent years a great variety of alternating current commutator motors, such as series motors, shunt motors and reaction motors have been built, their field for usefulness has been so limited, compared with synchronous motors and induction motors, that in this article attention will be confined solely to the latter.

### SYNCHRONOUS MOTORS.

By far the larger number of alternating current motors used at present are of the polyphase type. This type has many electrical advantages, such as higher efficiency, ability to start with considerable torque, and is commercially preferable on account of its lower cost. Single-phase synchronous motors are operated in very few places. They are, however, entirely feasible, even at 125 cycles, provided the rate of rotation of the generators is uniform; that is, provided the generators are belted to fair regulating engines or water wheels, or directly connected to engines of extremely close speed regulation.

As an interesting instance of such an installation may be mentioned the station of Chatham Electric Light Company, of New York, in which a smooth-core, high-frequency, single-phase alternator is run successfully as a synchronous motor from an iron-clad, high-frequency generator. This is not mentioned to show an ideal combination, but simply as indicating that, even under extreme conditions, high-frequency, single-phase, synchronous motors are feasible. Owing to their mechanical construction, smooth-core machines are not as feasible as iron-clad, since the winding is not as rigidly held, and therefore may strip off if the motor is thrown on to the line at the wrong time, or when a very large current would be taken.

Iron-clad synchronous motors run from iron-clad alternators should always be feasible under the assumption of fair speed regulation, as stated above.

Low-frequency synchronous motors are almost all of the polyphase type since, with the introduction of the lower frequency, polyphase systems, as a rule, were also adopted. An exception to this statement may be the monocyclic 60-cycle installations, of which there are a number in which synchronous motors are used.

Synchronous motors are of similar construction to generators. As a rule, they are not composite wound, but are separately excited. This construction is adopted chiefly for simplicity, and also because the field adjustment necessary to make a synchronous motor run non-inductively at all loads is very small—much less than that necessary in order to obtain constant po-

Digitized by Google

tential from the same machine run as a generator of the same electrical output.

To illustrate this, in Figs. 1, 2 and 3 are given saturation, compounding curves and phase characteristic of a small three-phase synchronous motor.

It is interesting to note that in order to maintain constant potential at a certain load when this machine is run as generator, the field excitation is higher than that when giving the same output as a synchronous motor, so that, for instance, when operating it as generator at 110 volts, the no-load excitation is 1900 ampere-turns; with 105 amperes load, which corresponds to 20 kw. output, the field excitation is 2430 ampere-turns.

From the phase characteristic given in Fig. 3 it is seen that, for the same output as a motor, the excitation for non-inductive input to the synchronous motor is but 2150 ampere-turns.

The lower curve on Fig. 3 gives the phase characteristic at no load, and shows that the alternating current increases if the excitation is increased, or reduced, from the value which corresponds to the non-inductive position. With reduced excitation the synchronous motor is made to take lagging current, when increased, to take a leading current. The upper curve shows the same relation with full load on the machine.

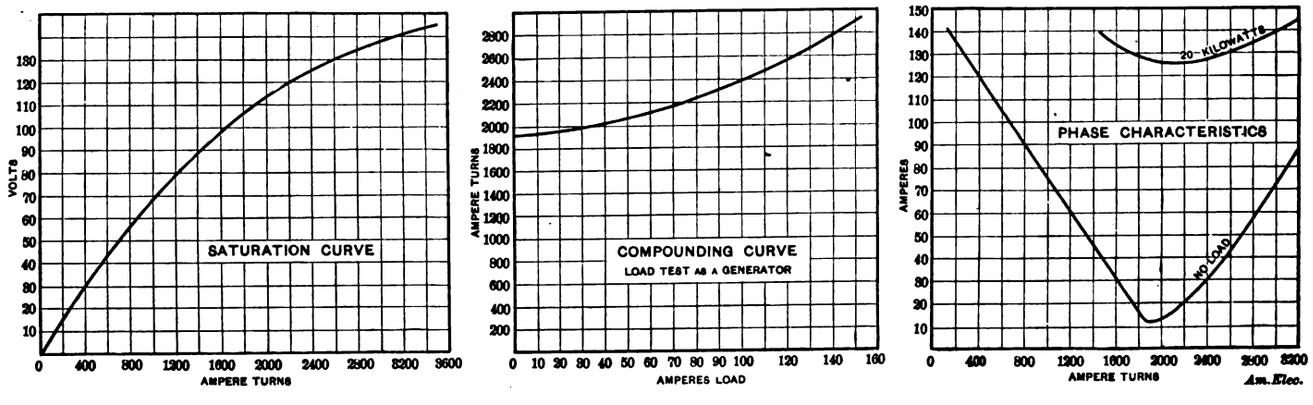
From this, it is evident that to make the synchronous motor run at minimum current at all loads, its excitation should be slightly raised with the load. However, even should the excitation be left constant, the increase in current at full load would be extremely small, 1 or 2 per cent; thus, it would be unnecessary to change the excitation with the load in this particular synchronous motor, if it were not that other results were expected, such as compensation for lagging currents introduced by other apparatus in the system. Even should the field of the synchronous motor break—that is, the motor run without direct current field—it would still run and give its rated output. The alternating current taken by the motor would, however, increase, and if the motor had a long air-gap, this increase will be large, though small with a small air-gap.

It is readily possible to build a synchronous motor in which, if the field is broken, the full load current will only be increased 30 per cent, or thereabouts. The current taken by a synchronous motor without field excitation is, however, lagging, and thus its usefulness as a compensator in systems of induction motors and such apparatus, which also take lagging current, would be nullified.

The effect of this compensation of idle currents, or what is called phase control, by a synchronous motor, although frequently discussed, is rarely appreciated.

Assume a system in which the wattless component of current is as high as 30 or 40 per cent, and that this is to be compensated for by a synchronous motor of the same capacity as the other load on the system. The excitation of the synchronous motor has only to be increased by such an amount that the full-load current taken by the motor is increased 4½ per cent and 8 per cent, respectively, which would not materially affect its overload capacity; indeed, it is almost impossible to load a synchronous motor sufficiently high to stop it, provided that the voltage impressed upon the motor is constant and the power behind it stable.

Often synchronous motors are used to give a stable point of voltage in the receiving circuit. This is done by changing the excitation of the motor so that it is made to take leading or lagging currents which, going over a line of some self-induction or other reactances, causes the voltage to increase or decrease as the need may be. This arrangement gives a condition similar to that obtained if the synchronous motors were generators.



In starting, a polyphase synchronous motor can readily be designed so as to give full load torque. Its current at starting, however, is large, usually four or five times the full load current, and consequently it is not the best motor for conditions where good starting torque is required. When a synchronous motor is started, it is advantageous to reduce the voltage so as to limit the current. This reduction in voltage can be accomplished in several ways—for instance, by inserting resistance in the line, by inserting reactance in the line, or by compensators.

By the use of resistances, the starting current is lessened by consuming electromotive force, that is, by waste of power, and is, therefore, as a rule, not to be recommended. Reducing the current by means of reactances in series with the line accomplishes the result without loss of power, but introduces an extremely poor power factor in the starting moment; consequently, this method, as a rule, will have a bad effect on the generator by reducing its voltage and causing a general disturbance in the system. The last-mentioned arrangement of reducing the voltage by the use of compensators is the proper method, since the compensator acts as a transformer and the reduction in voltage is not followed by loss in power or by the introduction of large wattless currents. In other words, the volt-amperes input for a given starting torque is very much less in the last case.

At the moment of starting the synchronous motor acts more or less as a stationary transformer in which the armature winding is the primary and the field winding the secondary; therefore, since usually the field winding has very many more turns per pole than the armature winding, the electromotive force induced in the field spools is extremely high, and special precautions have to be taken to insure safety from burning out. This is done by open-circuiting the field windings in several places so as to leave only a few poles connected in series; also, by short circuiting the field winding, and, finally, by making the body of the field spools of rather heavy metal, so as to act as a short-circuited secondary at the moment of starting.

Depending upon which of these methods are used, the starting torque and the relation between the starting torque and the starting current changes. As a rule, when the field windings are left open-circuited, the most favorable starting condition is obtained; with the field winding short-circuited, the condition is poorest, although the safety factor is highest in this case. By using a low-resisting short circuit around the spools, a fair starting torque with a fair starting current is obtained, and this method is probably the best all around. When up to speed, the fields are excited in the usual way by direct current.

Although induction motors, as well as synchronous motors, are sensitive to the speed regulation of prime movers, there is no doubt that a synchronous motor requires a much closer speed regulation than induction motors. Therefore, before deciding upon the installation of synchronous motors, a thorough investigation of the prime mover has to be made. As a rule,

FIGS. 1, 2 AND 3.—CURVES OF THREE-PHASE SYNCHRONOUS MOTOR, 20 KW., 110-VOLTS.

Digitized by Google

water power, which gives a uniform rate of rotation of the prime mover, does not offer any difficulties, but often steam engine driven alternators prohibit their use. This is frequently the case when the generator is direct connected to a slow speed engine; with belted generators difficulties are rarely experienced. The more poles a given alternator has, the the closer speed regulation of the engine is required. Indeed, the percentage speed variation permissible is indirectly proportional to the number of poles; therefore, very often low-frequency synchronous motor systems can be installed from steam engine driven alternators, whereas high-frequency systems would be prohibited.

It must finally be borne in mind that all generators feeding synchronous motors must be operated in parallel, since they will stop if the load is thrown off one generator to another without first having them in multiple.

In a concluding article the subjects of poly-phase and single-phase induction motors will be considered.

# Among our Foreign Contemporaries

Edited by CHARLES T. CHILD

**Calcium Carbide.**—At a recent meeting of the Polytechnic Society at Berlin, M. Nicolai read a paper on the manufacture of calcium carbide, from which the "Electrical Engineer" abstracts some interesting data. The author stated that the best proportions of mixture were 100 parts by weight of lime to 70 of coke. Lime averaging 99 per cent of calcium oxide and coke low in ash will produce almost pure carbide. The coke should not run higher in ash than 5 per cent. Charcoal proves unsuitable for the furnace process, but in the smelting machine invented by the author it can be used. In this machine the material to be smelted is compressed to a suitable depth on an electrical conductor, and the arc touches the compressed mass only at the moment of smelting. The burning of the carbon, or the carrying off of fine particles of lime, is impossible, because the hot gas developed escapes directly into the open air without coming in contact with the charge. In the manufacture of carbide care should be taken that the raw material is not burned by the hot gas, as is often the case in the electrical furnace. The raw material should be exposed to the electric arc only so long as is necessary for its conversion into carbide, and in this way the loss of material and of electric power may be reduced to a minimum.

---

**Explosions of Fire Damp by Incandescent Elements.** — Notice has been taken in these columns in other issues, of the elaborate experimental work of MM. Couriot and Meunier upon the conditions of explosion of mixtures of fire damp and air, such as are met with in coal mines. Later researches made by these experimentalists have been presented to the Académie des Sciences, and have shown conclusively that an incandescent filament will not ignite this mixture, even in its most explosive proportions. The bulbs of incandescent lamps were filled with gas, and the lamps not only carried up to their customary incandescence, but forced far beyond it. The only result noticed was a decomposition of the gaseous mixture with the formation of carbonic oxide and water vapor. In this atmosphere, surrounding the filament, a break in the latter giving rise to a flash would not ignite the remaining gas; if, however, a spark, especially one due to a rupture of a current of one or more amperes, took place in the gas, its explosion was found to be practically certain.

Probably the whole of the results of this work may be summed up by the statement that electrical apparatus are absolutely safe in fiery mines if they can be guarded against the possibility of a spark or flash. The breaking of an incandescent lamp will not fire the most explosive mixture, but the snapping of a switch may very readily do so.

---

**Home Made Fluorescent Screens.**—The (London) "Electrical Review" abstracts a communication in the "British and Colonial Druggist" describing simple fluorescent screens. The method of making the screen, as given by the author, is as follows: Take a plate of glass, say 6½ ins. x 8½ ins., and make a mat of stout paper, having an opening about 5 ins. to 7 ins. This mat is to be wetted with glycerine or gum-arabic mucilage and pasted over the plate, which is then to be covered with collodion, varnish, or mucilage containing a little glycerine. The powdered salt is then to be sprinkled quickly and evenly all over the surface. Calcium tungstate is recommended by the author as the best material, though he considers a salt of uranium (the particular salt not being specified) as giving excellent results.

If parchment, cardboard, ebonite or such material be used in place of the glass, one may put a coating on both sides, and in this way even up any inequalities of deposit. If glass is used, the coated side, which must face the tube (away from the observer), must be covered, over the layer of salt, with a piece of thin celluloid or opaque paper. When the platino-cyanides are used they should be mixed with varnish and spread on a glass or paper surface. The difficulty is to get an even coating, but a roller may be applied on any surface but glass, with satisfactory results. The author states that a vehicle of equal parts of paraffine and vaseline, melted together and containing the salt in the proportion of about one-quarter of an ounce for a screen of the size mentioned, gives most satisfactory results. It is applied while it is warm and sticky by means of a spatula. The trouble with this particular compound is that it is liable to melt and run in a warm atmosphere.

---

**Electric Mountain Climbing.**—Some interesting figures with regard to the new Gornergrat Railway, in Switzerland, are given in "Le Journal des Transports." This railway was opened on Aug. 20, last, and is the highest railway in Europe now in operation. By means of electric traction the traveler is taken up to an altitude of 9810 ft., making this ascent from the Zermatt Hotel, itself at an altitude of about 5000 ft.

The object of building the road was to substitute a more rapid, economical and infinitely more convenient method of transit for the mules, which have been used from time immemorial for this purpose. It appears that a mule costs 15 francs, and the driver expects 2 francs, and that this power can only be used in going up the mountain, because it is more comfortable and convenient to walk down than to ride down on a mule sloping forward at an acute angle. The electric line charges 12 francs to go up the mountain, and 18 francs for the round trip, and takes less than one-third of the time occupied by the mule transit method. This railway will be remembered as one of the very few on which polyphase motors are used for traction purposes. Three-phase current generated from water-power from a neighboring stream is fed directly to two parallel trolley wires and the track, and the locomotives are furnished with two trolleys; the ascent being, of course, at a perfectly constant and uniform speed.

---

**Electricity in Agriculture.** — The (London) "Electrical Review" abstracts at some length an article on this subject, recently appearing in "Electrotechnische Zeitschrift," describing two successful installations of electric plowing. It is stated that, in Germany at least, the cost of electric plowing compares favorably with that of steam plowing. In the first case described a farm is supplied with its whole light and power from a central station of 60 h.p. Alternating current at 1000 volts is generated and used principally for lighting. For driving the pumps, threshing-machines, plows and other machinery, a direct current at 500 volts is used. The director of the farm estimates the total consumption of energy at about 110,300 h.p. hours per year, about half of which is used for working the plow. Two hundred and fifty acres are plowed annually, and the estimated cost is $7.81 per acre.

On the royal farms in Prussia similar experiments have led to similar results. A communication to the Minister of Agriculture in that State puts the cost of electric plowing in heavy soil with deep cultivation at from $11.25 to $14.25 per acre, as against steam-power plowing at $21.25 per acre.

Digitized by Google

The mechanism used at Dahlwitz, the farm mentioned above, is extremely simple. The motor wagon contains a motor driving the winding drums, and the motor may also be coupled to the driving wheels of the wagon to give it the proper advance at the end of each traverse of the plow. Three men are required to tend the apparatus. The depth of the furrow is 8 ins. to 10 ins., and the speed of plowing about 3 ft. per second. At this rate of working, the consumption of current varied from 30 amps. to 50 amps. at 500 volts.

---

**Electrical Machinery in Australia.**—An article in a recent number of "L'Eclairage Electrique" gives the views of the French Consul-General in Australia as to the market for electrical machinery, and especially telegraph and telephone apparatus in that country. It is interesting to note that the imports of these articles for the year ending July, 1898, showed an increase of value of over $400,000 over those imported the year before, and the French official bewails the fact that none of these goods were French. He says that the imports came principally from England, the United States, Germany and Belgium. He reaches the conclusion that the only way in which the French manufacturer can successfully enter this market is by thorough study of the electrical conditions, so that he can exactly meet the demand to which these give rise.

This is an eminently sensible idea. The fact that such studies have not been made has led to the loss of much trade by English firms doing business in the Colonies. The expansion of German commerce into the remote parts of the earth has been very largely due to the intelligent study by German manufacturers of the conditions of the markets, including the desires of the purchasers. A striking instance of this was noticed recently in the Continental papers. A large German electrical manufacturing establishment sent two young men to China, where both were to study the language and become familiar with the conditions. At the end of a certain time one is to return to the office in Germany, while the other remains in China, and in this way a perfect understanding will be established between headquarters and the outpost of trade which they proposed to establish in the East. The idea is so good that it is certainly worth while for American manufacturers desiring foreign trade to give it careful attention.

---

**Telephone Line Protection in Switzerland.**—The Swiss Governmental Bureau of Telephones has issued a circular describing at great length and with much care the precise methods that shall be adopted by all users of telephones and telegraph apparatus in that country for the protection of their lines and instruments against heavy currents and lightning. The circular is described at some length by "L'Eclairage Electrique," from which the accompanying illustration is taken. The most interesting details are those connected with telephone protection, and the method recommended is shown in the diagram. At a point upon each side of the circuit, immediately upon its entrance into the building, is placed a tube containing the usual fusible wire cut-out, the length of the tube depending upon the voltage of power currents in the neighborhood. Between these fuses and the apparatus to be protected are heating-coils, which open the circuit for a steady current of 0.2 amp. flowing for a few minutes. The fuses blow at a current of 2 amps. The telephones are required to be mounted upon marble or slate boards, as are the various parts of the protective system. Between the connections of the fusible wire and the heating coil is attached an ordinary carbon lightning arrester, as clearly shown by the figure. In addition to these precautions to be taken by the operator of the telephone line, the owners of high-current lines of whatever sort are required to protect their

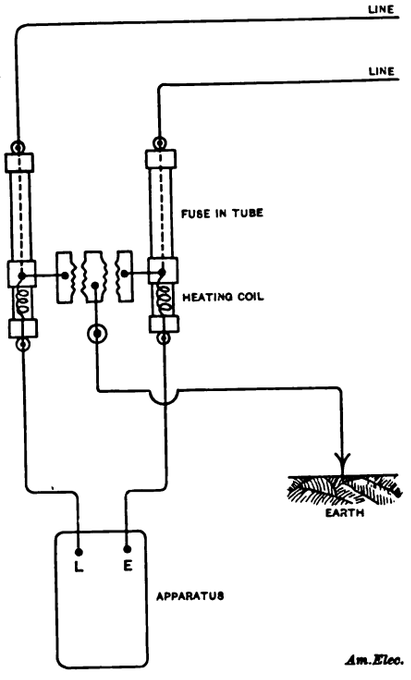


DIAGRAM OF TELEPHONE PROTECTIVE APPARATUS.

wires, at points where they cross telephone and telegraph lines, with a network of wires bound together to form a structure sufficiently strong to resist snow, high winds and the usual strains, and to sustain the weight of any number of telegraph or telephone wires or cables that may possibly fall upon it. The Swiss seem reasonably certain, if these rules are carried into universal effect, to be safe from any accidents due to the causes against which they guard in this manner.

---

**Electrical Waves and Selenium.**—"L'Elettricitá" abstracts from an article by Sig. B. Agostino, appearing in "Nuovo Cimento," upon researches as to the susceptibility of selenium to electric waves. The analogy existing between electro magnetic and luminous phenomena led the author to suppose that electric waves would perturb the conducting qualities of this material in a way analogous to the effect of visible light. The selenium was crystallized in small glass tubes having electrodes at their extremities and connected in one of the branches of a Wheatstone bridge. The tubes were placed in the focal line of a cylindrical reflector, which received the radiation from a Righi oscillator. Heavy metallic screens were interposed between the spark-gap and the Thomson galvanometer and electrometer used in the measurements. The result of the experiment made with the selenium tube in darkness, or exposed only to the action of the electric waves, showed a very small change in its resistance (not more than 1.5 per cent at most), and in some cases showed a diminution and in others an augmentation of the resistance. On account of these variations being of about the same magnitude as the limits of error of the experiments, the author concludes no variations can be attributed to the direct action of electro-magnetic waves.

This singular fact seems to indicate that the peculiar effect exercised by radiation upon selenium is confined to definite wave lengths. So far as the writer knows there have been no experiments made, until these described above, upon the action of radiation of wave lengths, other than those of ordinary visible light, upon this interesting material. As it seems unquestionably certain that the first definite steps in the direction of seeing by electricity, or transmitting light as we now transmit sound, will be in some way through the agency of selenium, it would unquestionably repay any experimenter having the necessary apparatus at his disposal to study this whole question at length.

---

**An Electrical Barber Shop.**—"L'Electricien" gives a very animated description of a barber shop in which most of the familiar operations are conducted by electricity. For example, hot water is obtained by passing the stream of a hydrant through a German silver tube in a soapstone case, the tube being electrically heated, so that the water is nearly boiling when it passes out at the spigot. "For the crimping of the frizzes of our young ladies there is no longer necessity for recourse to the hot iron. For a long time the defects of this method of heating have been noticed, for the capillary artist sometimes forgets and leaves the iron in the heating apparatus too long, so that when it is used with blonde or brown hair, if it does not make a burn, it makes the hair red, which is even more disastrous." The new curling irons heat themselves. In the interior of the rods is a ferro-nickel wire, which can be brought up to the proper temperature and will then remain at this same temperature indefinitely.

But it is in the cutting of the hair that electricity has produced the most complete revolution. The scissors have slowly given way to clipping machines, and these, in their turn, must disappear before an electrically heated platinum wire, with which the hair may be burned off. The apparatus as described, consists of a metallic comb, along one side of which is stretched the hot wire, and as this is passed through the hair, the red hot wire burns it off neatly and smoothly, and at the same time seals up

Digitized by Google

the ends of the hair; it being supposed in this way to produce a very desirable effect. The method is, of course, entirely antiseptic, but it hardly seems likely that the air of a barber shop will be very pleasant when these new methods obtain a wide popularity.

**Electric Metal Working.**—M. H. Brillié publishes, in the "Revue Générale des Sciences," a very important article upon the various methods of electric smelting, forging, soldering, etc. His paper is one of great thoroughness and value, and deals largely with the developments of these subjects in the United States. Among the numerous processes mentioned, however, are some that are worthy of particular note,

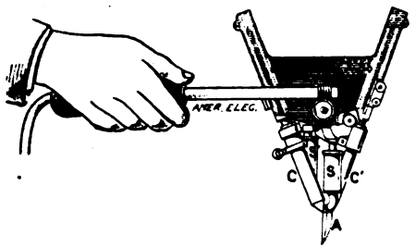

FIG. 1.—ZERNER'S ELECTRIC BLOW-PIPE.

and of these a few are described in detail below.

The electric blow-pipe of Dr. H. Zerner is illustrated in Fig. 1. The principle of this invention is extremely simple. An arc at a potential difference of about 85 volts and with a current of 20 amps. is established between the carbons C and C'. The two coils, S, are solenoids producing a magnetic field in a direction at right angles to that of the arc, causing the latter to be projected to one side, as shown at A. The regulation of the carbons is effected by the screw V, as clearly shown in the figure.

This simple apparatus is used a great deal in England, especially in the manufacture of bicycles for brazing the tubes of the frame, and in work on thick plates of steel, as, for example, boiler iron. The great advantages possessed by this form of instrument are at once evident, as it is easily handled, light, and gives an exceedingly high temperature and at a very definite point. The author suggests that it could be usefully employed in nearly every situa-

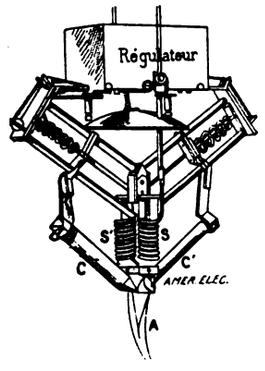

FIG. 2.—ZERNER'S ELECTRIC BLOW-PIPE.

tion where the oxy-hydrogen blow-pipe is now in use. It may be useful in the operation of lead burning in the manufacture of accumulators. Fig. 2 shows a similar apparatus, which is self-regulating and used for larger and heavier work than that described.

The Bernardos system was described at some length in these columns in the November issue. Fig. 3 shows an application of this method to the welding of a flange on a pipe. It will be noticed that the material upon which the work is being done is connected to the positive terminal of the circuit, while the carbon points, which are held in the workman's hands, are connected through the resistances, rr', to the negative side of the circuit. This operation is said to work with great rapidity and satisfaction, but a practical point of much importance in connection with it is to heat the metal to be operated upon to a dull red heat in an ordinary fire before exposing it to the arc temperature. The process is used considerably on the Continent for the repairing of boilers, cracks and fissures in steel plates being easily mended in this manner and filled up with melted metal.

The author mentions an exceedingly simple method of welding together end-wise two copper wires, or even wires of dissimilar metals, such as copper and platinum. They are connected, one to each side of a circuit of about 50 volts, and separated so that an arc plays between them. When the

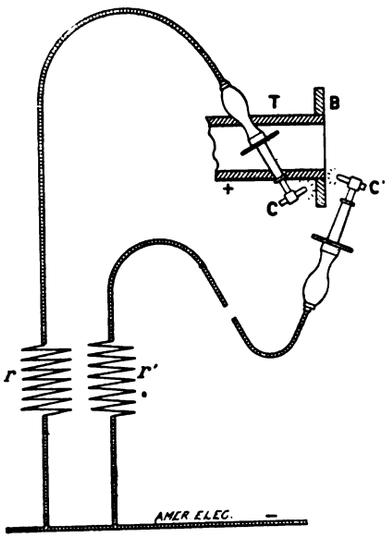

FIG. 3.—WELDING ON A FLANGE.

ends are white hot and melted they are thrust together and the current instantly turned off. The welding is said to be very perfect, and metals as dissimilar as copper and platinum may be readily welded together in this manner.

A very interesting application indeed is illustrated in Fig. 4. This is electrical heating by radiation. The figure shows the process applied to the soldering of metallic ornaments upon watch cases; *ss* are small spirals of platinum wire wound on the face of a slate block, upon which are laid the watch cases and, in position upon them, the metallic ornaments to be attached. Each case is covered by a metallic cover, C, which excludes the air and localizes the heat. Either continuous or alternating currents may be employed with perfect success, and the operation described above carried on with great celerity and cheapness.

M. Brillié's article goes into an extended

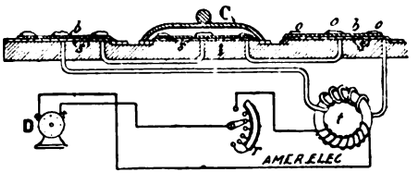

FIG. 4.—WELDING BY HEAT RADIATION.

description of many other processes to such a length that space does not permit its further abstraction here.

**Electro-Magnets on Cranes.**—Considering the enormous lifting power of electro-magnets, says "Le Génie Civil," it is astonishing that they are so rarely applied to hoisting and carrying apparatus. In all England there are only four or five. A description of these, abstracted by that journal, from "Glasers Annalen für Gewerbe und Bauwesen" may be of interest: At the Sandycroft Iron Works, in England, the hooks of all the cranes have been replaced by electro-magnets. One of them, which can sustain a load of two tons, consumes 5.5 amps. at 110 volts, or something less than a horse-power. It appears that on account of the saving of the time formerly required to attach the load to the hook, the same work can be done in an average of one-eighth of the former time required, and with three men instead of six. For loading cars with rolled iron and other metallic pieces the same economy has been noticed. At the Woolwich arsenal electro-magnets are used for the handling of projectiles weighing 790 pounds, intended for use in the 110-ton cannon of the English Navy. Formerly the handling of these monstrous projectiles was very troublesome, on account of the difficulty of properly slinging them in chains or ropes for attachment to the hook of the crane. The loss of energy occasioned by the use of these lifting magnets is absolutely negligible in comparison with the gain in convenience and saving of power occasioned by its use.

It will be remembered that the Illinois Steel Company, in this country, also uses magnets, of larger power than those described above, for handling steel bars and plates. The table above gives a comparison of the lifting power, current consumed, and weight of these magnets.

DATA OF LIFTING ELECTROMAGNETS.

| Lifting Power. | Power Absorbed. | Weight. |
|---|---|---|
| Sandycroft { 2,420 lbs.. | 606 watts, 0.8 h. p. | 297 lbs. |
| Sandycroft { 2,420 lbs.. | 220 watts, 0.29 h. p. | 253 lbs. |
| Woolwich 3,586 lbs.. | 120 watts, 0.16 h. p. | 44 lbs. |
| Illinois 12,880 lbs.. | 960 watts, 1.29 h. p. | ------ |

**Gas Driving for Small Electric Plants.**—An extremely interesting article in "L'Industrie Electrique" describes an installation for the production of wood gas, by the Riché process, for use in a dynamo-driving gas engine. Instead of burning the wood under a boiler in the usual way, if it can be converted easily and cheaply into gas and the greatly superior efficiency of

Digitized by Google

the gas engine is utilized, there will be an evident saving in cost for fuel consumed. The Riché gas is intermediate in heating power between ordinary illuminating gas and Dawson producer gas and Siemens' gas, having a heating power of about 110 metric calories per cubic foot.

Wood gas has been known since 1798 and many varieties of apparatus have been invented for its production. The peculiarity of the Riché process is that the gas made by direct distillation of wood is passed through a red-hot column of the charcoal resulting from a former operation, and, by judicious admixture of air, practically the whole of the wood, with the exception of the mineral ash, is converted into gas. Its relative composition is well shown in the subjoined table:

COMPOSITION AND THERMAL POWER OF GAS ENGINE FUELS.

| Kind of Gas. | Percentage Composition. | | | | | Heating Power B. T. U. per cubic foot. |
|---|---|---|---|---|---|---|
| | H | CO | $CO_2$ | N | Hydro-carbons | |
| Illuminating Gas..... | 49.6 | 9.6 | 1.6 | 3.8 | 35.4 | 588 |
| Siemens' " ..... | 25 7 | 4.5 | 69.8 | ... | ... | 87 |
| Water " ..... | 49.2 | 43.8 | 2.7 | 4.0 | 0 3 | 324 |
| Dawson (coke) " ..... | 18.4 | 26.8 | 7.2 | 47.0 | 0.6 | 151 |
| Riché " ..... | 44.2 | 22.0 | 21.3 | ... | 12.7 | 340 |

Space does not permit a description of the details of the process, but a considerable series of experiments have proven that one brake horse-power may be had for about 35 cubic ft. of the gas, the engine working at full load. In France, where wood is considerably more expensive than it is in the United States, the cost of manufacturing the gas is in the neighborhood of 15 cents per 1000 cubic ft., and motive power produced through its agency costs, therefore, for combustible ,0.6 cent per horse-power hour.

For small installations in out-of-the-way places, where coal is expensive, it seems that this process has many points of great value, and that it is well worth the attention of engineers who are exploiting electrical installations in our new dependencies. For example, in Porto Rico inferior coal costs about $5 a ton, at the coast; it cannot be had for any price in the interior. Wood, however, can be had for the cutting anywhere.

**An Electrical Expedient.**—Our somewhat spirited contemporary, "l'Industrie Electrique," gives a short account of an expedient adopted at the village of Spoletá, in Umbria, to avoid the disappointment of the public, who were expecting the opening of a new transmission line intended to supply the place with light and power.

"All the preparations had been made to worthily receive the current, which was to come from 15 miles away. The walls of the houses had been newly white-washed, the window shutters given a fresh coat of green, and the local policemen rigged out in new uniforms. More than this; at great expense an excellent theatrical troupe had been secured to give a free show in the village theater. All was ready; the installation in the town, the transformers, the line from Spoletá to Marmora, and all that was lacking was the dynamos. Five days before the inauguration the manager of the affair learned, to his horror, that the dynamos were still at Buda-Pesth. Not to light the town, and, above all, not to light the theater, at the advertised time, would be an humiliation to be avoided at any cost. To put in a temporary steam plant and make a provisional installation could not be thought of, because the many-colored posters which had been distributed over a considerable part of Italy announced that the current was coming from fifteen miles away." The only solution was the one adopted.

A few miles away from the generating station was another, supplying the village of Rieti, also fifteen miles away, but in precisely the opposite direction. A temporary line was run and both circuits put together to work in series, the existing supply being of the constant-direct-current variety. At Spoletá a motor was put in this circuit, and drove a dynamo, which accomplished the lighting. The total length of the transmission was 68.2 miles, the constant current being of 30 amps., and about 200 h.p. in motors being included in the circuit.

It is believed that this is one of the longest commercial transmissions that has yet been made.

## NOTES.

**Electrical Exhibition.**—The stockholders of the Electrical Exhibition Company, which so successfully carried out the electrical shows held in New York in 1896 and last year, decided unanimously at a recent meeting to hold another electrical exhibition in New York in 1899. The following officers and directors were elected: C. O. Baker, Jr., president; H. L. Shippey, vice-president; Geo. F. Porter, secretary and treasurer; H. H. Harrison, L. F. Requa, J. W. Godfrey, C. A. Lieb, directors; Marcus Nathan, general manager. As these gentlemen were connected with two previous exhibitions, their experience gives assurance that the electrical show of 1899 will be a success flattering to the industry which it is to represent.

**Thickness of Transformer Plates.**—In an article in the November number of the "Physical Review," Prof. F. Bedell and Messrs. R. M. Klein and T. P. Thompson publish a mathematical investigation as to the best thickness of transformer plates. While eddy currents decrease as the plates are made thinner, the hystereses loss increases with such decrease, since the magnetic density increases, owing to the greater percentage of space between plates. The conclusion from the investigation is that there is a wide working range for the best thickness of plate, say, from 10 to 15 mils for practical purposes.

**Cost of Generating Machinery.**—In a paper read before the recent annual meeting of the American Society of Mechanical Enginers, Mr. Wm. H. Bryan gives some interesting figures as to the cost of boilers, engines, dynamos, etc., for a modern commercial building, consisting of three 125-h.p. engines and three 75-kw. dynamos. The cost of the water-tube boiler plant was $13.97 per rated horse-power; ordinary boilers would have cost $11.44 per horse-power. Compound engines, with foundations, cost $11.38 per rated horse-power; dynamos and switchboard, $22.80 per rated kilowatt capacity; wiring, lamps, fans and motors, per kilowatt of dynamo capacity, $42.10, or $83.90, including lighting dynamo and engines.

**Chicago Electrical Association.**—At the regular meeting of the Chicago Electrical Association, on Dec. 16, Mr. Arthur Vaughan Abbott, chief engineer of the Chicago Telephone Company, delivered a lecture on "Wireless Telegraphy," illustrated by practical demonstrations with working apparatus. Mr. Abbott has been experimenting and developing his apparatus during the past year, and has established communication between his office and residence, two miles distant. After the lecture, the annual election of officers was held, with the following result: President, Thomas G. Grier; vice-president, J. M. Hollister; treasurer, Harold Almert; secretary, Cloyd Marshall; directors, F. S. Hickok, E. W. Jewell and Hayward Cochrane.

**Wire Insulation.**—The Electrical Bureau of the National Board of Fire Underwriters, in proposing specifications for rubber covered wire and cables, gives the rule that the rubber diameter in inch measurement shall be 3/2 × copper diameter +.062. This insulation must also be protected by a substantial braided outer covering sufficiently strong to withstand abrasion, and sufficiently elastic on all wires smaller than No. 5 to admit of the conductor being wound back over itself without injury to the braid. The complete covering must show an insulation resistance of at least 100 megohms per mile throughout eight weeks' immersion in hydrant water at ordinary temperatures. Each foot of the complete covering must show a dielectric strength sufficient to resist throughout five minutes the application of an alternating e.m.f. of 16,000 volts under specified conditions.

**Steam Turbines and Unipolar Dynamos.**—In a letter to the London "Electrical Review" the manufacturers of the Parson's steam turbine, refer as follows to an editorial reprinted in that journal from our columns, on "Steam Turbines and Unipolar Dynamos." "The first and principal worker to develop this class of dynamo has been Prof. Forbes, and he has, from time to time, taken out several patents on the sub-

Digitized by Google

ject. In 1886, not being aware of Prof. Forbes' works, we constructed a unipolar dynamo driven from a steam turbine, which, at 24,000 r.p.m., gave 1000 amps. at three volts, and we then patented the arrangement. In 1892 we supplied a unipolar dynamo constructed on Prof. Forbes' lines, but with considerable modifications, for the Elmore Company, which has worked successfully, and which, we believe, was the first unipolar dynamo put into commercial use. Its output is 6000 amps. at 1¼ volt, at 1000 r.p.m."

**Prof. Crocker in Japan.**—A Japanese correspondent sends us the following note concerning the recent visits of several distinguished Americans to Japan: "Japan has seen two great men in the electrical field during the latter half of this year. One is Mr. Alexander Graham Bell, so well known in connection with the invention of the telephone; and the other is Prof. Francis B. Crocker, the president of the American Institute of Electrical Engineers during the 1897-1898 term. The Japanese Institute of Electrical Engineers celebrated the occasion by entertaining these gentlemen at dinner in the famous Maple Club, in Tokio. Still another gentleman, now in Japan, connected with a very important matter of electric business, is Mr. James A. Scrymser, an American millionaire. He came to Japan with a view to securing a guarantee from the Japanese government for a subsidy on his project—a project for which we have waited so long, and the importance of which is so keenly felt, both in commercial and political circles—the laying of a sub-marine cable across the Pacific."

**Northwestern Electrical Association.**—The seventh annual convention of the Northwestern Electrical Association will be held at Hotel Pfister, Milwaukee, Wis., commencing on Wednesday morning, Jan. 18, next. The following papers will be read and discussed: "Trend of Central Station Design," by B. J. Arnold, Chicago; "Meter-Rate Systems," by E. L. Debell, Sheboygan, Wis.; "Design of Secondary Circuits in Alternating Plants," by George L. Thayer, Belle Plaine, Iowa; "Electricity Direct from Coal," by Prof. A. J. Rogers, Milwaukee; "Inductive Loads on Alternating Current Transformers," by Prof. D. C. Jackson, Wisconsin University; "Electric Vehicles and Their Relation to Central Stations," by H. M. Maxim, Hartford, Conn.; "Association Management," by H. L. Doherty, Madison, Wis. The association will, at this meeting, inaugurate the "Question Box" on a new plan designed to remedy the defects of that institution as usually conducted. Members are invited to mail to the secretary prior to Jan. 10, questions on any matter connected with their business upon which information is desired. All questions received will be printed and distributed with a request for prepared answers to be ready at the convention when called for. A banquet, theater parties, sleigh rides, etc., are being arranged for, and enjoyable entertainment for all is assured.

**Motor Vehicles.** — In a paper read by Mr. C. E. Woods before the Chicago Electrical Association, Nov. 18, some interesting data are given concerning electrical automobiles. Experiments by Mr. Woods show that solid rubber tires are more efficient than the pneumatic tire for use in moto-vehicles, the latter absorbing about 20 per cent. more energy. The lightest vehicle made by Mr. Woods is equipped with one 2½ h.p. motor and 36 storage cells of 16 ampere-hour capacity for two hours, which run the vehicle at a speed of fourteen miles per hour, carrying two people. The battery weighs 440 lbs. and the motor and vehicle 360 lbs., thus making a total weight of 800 lbs. The average of miles run on one battery charge is twenty. Another equipment, designed for four passengers, is an open vehicle, such as a trap or brake, and weighs, complete, 1800 lbs. The average of miles run on one battery charge is thirty, with two motors of 5 h. p. each. The discharge rate of the battery is 30 different storage batteries on the market which fill the requirements for a cab battery. Forty cells of one of the types weigh 1120 lbs. and give a 36-ampere discharge for three hours; the same number of cells of another type weigh 1500 lbs. for 37½-ampere discharge for three and a half hours; and 40 cells of the third type weigh 1000 lbs. for 36-ampere discharge for three hours.

**Electricity in Warfare.**— The December meeting of the New York Electrical Society was devoted to a consideration of the part played in the late war by electricity, and the further extensions in this field suggested by experience during the war. Addresses were delivered by Col. Eugene Griffin, who organized and commanded the First Regiment of Volunteer Engineers; Mr. F. W. Roller, late chief engineer of the U. S. S. "Nashville;" Mr. W. D. Weaver, late chief engineer of the U. S. S. "Glacier," and Captain Zalinski, inventor of the dynamite gun.

Col. Griffin gave an account of the organization and service of his regiment, which performed work of immense value during its short service in Porto Rico. He strongly urged the formation of a torpedo militia somewhat in line with a body of corresponding functions successfully established in England, and suggested the appointment by the Secretary of War of a commission of army officers to make a report of the subject. During the late war volunteer electricians performed most excellent service, particularly in the defense of Boston harbor, and if such an organization as was proposed were authorized, the professional electricians of which it would be composed would give, he believed, the first note of confidence to the nation on the outbreak of war, by promptly insuring adequate torpedo and mine protection to the navigable channels and harbors of every city on the coast.

Mr. Roller referred to the general failure of indicating apparatus aboard ship, and added that the unsatisfactory performance of the range finder could not be attributed entirely to electrical reasons, it being subject to a very considerable error on account of the shortness of the base-line. He spoke of the lack of electrical skill aboard ship, to which many failures were due. Electrical primers were not always satisfactory because of the low battery power employed, consisting of but several small dry cells. Electrical apparatus of a more robust nature gave very good satisfaction aboard ship, and he referred to the excellent service rendered by the Ardois signal system. The immense value in warfare of the search-light was dwelt upon; at Santiago it rendered impossible the escape of Cervera's fleet at night, not only illuminating the entrance of the harbor brilliantly, but, owing to the dazzling rays, rendering navigation of the tortuous channel exceedingly hazardous. The employment of electric power aboard ship, such as motors for ammunition hoists, turret training, ventilating fan driving, etc., gave eminently satisfactory results. The few failures that occurred were far less in number than those of the steam driving equivalents, and even then, in most cases, were traceable more to the lack of skill than to any inherent defects.

Mr. Weaver said that the lessons taught by the late war with respect to the employment of electricity aboard warships, though few in number, are important in their bearing. The most decisive results were the demonstration of the immense superiority of electricity over steam for the operation of turret-training apparatus, and the great success of electrical ammunition hoists. He referred to the failure of electrical range finders and of electrical indicating apparatus in general. He considered, however, that the Fiske range finder is inherently defective, and suggested the employment of an alternating current range-finding system similar to one proposed by Messrs. Crehore and Squier. The experience with electric power aboard ship proved to be very favorable, and its extension was urged. Among the cases mentioned distinctly calling for such application were in electric ventilation and in driving the work-shop machinery, ice machine, winches and ash-hoists. Mr. Weaver considers that the present steam pumps and some of the auxiliaries connected with the main engine should also be driven by electric power, as well as the anchor-hoists and steering-gear. In every case possible, however, new electrical applications, he said, should be thoroughly tried aboard merchantmen before endeavoring to place them aboard a warship, as the latter is no place for experimental work or the trial of new applications. The inefficiency that the war showed to exist in the electrical personnel aboard ship was referred to, and the present policy of the Navy Department and the present bureaucratic tendency to call a halt in the further use of electricity aboard ship were criticised. The suggestion was offered that the present unsatisfactory condition of the electrical engineering department aboard warships should be made the subject of a departmental, or even congressional inquiry.

To the sixteen thousand patrons of the AMERICAN ELECTRICIAN, as well as to its other readers and all connected with the electrical industry, the AMERICAN ELECTRICIAN wishes a most happy and prosperous New Year. We are happy to state that all the indications point to a most successful year for the industry.

**The Central Station Load Curve.**

In another column we print an article descriptive of an extensive refrigerating plant very largely utilizing electric power, and which is particularly interesting from the number of special fittings used and as an illustration of the flexibility of electric power. One of the objects, however, in preparing the article was the lesson that would be contained in it for central station managers seeking a solution to the problem how to flatten the load curve. A refrigerating and ice-making plant furnishes an almost ideal solution, for one can conceive of an arrangement whereby practically a flat load curve may be maintained over the twenty-four hours, in this respect almost rivaling the case where surplus power is used to operate a pumping plant.

**Improvement of the Steam Engine.**

In this number is printed the first half of an article by Prof. Durand on the improvement in the economy of the steam engine, which will be found a concise and valuable résumé of the principles upon which further improvements in efficiency must be based. It is pointed out that the present efficiency may be increased by the use of higher pressures, and by increasing the working efficiency of the steam—that is, increasing the percentage utilized of the entire heat in steam which is available for producing mechanical work. Aside from the practical difficulties in the way of using steam of very high pressures, the second method applies at all pressures, and if utilized at present pressures, the economy at higher pressures will probably be correspondingly enhanced. The concluding section of the article will discuss the several practicable methods of increasing the working efficiency of steam, such as in the use of superheaters and receiver reheaters.

**Alternating Current Motors.**

Owing to the mystery with which alternating currents have been surrounded in the minds of so many—possibly partly owing to the distinctive nomenclature and partly to the former method of treating the branch mathematically in a manner giving the impression that one not versed in higher mathematics could not pursue its study—the applications have not become so clearly understood as they should. In this number appears the first portion of an article from the pen of Mr. Ernst T. Berg which gives a complete résumé of the practical principles of alternating current motors. This article will be found of much interest, giving as it does the peculiarities of the various types of machines now in use and pointing out the applications to which each is best suited. In addition, the subjects of torque, idle current, frequency and speed regulation are treated in their practical aspects.

**Polyphased Electric Railways.**

An article in another column describes a Swiss mountain polyphased electric railway which, though of a very special kind, nevertheless brings out the flexibility in distribution peculiar to the employment of alternating currents. While the system described would be directly applicable to suburban and interurban town traffic, it lacks the quality of speed regulation so necessary in all other cases. It is true, almost perfect speed regulation without loss of torque may be secured with the induction motor, but as in the case of the direct-current series motor under rheostatic control, the efficiency decreases rapidly with the speed, practically the same power being taken at low speeds as at one approaching synchronism.

Where the stops are infrequent, this would not be a matter of moment, so that for such cases the application of the induction railway motor in itself presents no difficulties, and in operation and flexibility of power distribution is vastly superior to the direct current motor. But two other factors intervene—the double trolley and the line inductance. It is quite probable that the evils of the former have been exaggerated, and where a considerable number of cars are run, thus producing an approximately constant inductance effect, this can be neutralized where the employment of synchronized motors in circuit is practicable.

**An Electrical Militia.**

The suggestion of Col. Eugene Griffin that a national militia organization composed of electricians be formed and trained in time of peace to assist in harbor defense and coast communication during war, is one that should meet with the hearty support of our readers. One of the recommendations of the plan proposed is that the organization of such a corps would not be in the nature of an experiment. Great Britain has its corps of Volunteer Electrical Engineers, now under the command of the well-known electrical engineer, Mr. R. E. B. Crompton, and in whose formation the late Dr. John Hop-

Digitized by Google

kinson was a leader. So satisfactory has this corps proved that it is about to be greatly enlarged.

---

But we need not look abroad for arguments in favor of the measure. At the beginning of the late war a volunteer electrical corps was formed in Boston, and under Mr. Caryl D. Haskins and Dr. Louis Bell did most excellent work in the service which it is now proposed to organize on a national basis. The case with which Col. Griffin recruited the electrical contingent of his command, the First Regiment of Engineer Volunteers, for foreign service, and the excellent work it performed in Puerto Rico, are evidence of the spirit in which electricians generally would welcome the proposed organization, and of the earnestness in which they would assist in furthering its aims, either in person or by extending a moral support.

---

Those who fear that it would introduce another parade element in the militia system may disabuse their minds on that score, for, composed as the organization would be of men of technical skill engaged in a service involving technical work, it would be characterized by a spirit having little in common with that of a holiday marching militia. Nor would the body conflict with the present naval militia, for the natural occupation of the latter is in duty afloat, and patrol and auxiliary service in time of war will fully supply this. It is earnestly hoped that Col. Griffin's suggestion of the appointment of a board of army officers to report on the proposed plan will meet with favor in Washington.

---

**The Power and Pull of Electromagnets.**

A problem which frequently confronts the electrical designer is the following: Given a magnet of known shape, size, excitation and magnetic material, what is the pull upon an armature of known materials and dimensions at a specified distance? There is absolutely no reliable data on this subject. The matter of leakage enters into this problem so intricately that it is impossible to apply any mathematical formula, either rational or empirical. It is frequently the case that data of the most approximate character in this direction would be very welcome, and this it should not be impossible to experimentally obtain.

---

In connection with this subject it seems wise to suggest a series of experiments with a number of magnets with known dimensions, beginning with those of very minute size and proceeding upward to the largest size that would ever be used in electro magnetic mechanism where the function is to exert a tractive force. The experiment would not be particularly expensive. It would be somewhat tedious, but the results would be of incalculable value. With a single set of magnets the attraction of armatures of various shapes and sizes could be measured, and also the attraction of these magnets under the influence of alternating currents. The tabulated results giving magnetizing force, saturation of the cores, the dimensions of the magnets, and the pull at various distances, would constitute a valuable contribution to engineering data and place the profession under a very great debt of gratitude to the author.

---

Mr. Charles P. Steinmetz gave to the public the results of his invaluable researches on hysteresis, which at once made his name a familiar one the world over. It is to be earnestly hoped that the same spirit which animated him to make his admirable investigation and his no less admirable classification and discussion of the results, may influence some competent engineer who has opportunity at his disposal to follow in Mr. Steinmetz's footsteps, and make a similar research on the power and pull of electromagnets, which, even should it result in nothing more than a collection of experimental data, would be most widely appreciated.

---

**Electrical Engineering in the Navy.**

The record of the navy during the late war has been such a glorious one that any criticism which seems called for can be freely offered, with the knowledge that it will not affect injuriously the prestige of this great arm of national defense. It was not to be presumed, in view of the great changes of recent years in material —amounting, in fact, to a revolution—that the test of war should not bring to light some weaknesses. While as a whole the American warship has withstood this crucial test in a magnificent manner, it appears that one of the departments aboard ship—that having cognizance of electricity—has showed signs of most alarming weakness.

---

To merely quote an official utterance in support of this opinion, the following extracts from the report of the Chief of the Bureau of Equipment, which has charge of naval electrical engineering, show a state of affairs both unexpected and disquieting: "The bureau regards with much concern the constantly increasing demands for repairs and renewals to the electrical outfits and supplies of ships. While there are some notable exceptions, such as ships on the Asiatic station and the 'Oregon,' the experience of ships on the home station would seem to indicate that they cannot long be self-sustaining without dockyard electrical work." "The number of officers who are familiar with electrical engineering seems to be decreasing rather than increasing."

---

The relative smallness of the electrical plant aboard ship, and the superior reliability of electrical machinery which a long-extended experience in its operation has thoroughly demonstrated, are facts which both point as a cause of the failure implied, not to deficiencies in the plant itself, but to defects in the organization of the electrical engineering department of the navy. This latter, in fact, is tacitly acknowledged in the report quoted, for the recommendation is made that a specially trained corps of officers and men be organized for naval electrical engineering service. This recommendation does not necessarily reflect upon the zeal of the officers now having charge of the plants of warships, for their service in this connection is incidental to their navigating duties, and, in any case, a line officer cannot afford to neglect his distinctive military profession to the extent that would be necessary to thoroughtly qualify him as a professional electrical engineer.

---

The unsatisfactory condition of the naval electrical engineering department doubtless led to the recent action of the Navy Board of Construction in refusing, by a vote of four to one, to further extend the application of electric power aboard warships. It was proposed to operate electrically most of the auxiliary machinery aboard the new battleships, and the action referred to, since there is nothing experimental in electric fans, blowers, pumps, etc., can only be considered the result of a lack of confidence in the present naval electrical engineering system—a lack of confidence, moreover, on the part of officers thoroughly acquainted with the system. Whether or not the remedy suggested by the Chief of Bureau is the proper one to apply should be a matter for inquiry. The sooner this inquiry is made by the Navy Department or by Congress the better it will be for the navy, for the present condition is little creditable to this otherwise splendidly competent service.

## DESIGNS FOR SMALL MOTORS.

### ONE HORSE-POWER BI-POLAR MOTOR, WITH DRUM ARMATURE.

BY CECIL P. POOLE.

The armature core and field magnet frames, described in the preceding issue, may be wound for any voltage desired, but the most efficient windings, as the cores now stand, will be those specified below.

#### ARMATURE WINDING.

The armature core, after being finally assembled, is to be made ready for windings by applying the insulation. Cut out four discs of heavy canvas, 3 ins. in diameter, with a ¾-in. hole in the center; varnish two of them on one side with shellac varnish, and apply them to the end plates of the armature core, varnished sides in. The edges will turn over to cover the outer edges of the plates, and will have to be slitted at intervals of ⅛ in. all around to prevent bunching up. After putting on these varnish their outer faces, and one face of each of the remaining canvas discs; when the varnish begins to thicken put on the two other discs, one at each end, and apply considerable pressure to them until they dry. This is best accomplished by boring a hole in a piece of plank, large enough to pass the shaft, and setting the core on the plank, on end, next putting a short piece of board (6 or 8 ins. square) with a hole in its center on the upper end of the armature, and piling any convenient pieces of heavy scrap on the top board.

Next insulate the slots with troughs of oil paper, 1/64 in. thick, such as is used with the ordinary office outfit for copying letters; each trough should consist of two thicknesses of the oil paper, and the floor of the trough should be 4¼ ins. long, so as to project a little beyond the iron of the core and rest upon the edges of the canvas discs, which were previously turned over to cover the edges of the end plates.

The coils may then be wound directly in the slots, each coil consisting of twenty turns of No. 18 wire, four wide and five deep. Each slot will contain, when the windings are complete, half of each of two separate coils. It will facilitate the winding and insure electrical balance (as nearly as a core wound armature can be balanced) if the builder will make a diagram of his armature disc, numbering the slots from 1 to 24 successively around the circumference, as shown by Fig. 1. Then the winding will proceed as follows:

| | | | | | No. | | | | No. |
|---|---|---|---|---|---|---|---|---|---|
| First | coil | starts | in | slot | 1 | ends | in | slot | 12 |
| 2d | " | " | " | " | 13 | " | " | " | 24 |
| 3d | " | " | " | " | 17 | " | " | " | 4 |
| 4th | " | " | " | " | 5 | " | " | " | 16 |
| 5th | " | " | " | " | 9 | " | " | " | 20 |
| 6th | " | " | " | " | 21 | " | " | " | 8 |
| 7th | " | " | " | " | 3 | " | " | " | 14 |
| 8th | " | " | " | " | 15 | " | " | " | 2 |
| 9th | " | " | " | " | 19 | " | " | " | 6 |
| 10th | " | " | " | " | 7 | " | " | " | 18 |
| 11th | " | " | " | " | 11 | " | " | " | 22 |
| 12th | " | " | " | " | 23 | " | " | " | 10 |
| 13th | " | " | " | " | 22 | " | " | " | 11 |
| 14th | " | " | " | " | 10 | " | " | " | 23 |
| 15th | " | " | " | " | 18 | " | " | " | 7 |
| 16th | " | " | " | " | 6 | " | " | " | 19 |
| 17th | " | " | " | " | 14 | " | " | " | 3 |
| 18th | " | " | " | " | 2 | " | " | " | 15 |
| 19th | " | " | " | " | 20 | " | " | " | 9 |
| 20th | " | " | " | " | 8 | " | " | " | 21 |
| 21st | " | " | " | " | 16 | " | " | " | 5 |
| 22d | " | " | " | " | 4 | " | " | " | 17 |
| 23d | " | " | " | " | 24 | " | " | " | 13 |
| 24th | " | " | " | " | 12 | " | " | " | 1 |

After winding the first two coils, thin strips of varnished muslin should be laid over them, across each armature head from slot to slot, so that the next two coils will be insulated from the first pair; each successive pair of coils should receive this treatment, and after the slots are half filled (twelve coils being put on), a strip of oil paper 7/32 in. wide and 4¼ ins. long must be laid in each slot on top of the coil already in place before proceeding to put on the coil which next goes in that slot.

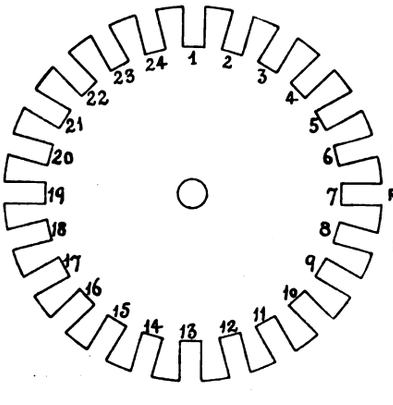

FIG. 1.—WINDING DIAGRAM.

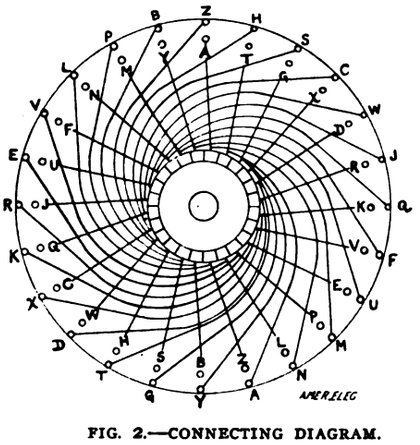

FIG. 2.—CONNECTING DIAGRAM.

The starting end of each coil should be kept leading out straight from its slot, and the finishing end should be brought across the head and secured to the starting end by a turn around it. When the winding is complete, untwist the finishing end of each coil from its starting end, and twist it and the starting end of the next coil to the right firmly together. This will leave twenty-four terminals to lead out to the commutator lugs.

Before connecting the ends to the commutator, the binding wires should be put on and the winding tested for grounds on the core. The binding wires are put on in two bands, and consist of small tinned iron wire; they should be put on beginning 1 in. from each end of the core, and making each band ½ in. wide. The binding wire should be wound on strips of thin varnished muslin laid around the core two layers deep, and the bands should be soldered at four equidistant points around the armature surface, not all the way around. The wire used should be not larger than No. 22 B. W. G. or No. 20 B. S. G.

Unless the machine is likely to be used in very dusty surroundings it is better not to put any covering over the ends of the armature after the winding is complete. If the instructions for insulating each pair of coils from the succeeding pair have been carefully followed out, any ordinary collection of dust will not be liable to cause a breakdown in the heads. The winding just described is intended for a 110-volt machine. If it is desirable to wind the armature for a 220-volt circuit, use No. 21 double cotton-covered wire, making each coil five turns wide and six layers deep.

The commutator had better be purchased from any well-known manufacturer of commutators, as its market price will be less than the cost of material and labor necessary to make one properly. It must have twenty-four segments and be not more than 2 ins. long along the shaft; the diameter does not matter particularly—take one of a stock size from the maker. In connecting up the coils to the commutator carry the ends previously twisted together straight out to the commutator segments. Fig. 2 shows the connections diagrammatically. The slots are omitted and each coil is represented as having only one turn for the sake of simplicity. The coils are lettered, to facilitate identification of opposite ends. The ends leading straight to the commutator are the starting ends; those leading around being the final ends. The diagram is not intended to show the relative radial positions of the coils, and care must be observed to avoid becoming confused. For example, coil A may or may not be under coil Z at its starting side; they are both in the same slot, but it does not matter which is on top. If coil A was the first one put on, it will, of course, be in the bottom of both of its slots, and coil Z will come on top of each side of it. The diagram only shows the relative angular positions of the coils and the manner of connecting their ends.

The brushes should be of carbon, ⅜ in. thick, and of a width ⅛ in. less than the length of the commutator face, which should be about 1½ ins. The brush holders may be copied from any standard type to which the builder of this motor has access, except those of the Baylis design, made by the C & C Electric Company, which are patented.

#### MAGNET WINDINGS.

The iron-clad magnet requires two magnet coils, one on each pole; for 110-volt circuits these coils consist of No. 22 wire wound in 61 layers, each layer being 50 turns long. If both the coils are wound in the same direction—in other words, if they are precisely alike as to the manner of winding, as they should be—the beginning end of one must be connected to the final end of the other, the two remaining ends being carried to the terminals of the machine. The best arrangement is to connect the two ends that are farthest apart, making this connection on the pulley side of the machine. For 220-volt circuits the wire must be No. 25 gage, wound to a depth of 75 layers, 65 turns to each layer. These

Digitized by Google

coils should be wound on a block, the cross-section of which is of exactly the same shape as that of the magnet core at its largest part, but which measures ⅛ in. more in each direction. After winding each coil, tie it at each corner with coarse linen thread (cobbler's thread) and cover it with strips of muslin wound at right angles to the direction of the wires, and so put on as to have the edge of each convolution of muslin lay just alongside that of its neighbor—touching it but not lapping it. The muslin must be one-fourth the width of the inner edge of one side of the coil, so that four turns will cover one side evenly. Put the muslin on in two layers, the turns of the second layer covering the joint between the turns of the first layer. Then wind strips over the corners of the coils, two layers deep. After the coil is covered with one layer, varnish the muslin covering heavily with shellac; when this is nearly dry, put on the next layer and the corner strips, and after varnishing the whole, set the coil aside to dry. Do not put any varnish on the wire itself. Next cover the iron cores of the machine with a layer of muslin, this time lapping the edges of successive convolutions; varnish the muslin, and when it and the coils are thoroughly dry, put the latter on. Unless the pattern for the field magnet has been very exactly made, and the casting is an unusually perfect one, it may be necessary to file the corners of the pole pieces slightly to get the coil between them in putting it on the magnet core. In filing these corners, be careful to round them, leaving no sharp corners or edges whatever. It is advisable to do this, even if it is not mechanically necessary for the introduction of the coils.

The Jenny type of magnet has only one magnet coil, which consists of No. 25 wire, wound to a depth of 65 layers, with 148 turns to a layer, for 110-volt service. For 220 volts, use No. 28 wire, wound to a depth of 81 layers, 186 turns to each layer. All the wire specified herein for both armature and field windings should be double cotton covered. Circular magnet heads of vulcanized fibre should be used to protect the ends of the coil, as the full voltage of the machine exists between these ends; these heads should be ⅛-in. thick and 6⅜ ins. in diameter, with a hole to fit the magnet core snugly if the coil is wound directly on the core. If not, a bobbin should be made, the center consisting of a tube of 1/32 in. fibre, 4¼ ins. long, and of an internal diameter to go easily over the core; the heads of the bobbin to be of ⅛-in. fibre, as above. If the coil is wound on the core, the latter must be covered with three layers of muslin, each layer varnished with shellac. The whole must dry thoroughly before the wire is wound on.

The data of the machine are as follows:

IRON-CLAD TYPE.

| | 110 volts. | 220 volts. |
|---|---|---|
| Resistance of armature winding | 1 ohm. | 3.15 ohms. |
| Armature capacity, maximum. | 8.3 amp. | 4.7 amp. |
| Armature capacity, normal | 7 amp. | 3.8 amp. |
| Armature loss, $C^2R$, normal | 49 watts. | 45½ watts. |
| " hysteresis " | 11.7 " | 13 " |
| " eddy currents | 1.3 " | 1.5 " |
| Total internal armature losses. | 62 " | 60 " |
| Magnetic flux per sq. in. in armature core | 71,800 | 72,000 |
| Revolutions per min., loaded | 1,800 | 2,000 |
| Resistance of field winding | 220 ohms. | 682 ohms. |
| Current in " | ½ amp. | 0.322 amp. |
| Heat loss in " | 55 watts. | 70.85 watts. |
| Density per sq. in. in core | 38,000 | 38,160 |
| " " " gaps | 25,500 | 25,570 |
| Efficiency, approximately | 76% | 75% |

SINGLE COIL TYPE.

| | | |
|---|---|---|
| Armature data same as above. | | |
| Resistance of field coil | 443 ohms. | 1,400 ohms. |
| Current in " | ¼ amp. | 0.16 amp. |
| Heat loss in " | 27½ watts. | 35.2 watts. |
| Density per sq. in. in core | 89,750 | 90,000 |
| Efficiency, approximately | 78% | 79% |

An amateur motor builder will be wise not to attempt to make a starting box for this size of machine; one can be purchased for a moderate sum from any of half a dozen reputable manufacturers, and, as either of the motors here described is well worth the outlay necessary to insure its protection in this particular, the writer advises buying the starting rheostat.

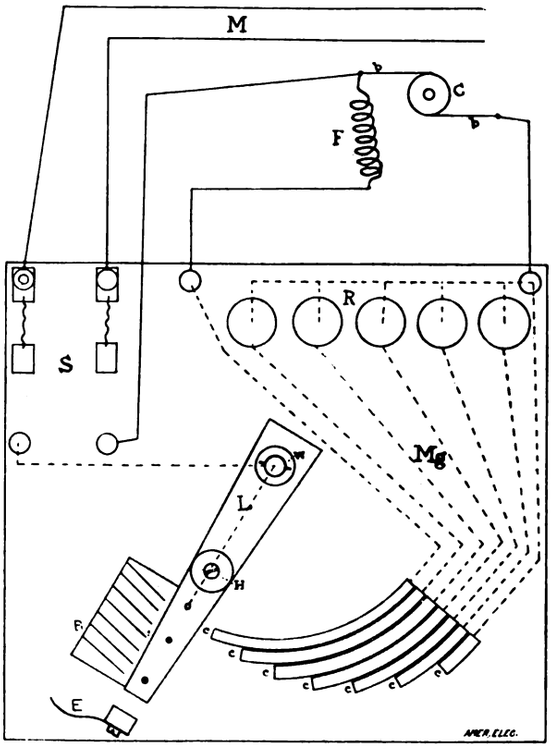

FIG. 3.—STARTING RHEOSTAT AND CONNECTIONS.

If, however, the reader particularly desires to make his own starting rheostat, the arrangement shown by Fig. 3 will be found easier to construct than anything in the shape of a wire rheostat. In the sketch, L is the lever, pivoted on a ½-in. metal post, and normally forced downwardly by a coil spring of three or four turns (not shown), which is located under the washer, W. A pin through the post secures the washer, spring and lever. H is the handle; a wooden handle, such as coffee grinders are given, or a large porcelain knob will answer. B is the contact brush of copper, slitted tangentially to the circles of the contact strips, c, c, c, c, c, c, c; these circles have their common center, of course, in the center of the post on which L is pivoted. An end view of the brush, B, is given by E, showing the convex shape given the under face of the brush to enable it to pass smoothly over the contact strips. The ends of these should be beveled to avoid digging into the brush.

The connections are shown diagrammatically. R is a bank of five 32-c.p. incandescent lamps, rated at 110 volts (100 will be better, and they can probably be readily obtained); C is the motor commutator; b, b, the brushes; F, the field winding; S, a double-pole combined switch and fuse block, and M, the service mains. A glance at the connections will show that the functions of the lever L are to first connect in the field, next the armature in series with one lamp; at each successive step a lamp is added in parallel with the first one until all are in, and the last position of the lever cuts out the lamps, leaving the armature in circuit direct.

The lamps should be mounted on the base with the lever and contacts, and it is preferable, though not particularly urgent, that the switch S be mounted on that base also. The sketch shows the lever in the "off" position; the switch, S, should never be closed, except when the lever L is in this position. If the reader desires to make the arrangement automatic he need only add a retractile spring to pull the lever L to the "off" position; a bar of iron ⅛ in. by ¼ in. by 2 ins. on the right hand edge of the lever, and a small magnet connected in series with the field, F, and located on the base about Mg, in such a position that it will hold the lever, by means of the bar of iron, when it is brought to the "on" position.

## CONDUCTORS FOR THE THREE-WIRE SYSTEM.

BY WM. HERBERT DONNER.

The advantages of the three-wire system of arranging a lighting circuit have been often pointed out and commented upon; nevertheless, it cannot be said that all engineers are able to explain correctly what the saving in copper really is, as compared with the ordinary two-wire method of running leads. The reason is that there are two ways of regarding the matter. We may require an equal drop of potential along the line in the two cases, or an equal *percentage* of drop, and the size of wire will be different according as we work by one or another of these formulæ.

It is frequently stated that the amount of copper used in the outer conductors of the three-wire system is one-fourth of that required in the ordinary two-wire system, the explanation being that the working e.m.f. is doubled, thus necessitating one-half the cross-sectional area of wire, and the current is halved, thereby cutting down the copper section by another equal amount. These two reductions then constitute a total reduction of area to one-fourth the original size.

Digitized by Google

But the loss in the two systems will not be the same if this process is carried out. A very simple proof may be deduced from a consideration of Ohm's Law. Suppose we have a two-wire circuit supplying current for 100 lamps, each lamp taking one-half ampere at 100 volts, and that the drop from generator to lamps is 5 per cent. The e.m.f. at the generator will be $\frac{110}{95} = 115.8$ volts, and the drop of potential will be $115.8 - 110 = 5.8$ volts. Then the resistance of the leads will be $R = \frac{5.8}{50} = .116$ ohms.

Now, if we figure on the three-wire system and allow only one-fourth the weight of metal in the outer leads, the resistance of these leads will be quadrupled and we shall have $R = .116 \times 4 = .464$ ohm. Then, since two lamps are in series throughout, the current is halved, and the drop $E = CR = 25 \times .464 = 11.6$ volts. Obviously, if we desire the same drop from generator lamps, it will not do to calculate by means of the above rule. What we have obtained is, however, the same *percentage* drop of potential, for 11.6 bears the same ratio to 231.6 (which is the doubled potential of the generator) as 5.8 does to 115.8. In both cases the drop is 5 per cent.

It will now be evident that any rule for determining the size of wire for a given drop of potential (not percentage drop) which is based upon a reference to previous calculation for the two-wire system should specify a size which is one-half the cross-sectional area of that necessary for the latter system. An excellent, and well-known, rule for calculating a two-wire system is that the required resistance per foot of the conductor should be equal to the drop in the circuit, exclusive of the lamps, divided by the product of the number of lamps and the single distance.

This simple rule is true only in the case of 110-volt circuits and 16 c.p. lamps, but may of course be modified to suit any current or e.m.f by inserting a suitable coefficient. The derivation of the rule mentioned is that the resistance of that portion of the circuit consisting of the leads is, in accordance with Ohm's law, equal to the drop of potential divided by the current. This takes into account the whole length of the circuit, or the double distance.

Now, a 16-c.p. 110-volt lamp takes approximately ½ ampere, so that we may write

$$R = \frac{e}{l \times \frac{1}{2}}$$

where R is the total resistance of the leads, and l the number of 16-c.p. lamps. Let d represent the single distance from the generator to the lamps. Then we may divide each of the terms of the above formula by 2d, which will give us the resistance for one foot of the wire, thus:

$$\frac{R}{2d} = \frac{e}{l \times \frac{1}{2} \times 2d} = \frac{e}{l \times d}$$

If we wish to adapt this formula to the three-wire system, we must do so with due regard to Ohm's Law, as already pointed out, and we shall find that the required resistance per foot of the wire will be double that of the two-wire system using lamps of the same current and voltage. Then, for a three-wire system the resistance per foot of the conductor,

$$R = \frac{2e}{l \times d}.$$

As an example, we will consider the following problem: A feeder is required to deliver current for 120 16-c.p., 110-volt lamps, the distance from the generator to the distributing board being 200 ft., and the allowable drop 1.5 volts. What size wire should be used?

The above formula will at once give the resistance per foot of the wire, and

$$R = \frac{2 \times 1.5}{120 \times 200} = .000125 \text{ ohm.}$$

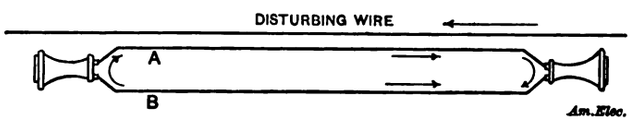
Wire tables give, usually, the resistance per 1000 ft. of conductors, and by reference to such a table we find that No. 1 B. & S. wire has a resistance of .124 ohm per 1000 ft., and will therefore be suitable.

It may here be mentioned that it is always advisable to check any calculation by comparing the results with the Underwriters' table showing the permissible current which the wire may carry. In this case the limit is 95 amperes. Since two lamps are connected in series, and each requires half an ampere, the actual maximum current is $\frac{120}{4} = 30$ amperes.

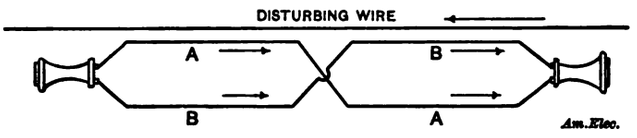
It is generally sufficient to make the neutral wire equal in size to the outer conductors, as it is then capable of carrying all the current from one side of the system in case of a main fuse blowing. In such an event, which is not very likely to occur, there will be double the fall of potential between the distributing board and the lamps, because the distance still remains the same while the e.m.f is halved. This is not a serious matter, and the condition would not last long, so that it is not necessary to guard against it. However, the neutral wire may be made twice the cross-sectional area of the outer wires, in which case the drop of potential is 1½ times that of the three-wire system when one side is disconnected. The chief advantage of such an arrangement is, that the two outer wires may at any time be connected together and the larger wire be used as a common return for a two-wire system.

The actual saving in wire by the use of the three-wire over the two-wire system is one-fourth when the neutral is made the same size as the outer wires, and when an equal drop is considered. For an equal percentage drop, however, which is actually a larger drop with the 220-volt circuit, the wires are smaller, and a saving of five-eighths is obtained in the weight of copper.

## AMERICAN TELEPHONE PRACTICE.



### LINE DISTURBANCES.



BY KEMPSTER B. MILLER.

The one remedy for all the troubles due to disturbing noises from any of the causes is to make the line a complete metallic circuit. Even this will not completely stop noises from most of the causes, and all additional precaution must be taken, by making the two sides of the circuit alike in all respects and properly transposing them at frequent intervals, in order that they may be as nearly symmetrical with respect to the disturbing source or sources as possible.

Merely making the line a metallic circuit, as in Fig. 1, does not give complete freedom from inductive troubles from other wires, whether the induction be electromagnetic or electrostatic. Considering the question from the standpoint of electromagnetic induction, a current flowing in the disturbing wire would set up a field of force, the lines of which would cut conductors A and B. A being closer, however, would be cut by more lines than B, and consequently any currents induced in A by changes in this field will be stronger than those in B. If a current starts to flow in the disturbing wire from right to left, as shown, the induced currents in A and B will each be from left to right, as indicated by the arrows. These currents will partially annul each other, but that in A, being the stronger, will predominate, and the resultant will flow in the circuit in a direction indicated by the small curved arrows.

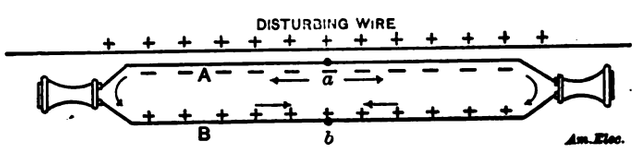
A single transposition in the center of the metallic circuit will completely annul the electro-magnetic induction if the disturbing wire is parallel to the two wires throughout its entire length, and if it carries the same current in all its portions. Here an impulse in the direction of the arrow in the disturbing wire (Fig. 2) will cause impulses in the opposite direction in both wires A and B. As the average distances between the disturbing wire and A and B, respectively, is the same, the strengths of the induced currents in A and B will be equal, and they will, therefore, annul each other, producing no sound in the receivers.

FIGS. I AND 2.—ILLUSTRATING LINE DISTURBANCES.

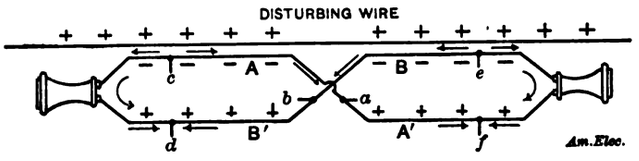
It is found, however, that a single transposition in the center of the metallic circuit will not free the line from cross-talk, even though the average distance from the two wires and the disturbing wire is the same, and the current strength is uniform throughout the entire length of the disturbing wire.

Mr. Carty's experiments throw much light on this point. In Fig. 3 is shown a disturbing wire and a metallic telephone circuit composed of two wires, A and B, of which A is nearer the disturbing wire than B. At a time when the charge on the dis-

Digitized by Google



turbing wire is positive, as shown, a negative charge will be drawn by it toward the disturbing wire and a positive charge will be repelled from it. The result is that the distribution of charges on the two wires, A and B, will be somewhat as shown, a negative charge being held on the wire A and a positive charge driven to the wire B.



In order for this rearrangement to have occurred it is evident that a flow of electricity must have taken place from A to B, and as two paths were afforded from the center point a, on the wire A, of equal resistance, this flow must have been from that point in each direction as indicated by the arrows, through the receivers and toward the center point b on wire B, where the two currents met. Upon the charge on the disturbing wire becoming zero the potentials on A and B become equal, by a flow of positive electricity from the center point of wire B to that of wire A. The negative charge on the disturbing wire, which follows the positive charge, will cause this latter to flow from b to a to continue until A is positively and B negatively charged.

It is evident, therefore, that alternating currents flow through two receivers, and that these currents differ in phase from that in the disturbing wire by 90 degs., which is characteristic of the action of condensers. Further consideration will show that the points a and b are neutral, and experiment bears out this conclusion, for by opening the wires at those points the sound in the receivers at the ends still continues.

Where receivers are connected in the circuit at a and b no sound is heard on them, although plainly audible in the end receivers. A single transposition in the center of the line, as shown in Fig. 4, will tend to reduce the sound in the end receivers, but will not cause silence. The static charges on the portions of the wires nearest to the disturbing wire now find four paths instead of two to the more remote portions of the circuit, the flow being clearly indicated by the arrows. The center points a and b are no longer neutral, and receivers placed in the circuit there will be subject to noises.

It is evident that if receivers of equal impedance to those at the ends of the line, were placed at a and b, the neutral points c, d, e and f would be found at the quarter points on the line; i. e., midway between the transposition and each end. As a matter of fact, however, no instruments are placed at the point of transposition, and the neutral points are shifted toward the ends of the line, because the impedence of the receivers at those points makes it easier for most of the current to pass through the transposition wires. Theoretically, the currents set up in a metallic circuit by electrostatic induction from another circuit can be eliminated only by making an infinite number of transpositions. Practically, however, it is found that on long circuits transpositions every quarter or half mile are amply sufficient to render them unnoticeable.

FIGS. 3 AND 4.—ILLUSTRATING LINE DISTURBANCES.

## THE ELECTRIC LIGHT AND POWER SWITCHBOARD.

BY S. H. SHARPSTEIN.

The switchboard question is possibly as difficult as any the engineer and superintendent has to decide upon. It is very essential to so design and construct it that it will never cause the circuits it controls to shut down, especially when the greatest number of lamps are burning.

If a generator breaks down another can be put in its place; but if an arc occurs on the switchboard the machine or machines that feed the arc will keep right on working, as a rule, until the board is ablaze. Built as some modern switchboards are, with rubber covered wire, and in many places sheet hard rubber being used, when once a blaze is started destruction is quite sure to follow.

One of the most peculiar things in modern electrical work is the way fire underwriters will drive the electric lighting and power people from one position and sometimes let them take up another much worse than the first. Some of the modern boards, with complicated switches breaking high-voltage circuits, are sure sooner or later to cause fire, since so much highly combustible insulation is present to burn.

High voltage wires are placed close to each other, and for safety the insulation is depended upon. After a little time dust and dirt accumulate, and when the switches, hemmed in by the wires, get somewhat worn and burned, fire is likely to occur. This applies more particularly to the alternating current boards that are being installed in many stations.

The popular method is large units and but few circuits. This being the case, each machine or circuit panel of the switchboard controls the current for a large district. The income that is influenced is necessarily large, hence it is economy to leave ample space for such panels and to design and construct them with care.

Wood has been discarded for fronts; slate is used only for low voltage boards; marble is almost exclusively used for high voltage boards because of its higher resistance. With a pressure of two or three thousand volts, the darker marbles are best because they do not show the dirt so plainly.

When it is understood that a slab of white marble can be badly discolored by laying it on a clean pine stick, where it will absorb the oils from the wood, or by allowing it to come in contact with anything that will impart lubricants to it, it is easily understood why such marble should not be used for a switchboard unless it is to stand in a clean place and be cared for by a competent person. Many times grease and even oil is used on the working parts of a switch, and therefore it is an easy matter to get them on the marble. Because of the higher resistance of the white marble it is very much used, where the darker grades are prohibited because of their lower resistance.

Sooner or later all apparatus on the board will have to be removed for repairs; therefore the designer should bear in mind the desirability of having the board constructed so that each slab containing apparatus be arranged to be removed with ease. Each panel should contain a number of slabs unless there are no busbars and wires in the way of making repairs. Breakage is liable to occur in shipping, and small slabs are more easily replaced.

As a rule, it is not customary to run alternators in parallel; for this reason the board should be constructed so that each machine can be easily connected or thrown onto any circuit leaving the station, or so that all the circuits can be worked from one machine when the station load is light. The switches and cables should be so arranged that it will be impossible to short circuit any machine while switching at the board.

When a generator is working on one circuit, it is easy to vary the pressure somewhat by means of the exciting circuit as the drop in the line increases or decreases, but when two or more circuits are run from one machine, it is essential that each circuit should have some method of varying its voltage independent of the machine or other circuits; therefore it is necessary that every circuit panel have a voltage regulator.

If the generators be single phase, each circuit panel should have a double-pole, double-throw switch with ample jaw contact to keep from heating and with sufficient break to keep from arcing if the circuit it controls be crossed. When the voltage gets high it takes quite a large switch to have break enough to open the circuit under the above conditions, without excessive arcing, but all devices for cutting off or blowing out an arc are apt to become a nuisance on a switch sooner or later, and should not be adopted without close consideration.

If cities could be lighted with a pressure at the machine and on the mains of ten volts, the damage to station apparatus when a cross occurred might be slight. As the conditions outside the station develop in complication, the chances for crosses from main to main increase. With very

Digitized by Google

high voltages such crosses are very often disastrous, especially when close to the station or generator. The only good feature about a fuse is its cheapness of installation; experience has demonstrated that, as a rule, it is out of place in a generator circuit on a switchboard.

In an easily accessible position may be placed, on each circuit panel, an automatic circuit-breaker. As in the main switch for high voltages, both legs of the circuit ought to break with a gap amply large to open the maximum current without any complicated apparatus to cut off the arc. The blades and jaws for carrying the current must be guarded from being burned by arcing, as such burning causes the blades to hang in the jaws when the switch should open. A good spring is the most convenient for throwing a circuit breaker switch, and the lever by which the switch is closed and spring set should work through a long arc so that the manual working of the device will not be difficult. There is no reason at this day for installing any breaker that will not work at once at the amperage for which it is set, whether at the time of adjustment or one or two years later. One requirement of vital importance to the safety of the board is to have the breaker positive when the blades leave the jaws. A slow movement is sure to cause arcing and burning.

Often a cross will occur, operate the breaker and at the same instant burn away so as to clear the circuit sufficiently for working. At such a time, if the breaker switch is replaced immediately, the cessation of light is short and of no importance. The practicability of such apparatus is then apparent. On another occasion the cross might stay on, the attendant would, as before, take hold of the breaker lever and replace the breaker switch; before he would have time to realize what was taking place much damage might be done by his holding the breaker switch closed. It follows that a circuit breaker should be so constructed that when the switch is closed on a short circuit it will open again independently of the breaker lever. Occasionally a cross can be burned off, especially with overhead construction, where one wire may touch or fall across another.

Every machine panel should contain an ammeter to indicate the quantity of current the machine may be generating; also a voltmeter to show the voltage of the current. There was a time when it was thought that cheap indicators were good enough for this purpose, but experience has proven that looking at an instrument and then making a guess is not a good method to adopt where dividends are desired on money invested in incandescent lighting. Accurate and dead-beat voltmeters only should be used. A voltmeter that is not dead-beat is only a snare when there is trouble on the circuits or with the machine and the switching must be done in a hurry.

One question of vital importance is the illumination of the board; the attendant must read his instruments, and the light should be so arranged that he will not be compelled to look at a glowing filament. Often times a shade and bracket can be placed so that the only light seen by the attendant is that reflected from the face of the switchboard or the instruments. This is much to be preferred. A good way is to have the instruments all made with the divisions on a porcelain face behind which can be placed a small lamp.

Occasionally the insulation of a generator will become broken down. Every machine panel should contain a detector to remain connected and indicate a cross to the frame just as soon as it occurs, and as long as it remains. One detector for a number of machines and the manipulation of a switch to hunt for breakdowns of this kind is not to be recommended.

It is just as essential that every circuit panel be provided with a reliable instrument to show at once when a cross to the ground occus. Every circuit panel should also have a good volt and ammeter. Some superintendents place on each circuit panel a reliable recording wattmeter, which is essential where a close watch is kept on the economic action of boilers and engines; it also helps to detect any great error in meters outside the station where all the current sold is measured.

Where generators never run in parallel it is quite essential that the busbars of each machine should run back of each circuit panel. It follows that each leg of each machine circuit has got to be connected to each circuit panel. If the generators be small, often there will be a great number of switches, usually plug switches, on the face of the circuit panel. The expense of a number of these plug switches sometimes influences the purchaser to get them poorly designed and constructed. The result is a constant source of trouble and annoyance.

When cables are used, the plug switches should be secure from being loosened by one cable raking over another when the switchboard attendant is working in a hurry. They should be so strong that a good hard thrust from a nervous attendant cannot break them.

Many times all the exciter switchboard apparatus, in stations where alternating apparatus is used, is put on the machine panels; but it is better practice to have a separate panel, just beside the machine panels or on the opposite side from the circuit panels, for the exciters. If but one set of exciter bus-bars is used, on this should be placed an ammeter and double-pole knife switch for each exciter circuit, a rheostat and switch for the fields of each exciter, and a voltmeter in circuit with each exciter to enable the attendant to get the proper voltages before connecting with the bus-bars. One voltmeter with the necessary switch would answer for all the exciting machines. The proper method of installing this apparatus is not an easy problem. It seems like a waste of space and energy to run a small machine with its belts for each alternator. This is the more independent way, but it is not good engineering in large plants.

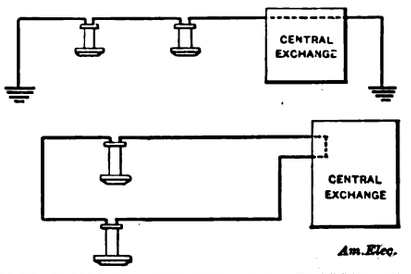
When all the exciters feed into a common bus system and the large generators are fed from the same, the breaking down of one exciter can often be bridged over by the remaining exciters doing the extra work for a time. Then again if there be trouble with one exciter it is apt to so overload the others that the whole system of machines might be short of exciting current until the disabled machine was cut out. With large exciting machines and proper circuit breakers this trouble could possibly be avoided. Where one set of bus-bars is used it helps to simplify the backs of the machine panels by having only one circuit from which to take the current for exciting the alternators. Whether the exciting current be taken from the individual exciter or from a pair of bus-bars, it should be controlled by a knife switch on the face of each machine panel. Each machine panel should also contain a rheostat connected into the field circuit of the alternators as it leaves the exciter bus-bars.

It is necessary to place upon each machine panel a switch of ample carrying capacity so as not to heat with the maximum current, and to break any current that it is possible for the machine to generate at full speed and on short circuit. As with the automatic breakers and main switches on the circuit panels, so these switches should break each leg of the circuit in at least two places. All the above mentioned manual switches should travel independent of the operator after the blades have left the jaws. Good designing and workmanship will produce a switch that will be actuated by a spring in such a way that the initial travel of the blade will be very rapid and tend to break the otherwise produced arc.

## TELEPHONE PARTY LINES.

WHITTEMORE-BARRETT-CRAFT SYSTEM.

BY H. S. WEBB.



For a long time after telephones came into use it was customary, when economy or other conditions required that more than one telephone should be connected to the same line or pair of lines, to connect them in series as shown in Figs. 1 and 2. Whenever two or more telephones are connected to the same line or to the same pair of lines it is called a party line system. The above arrangement of telephones has the disadvantage that when the operator at the central station sends a ringing current over the line all the bells on that circuit will ring, thus requiring a distinctive number of rings for each subscriber. Furthermore, when any two subscribers are talking there is nothing to prevent another subscriber on the same line from taking down his receiver and overhearing the whole conversation. When one telephone is in use the bells of all the others remain connected in the circuit, and therefore the number of telephones which can be placed in one circuit and not interfere with the conversation is very limited. Scarcely ever more than four can be used successfully in this way. This arrangement is very apt to give bad service and cause much trouble.

Instead of connecting them, as above, in series, or "looping in," as it is called, a much better plan was afterward adopted,

Digitized by Google

that of connecting all the telephones in multiple, or what is known as the "bridging bell" method. Fig. 3 shows the method ot connecting two or more instruments in multiple on a metallic circuit. If they are connected to an earth return circuit then all connections made to line B in this figure would be grounded at each station.

The subscribers' bells being always in

FIGS. 1 AND 2.—GROUND AND METALLIC RETURN.

circuit, they are made of high resistance, about 1000 ohms. The impedance of this bell is so high (about four times its resistance during the conversation when the average frequency of the current is about 300 periods per second) that it does not permit an appreciable part of this current to pass through it, thus forcing practically the whole current through the receiver. The generators are wound to furnish an e.m.f. so low that they will not ring the high resistance bells at the subscribers' stations, but they will operate the low resistance annunciator at the central station. For this reason the generators have a low resistance, and consequently they must have an automatic device which normally leaves the armatures of the generators on open circuit, closing the same only when the handle is turned.

Fig. 4 shows the connections of a "bridging bell" subscribers' telephone set. In order to show more clearly in one diagram the connections of the Warner switch I have altered the detail of the switch contacts slightly, placing one contact spring behind instead of alongside the other. This figure also shows the automatic "cut-in" device for closing the normally open armature circuit. When the handle is turned, a pin on the crank axle slides up the side of a V-shaped recess in the hub of the driving wheel, so drawing the other end of the crank axle away from a spring, the fixed end of which is always connected to one terminal of the armature, and allowing this spring to come into contact with a point connected to the line 1.

Now the generator at the central station is so designed that it can easily ring these high resistance bells. Since the frequency of this ringing current is much smaller than that of the current during conversation, the impedance of the bell for this current will not be much greater than its resistance.

By this arrangement twenty instruments have been successfully operated on one pair of lines, but for various reasons it is not advisable or customary for companies operating exchanges to put more than six subscribers on one pair of lines. However, I know of one case where there are seven on the same circuit, and doubtless there are other such cases.

This "bridging" system has several advantages over the "looping" method. First, a larger number of subscribers can be put on the same circuit. Second, a subscriber when he calls up the exchange does not ring all the other bells on his line. Third, the numerous cross connections between the two sides of the circuit through the high resistance bells tend to free the line from electrostatic charges, so that the circuit is freer from the evils produced by electrostatic induction.

It, however, still possesses two faults in common with the "looping in" method. First, the operator cannot ring one bell without ringing all the others, requiring, as before, a distinctive number of rings for each subscriber. Second, any subscriber can take down his receiver and overhear the conversation between two other subscribers, and he can also interfere with conversations by ringing up when the line is already in use. To obviate these two objections to party lines, several attempts have been made, using various systems of selective devices. The only one that I know to be in successful operation to any extent in this country is the party line selective system patented by Whittemore,

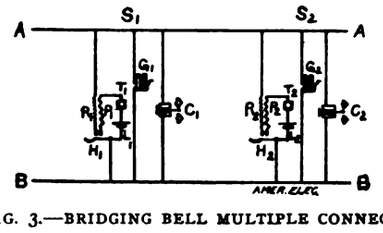


FIG. 3.—BRIDGING BELL MULTIPLE CONNECTION TO SINGLE CIRCUIT.

Barrett and Craft and assigned to the American Telephone & Telegraph Company.

By the aid of the diagram in Fig. 5 the principles upon which the system is based can be readily explained. Let there be two metallic conductors, A and B, between stations C and S, and also a connection to ground at both places, which is practically equivalent to three wires from C to S. It is evident that the following combinations of currents can be sent from the battery L at C to S over the two line wires and the ground.

A current can be sent in either direction over A, using the earth as a return and not using B at all, thus giving two selective signals. Similarly, a current in either direction can be sent over B without using A. Without using E a current can be sent in either direction over A and B in series. A current can be sent in either direction over A and B connected in parallel, returning through E; also, in either direction over A and E in parallel, returning through B; and finally, in either direction through B and E in parallel, returning through A.

This gives twelve different combinations, furnishing means for twelve selective signals. In using either A or B in parallel with E, the return circuit being through B or A respectively, balancing resistances would have to be used in order to make the current divide equally, that is, to properly balance the system, requiring close adjustment, for which reason the last four combinations have not been found to be of practical value. In the accompanying table are tabulated the eight useful combinations:

CURRENT COMBINATIONS.

| | Line A. | Line B. | Ground. |
|---|---|---|---|
| 1..... | + | 0 | − |
| 2..... | − | 0 | + |
| 3..... | 0 | + | − |
| 4..... | 0 | − | + |
| 5..... | + | − | 0 |
| 6..... | − | + | 0 |
| 7..... | + | + | − |
| 8..... | − | − | + |

Fig. 6 is a diagram of connections for eight stations; $S_1$, $S_2$, $S_3$, etc., are the subscribers' stations from which two wires, A and B (the outgoing and return conductors of a metallic telephone circuit), run to the central exchange, at which is located a system of eight calling keys, C, a separate key for calling each subscriber. The dotted line represents the earth return circuit. At each of the eight stations there are two relays, connected in derived circuits or earth branches m and q of the main lines respectively, and these circuits, after passing through the relays, unite and connect to earth at $E_2$.

At each station is a direct-current vibrating bell and battery in a local circuit c, which can be opened or closed at two points, 11 and 12, one at each relay. This local circuit is normally open at either one or both of these points. In order to ring the local bell the circuit must, of course, be closed at both points 11 and 12. R and $R_2$ are the local relays which control these local circuits.

The relays at each station differ either in arrangement or construction from those of all other stations. Thus at station S the line A is branched through a polar relay made responsive to a plus or positive current, and line B through a neutral relay

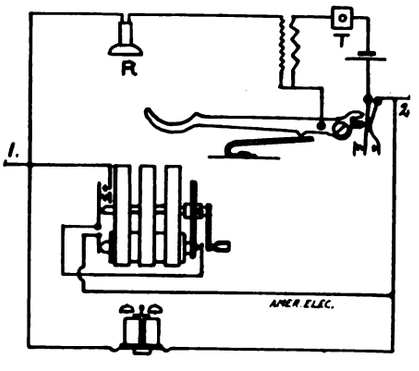

FIG. 4.—BRIDGING BELL CONNECTIONS.

adapted to respond to currents of either direction traversing B. Station $S_2$ also has a neutral relay on B, but a polar relay responsive to a minus current in A. The third and fourth stations have neutral relays connected to A and polar, plus and minus, relays connected to B. The fifth and sixth stations have each two polar relays, one of either sign, but reversed at

Digitized by Google

the two stations with respect to the two conductors A and B. Station $S_7$ has two polar relays of plus sign, and $S_8$ two polar relays of minus sign.

The plus and minus signs in the diagrams indicate the direction of current with reference to the central station end of the lines to which each relay will respond. Each polarized relay is arranged to close its own local contact point only when the current in the direction to which it responds passes through it. The neutral relays, indicated in the figure by a $\pm$ sign, on the other hand, will open the local circuits when excited, as they will be by any current, either positive or negative. Thus the local contact points of the polarized relays are normally open, while the local contact points of the neutral relays are normally closed.

At the central station C are located the calling battery or generator G, and the group K of eight circuit-changing calling keys, each key corresponding to the arrangement of relays at some one station. Thus if any key is depressed only such combination of currents is sent over the lines as will operate the local relays of one particular station in such a manner as to close both local contacts, while one or both local contacts at the relays of all other stations remain open. Hence all that is necessary to call a particular station is to depress the one key corresponding to that station.

Depressing key 1, for instance, puts the negative pole of the central station generator to ground through one side of the key, and sending through the other side of the key a positive current over line A, through all the R relays, returning to the central station through the ground. But no current will pass through the $R_2$ relays because line B is left on open circuit at the central station. Thus at S contact 10 will be closed by the polarized relay R, since a current flows through it in the positive direction and 11 will remain closed because no current at all passes through its neutral relay $R_2$. Thus the bell at station S will ring, since its local circuit is closed at both 10 and 11.

Furthermore it will be shown that no other local bell circuit will be closed. For at $S_2$ the polarized relay R will not be

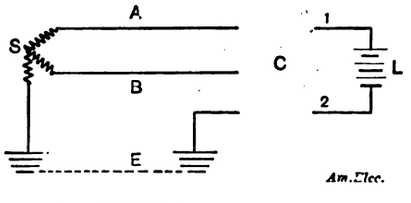

FIG. 5.—DIAGRAM OF PARTY LINE SYSTEM.

operated by a positive current, hence its contact at 10 will remain open. The local circuits at $S_2$, $S_4$, $S_5$, $S_6$, $S_7$, $S_8$ will be open because there is no current through their polarized ($R_2$) relays, thus leaving these relays in their normal positions, that is, with their contacts at 11 open. Thus, the only station called is S. Similarly it may be shown that by depressing key 2 the only station called will be $S_2$ and so on.

The inventors have also designed and patented an eight-station system in which the neutral relays are all replaced by specially wound and connected polar relays. This was probably to prevent any one else doing the same, because in this case the neutral relays are simpler and doubtless much cheaper and more easily adjusted and kept in order than the polar relays.

In a succeeding article, a description will be given of the method for preventing one station from overhearing the conversation taking place between two others.

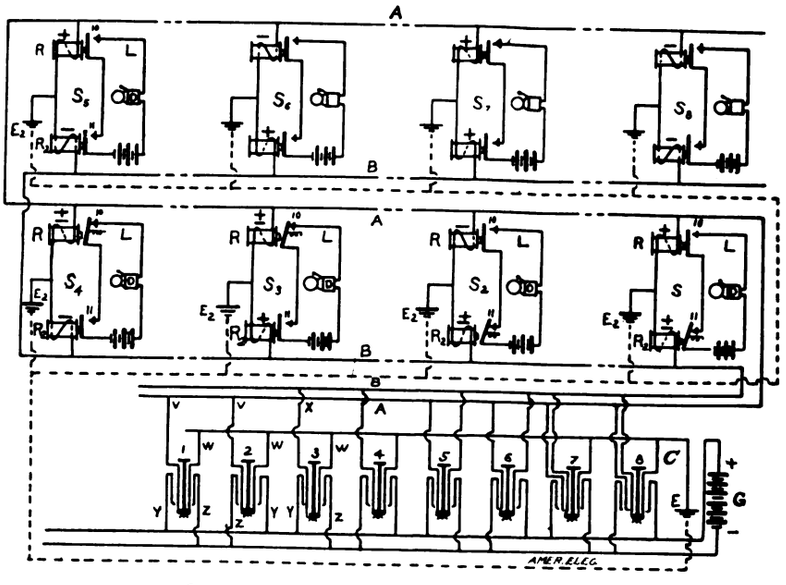

FIG. 6.—DIAGRAM OF CONNECTIONS FOR SIX STATIONS.

## ELECTRIC RAILWAY PRACTICE.

### CAR EQUIPMENTS.

BY WALTER MUNROE.

The parts of a car equipment that need to be looked after are quite numerous—in fact all parts should be examined at more or less frequent intervals. Let us consider first the trolley. The trolley wheel should revolve freely at all times. If the bushing is at all tight and prevents the easy motion of the wheel, there is a sliding action between wheel and trolley wire, which causes unnecessary wear on trolley wire and wheel. They should be examined at least once a day to see that they run freely and are not worn excessively. At the same time the trolley pole should be moved about by its cord to see that it moves freely in all directions. This is important, for if the pole is at all sluggish in following any change in the trolley wire, there is likely to be destructive sparking. This may be particularly noticed if running at a considerable speed where the trolley wire is at all loose between supports. Just after passing each supporting insulator the wheel may be heard to jump, and a flash can easily be seen between wheel and wire. The main wire should be examined occasionally where it is connected to the trolley base.

The hood switches should be looked after to see that they are not loose, and also that the blade and jaws are smooth and make a good firm contact. Upon examining the fuse box, we should see that the fuses are clamped firmly by the contact screws. It is also important to keep out all dust and dirt, as otherwise it may cause a fire when a fuse blows.

There are quite a number of types of lightning arresters in use made by the same and also by different manufacturers. In general it may be said that they should be kept clear of all foreign matter. The later types require less care than the earlier ones. The gap space in the ground circuit should be well looked after.

Coming to the resistance boxes we find a considerable difference among the different makes, particularly as regards protection of the points of connection and exposure of resistances. All the pieces of apparatus that are placed beneath the car floor are bound to be exposed more or less to flying mud and water. So that their protective coverings and also their position determine, to a considerable degree, their liability to give trouble.

In looking after the controller, there are several points which should be kept well in hand. The contact fingers should bear sufficiently hard on the rings to make a good firm contact without undue pressure. Prevent all cutting action and remove immediately all burns that may be formed on the surfaces. The contact fingers should be occasionally moistened with vaseline or some similar compound. All the bearings and interlocking parts should be kept clear and lubricated, but care should be taken not to use too much oil, as it might get on some of the conducting contact surfaces. It can be easily seen that any dust or dirt inside the controller is quite likely to get between the contact fingers and the contact rings on the revolving cylinder. If this happens, there will almost assuredly be destructive sparking or cutting upon their surfaces. Competent men should try the controllers frequently to see that they revolve properly. At the same time they

Digitized by Google

should be carefully examined inside, for the above mentioned points. The connection boards should be gone over occasionally for loose contacts.

In considering the motors, it is well to look at them from at least two standpoints; namely, mechanical and electrical. We will first consider some of the *mechanical* features. Some roads use brass or bronze linings for their armature shafts, and if these linings wear unduly, several things are likely to happen. A much too common occurrence is to have the bearings wear down so far that the armature core strikes the pole pieces. Now the armature of a modern railway motor is ironclad and is laminated. The coils lie well inside the slots, and it is the tops of the teeth that strike. When this occurs, the laminations are bent and pushed out of place, closing up the slots, cutting and short-circuiting armature coils, and doing a great deal of damage generally. Very often after such an accident the core will have to be stripped and entirely rewound. This, of course, is expensive. If this occurs out on the road, there is likely to be a long delay for the cars. If there are two motors on the car, the damaged one may be cut out in the controller and the car brought to the repair shop with the remaining motor. Again, the armature may be so damaged that it will not revolve, in which case its axle must be freed in some manner. With some types of motors the armature might be pulled up through the traps in the floor, but a tripod and a tackle would be needed for this, which would mean considerable delay. In any case, removing the gear or pinion will free this particular axle.

Excessive wear on the car axle linings as well as upon the armature bearing linings is quite likely to throw the shafts out of line. If this occurs the gear teeth will be worn unevenly or may even be broken. Excessively worn bearings, in any case, cause considerable play of the shafts, and this will cause excessive noise and jolting of the entire motor. The clearance of the armature cannot be too closely looked out for, as neglect of this point will almost certainly result in ruin to a large part of the armature coils.

The proper lubrication of the bearings is, of course, important. Both grease and oil are used for this purpose. Oil is generally used for the motor doing the heaviest service, and the oil is usually retained by some substance, such as waste placed in the cups. When grease is used, it should be stirred up frequently and the vent hole kept clear. In the winter a softer grease is usually used in order to make up for the difference in temperature. The small channels in the babbitted linings should be kept clear of all hardened grease by occasionally pouring through them a little gasoline, this being *independently* of the regular overhauling of the moters. The nuts on all parts should be kept tight for very obvious reasons. Gears and gear cases should be well looked after to see that there is sufficient grease or oil to keep them well lubricated.

It is well known, or should be, that it is of vital importance to keep the commutator in good condition. It should be covered with a smooth, dark colored glaze and be free from burned spots. It may be treated from time to time with vaseline or some similar compound. The brushes are sometimes treated with a compound that is spread over the commutator as the brush wears down, and this serves as a sort of commutator dressing. Any slight irregularities may be remedied with sand-paper, but when grooved or cut or worn unevenly, it should be turned down in the lathe. If burned spots appear, the commutator should be carefully examined and tested, and the armature coil leads inspected for trouble. Be sure to determine if the fault is due to a loose bar or to crumbled or displaced insulation between bars. The brushes should be pulled up every night to make sure that they move freely in the holders. As the commutator wears down the brush holders should be moved down a corresponding amount so that the distance between the end of the brush and the commutator surface remains always about one-quarter of an inch. A competent man can, by looking at a motor commutator, get a very good idea of the condition of the motor, and he can also tell very closely the care that the motor has had. Keep the brush holder contact surfaces clean, smooth and free from foreign matter.

All the modern motors for ordinary railway work are very completely inclosed. In spite of this, however, some dust and dirt will work itself inside. Now if any of the surfaces are at all moist or oily they will immediately become covered with copper and carbon dust from the inside, and dust and dirt from the outside. This is particularly liable to settle on the inner end of the commutator where the armature leads are attached. It also slowly works itself through or under the protecting heads placed over the armature coils and leads at this end of the armature core. The packing together of this dust at this point is very dangerous, for there is much crossing of leads and considerable differences of potential between them. The chances are very good for the bridging over of one or more commutator segments or for a short circuit among the leads. In either case the commutator is likely to be badly damaged or the armature burned out.

When motors are new and run for the first time, they should be carefully examined at the end of the run to see that neither one is unduly heated. If one is a great deal warmer than the other, the hotter one is probably injured or else it is doing more work than the other. This would occur if its field was weak from any cause.

Maintenance (and this includes inspection) in order to be thorough and of value, must be carried out systematically. That is to say, certain definite rules should be laid down that at a certain definite time intervals certain definite inspections should be made. For example, trolleys and trolley wheels, bearings, grease cups, commutators, brushes and accessories should be examined at least once a day. When running his car the motorman should report any unusual noises or behavior of any part of the apparatus.

A very convenient method now used on many roads is to have printed slips to be filled out by the motorman as a report when anything works badly. The printed headings might be: motor, controller, switches, trolley, brake rigging, etc. These slips should be placed where easily accessible, and should be used by the car barn foreman or inspector as a means of saving delay in remedying troubles. The slips should have proper spaces for date, number of car, trip, etc., and a small space for a few remarks. Many motormen, if they see a large space headed "Remarks," would feel in duty bound to fill in with useless or trivial details.

## GENERAL METER PRACTICE.

BY LYMAN C. REED.

The purpose of this article is to deal with the practical management of a modern meter department, and not to give a scientific dissertation on meters.

The management of central stations, in all the details of the art, has become so well defined in all its different bearings and outlines that we pause to wonder at the apparent crudity of present meter practice. The most important feature, after producing electric current at a minimum cost, is to have it accurately measured at the consumer's at a minimum cost to the producer. A carelessly managed meter department frequently means a loss of thousands of dollars, and one that is conscientiously operated but by incompetent men may be even more disastrous in its results. Granting that the best meters on the market are used, a competent engineer with the proper facilities at his disposal is essential to the best results.

The keeping of records, rendering of bills, and all the general work incident to the bookkeeping part of the department will not be dwelt upon at any length, as the art of bookkeeping is so well defined as to need no special explanation. However, a well-devised system of records is essential to accuracy, and we do not wish to be understood as belittling in any measure the importance of this part of the work. As different systems are in vogue in different parts of the country, it is simply necessary to adopt some fixed system of keeping records and follow it in detail.

The object of this article is to deal with the purely electrical and mechanical features encountered in different stages of the work. It is an almost universal feature to use some one of the many forms of motor meters. As these all bear a great resemblance in their general features, we will take the Thomson recording watt meter as a fair sample of the type, and use it to illustrate in general the features of meter practice which we wish to set forth.

The absolute accuracy of a meter under all loads is, of course, the goal at which we wish to arrive, but as yet this has not been accomplished, and we must content ourselves with the most accurate manipulation possible of the meters we have.

The testing of meters to insure accuracy may be divided into two divisions. First,

Digitized by Google

testing meters before installation; second, testing meters in circuit to insure continued accuracy.

Testing meters before installation cannot be too carefully done. The very best instruments should be used and a convenient and suitable testing board provided. In this connection, I would like to make a small digression and describe a board suitable for all voltages from 50 to 1000 volts.

With a central station furnishing current to consumers at 50 and 115 volts, alternating; 115 and 230 volts, direct current, and

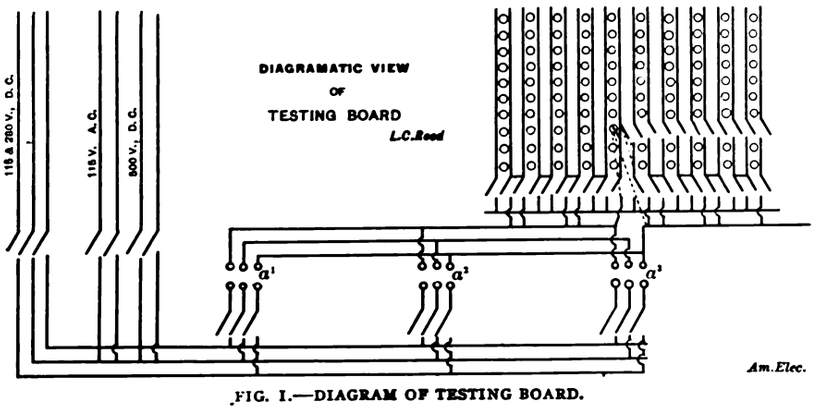

FIG. 1.—DIAGRAM OF TESTING BOARD.

500 volts direct power services, the problem of using one lamp bank on testing board for these different voltages became an interesting one, and was solved as shown in the accompanying diagram and photograph, the latter giving a view of the front of the board. The board and bench are of white marble, the board being 8 ft. x 8 ft., with the lamps and all wires on the back, switches and instruments on the front. By employing single-pole switches and making the "risers" for the lamps the same potential in between the rows, no difficulty was experienced in adapting the lamps to any of the voltages given. The diagram of connections and photograph will readily show how the board is operated. Nevertheless, a few words in explanation may serve to make it clearer.

The lamp bank consists of ten rows of lamps, five rows on each side of the three-wire system. The board is provided with a connecting switch, so that all the lamps can be used on 115 volts either alternating or direct. To burn a bank on 500 volts, the switches at the ends of each five rows are closed and all the intervening switches opened; then by having risers tapped permanently together, as shown, the five rows are put in series.

The throw-over switch also enables all lamps to be burned on 500 volts. The five rows at the right of the board are broken by a row of single-pole switches, so as to enable any number of lamps being turned on without resorting to unscrewing the lamps. This arrangement also allows of three different loads being obtained for 500-volt circuit.

If at any time it is desired to burn a bank on 1000 volts, the end switches are closed and tie-over switch put in, all other switches being opened. It will then be obvious that all ten rows of lamps will be in series. Of course, it is understood that only one kind of current can be used at a time. The other connections are sufficiently plain to warrant no further explanation.

The instruments consist of a 500-volt voltmeter, scale 250 to 600 volts; a double scale 115 and 230 voltmeter, direct current; a double scale ammeter reading from 0 to 10 in 1/10-amp. divisions, and from 0 to 50 in ½-amp. divisions. All instruments are of the standard Weston station type, illuminated dial.

I merely point to this as a sample of testing board, which, after a year's service, is found to fulfill the many demands to which it is put. No alternating instruments are shown, as we only have the portable type.

An absolutely steady potential is essential to correct testing, and leads direct from the storage battery should be taken to the testing board. Where no storage battery is in use, one especially for the purpose should be obtained, as the absolute accuracy obtainable will more than pay for the cost. The instruments used in testing should be calibrated frequently by any of the best methods in use, so as to eliminate all errors due to this source. Meters should be tested particularly for light load accuracy, as well as overload accuracy, and the best possible adjustment given them. While great stress has been laid upon overload accuracy, too much cannot be said in favor of having meters correct on small load. The major part of the station's income is registered on from 5 to 20 per cent the rated capacity of the meter.

To bear this statement out, we will cite a probable modern plant of, say, 100,000 16-c.p. lights or equivalent. In the plant itself there would be not over one-third this amount in engine capacity, while the mean load line would be not more than one-third of this amount, or one-ninth of 100,000 lights would represent the mean load line for the twenty-four hours. The capacity in meters would be fully 75 per cent of the 100,000 lights, or 75,000 lights meter capacity. The mean number of lights burned would therefore be 11,000, or 14.7 per cent would represent the average working load of the meter. Hence it can be seen how essential it becomes to have meters correct on light loads, as well as overloads.

The above gives the general average. There are, of course, special cases where meters work under better conditions. On large installations, where the the total number of lights is only burned for a few hours during the day, a meter of sufficient capacity to carry full load will be found to be very slow on from 1 to 15 per cent of this load. In a recent article in the AMERICAN ELECTRICIAN a parallel switching arrangement was described, which gives the highest attainable accuracy under all loads, and is especially adapted to all consumers that use a small amount of light in the day time and small all-night burning.

The selection of meters for installations should be a subject of careful consideration, and the special conditions prevailing studied, so as to put in as small a meter as possible without endangering the complete destruction of the meter by overload. It frequently is better practice to burn up a meter than to put in one so large as to be very inaccurate on the consumer's usual load. A load curve of the consumer's burning, if conveniently obtained, would be of great assistance in this connection. The placing of meters, therefore, becomes

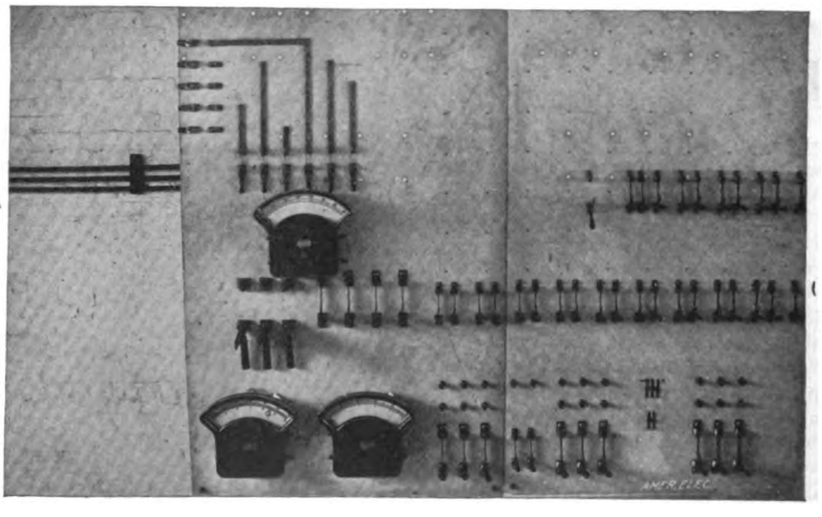

FIG. 2.—TESTING BOARD.

Digitized by Google

a subject for the exercising of nice judgment, for which no definite rule can be laid down, but the matter must be decided by the exigencies peculiar to the case in hand.

Before taking up the subject of testing meters on the outside, it might be well to say a few words about repairs. The repair room should be fitted up with workbench and vise, and also supplied with all necessary tools needed in repairing meters. A good mechanic should be obtained, and all repairs can be made except the actual making of parts, which can be more cheaply obtained from the manufacturer.

Any number of unserviceable meters that would otherwise have to be shipped back to the manufacturer can be repaired and put in perfect order. The meters repaired are given a rough test by the repairer before sending to the testing room. The final test should only necessitate the careful adjustment of the meter. The changing of meters from 50 to 100 volts, or any other changes are all made here, and a fully equipped repair room will be found by far the cheapest way of keeping meters in repair. All cut-off meters and meters changed for inaccuracy are sent to the repair room, thoroughly cleaned and renovated and placed in the testing room for final adjustment. It is often found necessary to get up some special arrangement connected with meter operation, and the presence of a skillful mechanic is a great help in cases of this kind, and often saves the expense of getting the work done by some model worker.

In a following article will be considered the subjects of keeping meters in perfect condition after they are installed, and also special tests demanded by consumers or thought necessary by the general manager.

## STEAM AND WATER STOP VALVES.

### GATE VALVES.

The value of a good stop valve is not always appreciated by station managers or engineers, until they have at some time or other had an experience with inferior or worthless fittings of this class. In fact, possibly few people realize that no steam plant yet installed could be operated without the stop valve in great quantity and variety. Many station managers appreciate the valve and allow its full importance to be set forth at once. For buyers of this class there are many excellent valves in the market for which a fair price is asked. For the other class of buyers I am sorry to say that there are valves also, and valves that can be bought for less money than the good ones.

It usually needs but one experience of this kind to teach the engineer his lesson, but when the manager does the purchasing he does not always get the experience, and so continues to receive inferior fittings upon the mistaken score of economy, and thus in fact gives to the engineering department the dearest fittings he can buy, instead of the cheapest, as he thinks he is doing. But there is another side to the story. No matter how good a valve may be it is possible—yes, it is quite easy—to spoil it the first time it is closed under pressure. A very small bit of dirt—a fragment of iron from a pipe thread—will, if caught on the seat when the disc is screwed down, so cut into the working parts of the valve that

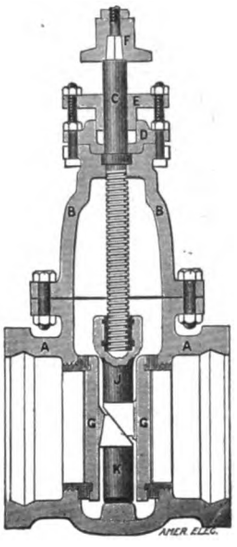

FIG. 1.—LUDLOW DOUBLE-GATE STRAIGHT-WAY VALVE.

a channel will be scored across the seat, and never more can that valve be made tight again until the damaged parts are repaired or renewed.

It is here that the unskilled handler gets in his work of destruction alike on the best and poorest of valves. If he screws down a valve after it is evident that some foreign substance is caught on the seat he will surely cut the seat or disc—and the unskilled man always does this. If the valve does not close tightly he puts all his strength on the hand wheel and forces the seat and disc together if possible.

Although the solid metal-to-metal surface valve is the best and most reliable under skilled handling, the very fact that there are unskilled and careless valve handlers has led valve makers to adopt all manner of expedients to prevent damage to valves as above described. To this end have been invented all the soft and removable discs, the flexible seats and elastic working parts. Thus they are all makeshifts designed to enable cheap labor to be utilized in places otherwise impossible to use it. I call attention to these points to aid in a solution of the problem why some engineers work with inferior valves while others of that class spoil even the best valves that are placed in their hands.

Valves are divided into two great classes, globe and gate, between which the honors are about evenly divided at the present time. The globe is the oldest form, and was the most popular type of valve until quite recently. Now the two forms are about equally used, with a strong and constant increase in favor of the gate valve, which possesses certain inherent advantages that may make it the valve of the future as soon as the constant improvement which it is now undergoing has led it to practical perfection.

The first gate valve was a very crude affair, not at all like the finished ones of the present time, an excellent type of which is shown by the accompanying engraving, Fig. 1. This valve, the Ludlow, is so constructed that the internal mechanism consists of the stem, two gates and two bevel-faced wedges, the wedges being entirely independent of the gates (or discs) and working between them.

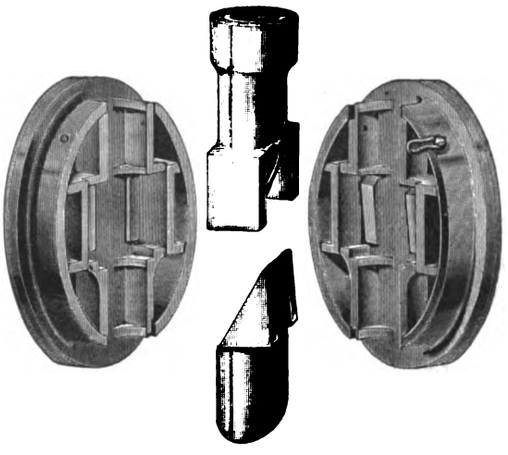

FIG. 2.—GATES AND WEDGES FOR DOUBLE-GATE VALVE.

By the action of the stem, C, which works through the nut, J, in the upper wedge, the gates descend parallel with their seats until the lower wedge strikes the stop (or bolts), K, in the bottom of the case—the gates and upper wedge continuing their downward movement until the face or bevel of upper wedge comes in contact

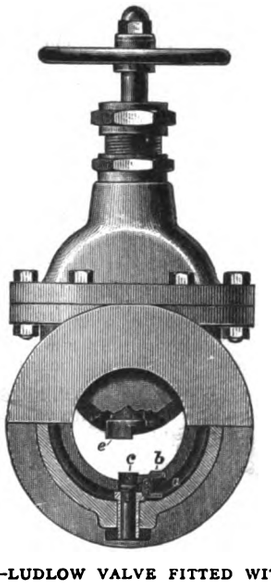

FIG. 3.—LUDLOW VALVE FITTED WITH AUTOMATIC DRIP.

with face or bevel of lower wedge. The gates then being down opposite port or valve opening, the face of the upper wedge moves across the face of the lower wedge, bringing pressure to bear on the backs of both gates from central bearings, thus forcing them apart and squarely against their seats.

Digitized by Google

In opening the valve the order of things described above is practically reversed, the first turn of the stem releasing the upper wedge from contact with the lower wedge, thereby releasing both gates (or discs) from their seats before they commence to rise. This removes all, or nearly all of the grinding which formerly damaged the gate valve at opening and closing, at which time the gate or disc had to be drawn off the seat while under pressure. The construction also allows the valves to work equally well with the pressure on either side of the gate. The gate rings, n, n, are easily removed when necessary, and the case rings, t, t, are also screwed into the main casting of the valve body.

These valves are also made, when so desired, with an automatic drip which will drain the valve chamber alone, or the entire connecting tube if so desired. Fig. 3 shows the construction and manner of operating the drip. The stem, c, forms the controlling connection with the valve

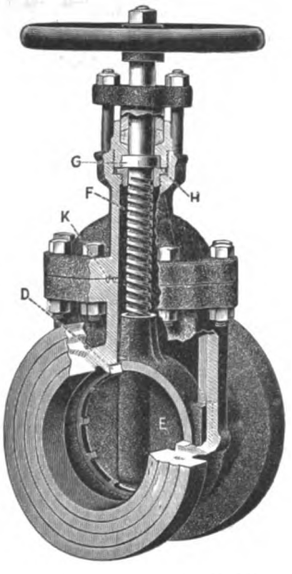

FIG. 4.—THE VICTOR VALVE.

which drains the cavity a. The mechanism b serves to make connection between the dip valve stem and the main valve stem, e, so that the final turn in closing the valve opens the drip. When the valve is to be opened the first turn closes the drip, which then becomes disconnected from the main stem.

A single gate valve of the same manufacture is for use under low pressures, or otherwise where double gate valves are unnecessary. In this valve the pressure comes against the back of the gate. The seat ring is screwed in, and the gate valve is dove-tailed and riveted on, while both rings have ground faces, thus making a steam and water-tight joint.

Fig. 4 shows another form of gate valve, made by the Lunkenheimer Company, and known to the trade as the "Victor" valve, the seats and discs of which are so made that they can be renewed when worn without the necessity of taking the valve body from the connecting pipes.

The discs in these valves are all made to standard tapers so that they are interchangeable. The seats are finished separately from the valves and faced off straight. The recesses in the body which receive the seats are threaded exactly to the angle of the taper on the disc, and when the seats are secured in place they fit accurately to the disc. This method is

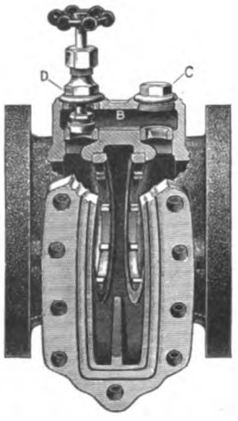

FIG. 5.—VICTOR VALVE, WITH BY-PASS.

claimed to be superior to facing off the seats after they are secured into the body, for the reason that this latter method does not permit of renewing the seats when they are worn; and should the seats become slightly unscrewed, the integrity of the bearing between them and the disc would be impaired, causing the valve to leak. The seats and disc are both made of hard phosphor bronze so as to insure durability and reduce to a minimum the cutting action of the steam on the same.

In order that the stuffing box of the valve may be repacked under pressure, the disc is made so that when raised it makes a joint in the hub so as to keep the steam from leaking out at the top.

The joint between the hub and body is formed by two seamless copper wire washers, which are imbedded in the top surface of the body, and the hub when screwed in place forces them down, thereby forming a joint which is practically indestructible.

The method of by-passing employed by the manufacturers of "Victor" valves is

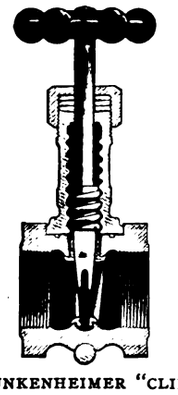

FIG. 6.—LUNKENHEIMER "CLIP" VALVE.

quite novel and possesses features of merit. As will be seen in Fig. 5 herewith, the by-pass instead of being formed externally consists of a cored passage which leads around the disc and has two valve seats, only one of which is intended to be in use at a time, the opening to the one not in use being closed by a plug. Should the seat of the valve in use become worn or leaky, the position of the valve trimming and plug can be reversed, thus making use of the reserve valve seat, and the worn one can be renewed and reground. The principal advantage of this style of by-pass is that it is entirely self-contained, and is not affected by extremes of expansion and contraction. When it is desirable to cover the exterior of the valve with some non-conducting material this can be done very easily.

The "Clip" gate valve, also made by the Lunkenheimer Company, is intended for use when pressure does not exceed 100 lbs. per square inch. The hub is secured to the body by a V-shaped clip which passes around the body and through lugs in the sides of the hub and holds the same firmly to the body by means of two nuts. This construction is very convenient when it is necessary to take the valve apart for examination or repairs. The joint between the hub and body consists of a seamless copper wire washer, which is firmly imbedded in top part of body and forms a joint against the upper side of hub when the same is in place. The disc has two seating faces, and takes pressure from either side. The stem has a coarse thread which makes it possible to open or close the valve very quickly. The stuffing box on the small sizes has a special packing arrangement to prevent the same from working loose.

## ECONOMY OF STEAM PRODUCTION.

BY A. L. HARRISON.

As the economic production of steam is independent of the application or use of steam, in considering the possible economies in producing steam, I shall, therefore, consider only the boiler and appurtenances, and boiler-room practice.

Boiler-room practice too often represents principally an outfit more or less wisely selected and left to the varying whims of the fireman—the engineer seldom being seen in the boiler room, except when steam is short, and then he comes to ask the fireman, "what is the matter?" The modern progressive engineer, however, takes charge of the boiler room as completely as of the engine and dynamo room. The firemen do their work as his assistants and under his direction. He makes the necessary visits and observations to know the conditions and practice in the boiler room. It is true that in too many cases there is little or no appreciation on the part of the employer, but an engineer should have some self-respect to maintain; enough professional dignity and pride to put at least a good degree of conscience into his work, for the work's sake, even though proper appreciation on the part of the employer or superior be lacking. Intelligent, constant supervision of all the details of boiler room practice is necessary to secure the best economy.

There is, however, many cases where the boiler and its appurtenances and arrangement, one or more, or all, are such as to preclude the possibility of securing the

Digitized by Google

best economy. In such cases it requires a wise, faithful engineer to realize the best practicable economy.

The encouragement of an improved, progressive practice is what is wanted. And since there are few (I know of none—no, not one) ideal boiler plant, it is necessary to discuss the best methods for securing economy in the average plant as it stands, as well as how to secure an ideal plant.

I find in most plants boilers that are not best suited for the work required. The units are either too small or too large, or the total capacity too small. The latter is a very prevalent difficulty, and one which represents serious difficulty to the competent, conscientious engineer. The duty must somehow be secured, even if risks must be taken involving possible serious damage to both property and life. "We must have the steam; if you cannot get it we must secure an engineer who can," is the practical situation confronting too many engineers, and the usual consequence is a waste of fuel, if, happily, no more serious results follow.

But there are many cases of waste which might be abridged if the best practicable use were to be made of existing appliances. Some engineers make the mistake of clamoring for a new style of boiler. There is no fact more thoroughly established by experience than that there is little in the economy that can be realized under like conditions, from one type of boiler over another, so far as the standard types are concerned. By standard types I mean those types which are in such general use as to have become commercially established. Even the common return tubular or fire tube boiler can, within the limit of a safe steam pressure, hold its own with the best water tube boilers, especially if the comparison cover a considerable period of service. This latter cause is true because of the fact that the heating surface of a common horizontal multitubular boiler can be more easily kept clean on both the water and the fire side.

There is a vast amount of waste of fuel due to dirty boilers, and the greater part of unnecessary waste from this cause, especially in the use of water tube boilers, is due to the fire side of the tubes becoming encrusted with soot commingled with the fine ash carried to them by the draft, and other products of the fire, which in the furnace heat becomes gasified and subsequently, when cooled by contact with the water surfaces of the boiler, return to a solid form, and lodge on or adhere to the tubes.

Authorities, I believe, unanimously agree that an eighth of an inch of coating of soot and ash on the outer surface of a water tube wastes more heat than a quarter inch of scale on the inner or water surface of the tubes. No one of sense would think of running a boiler with a quarter of an inch of scale on the inner surface. The waste of fuel in such a case is made the more emphatic and receives more prompt attention because of the danger of damage to the boiler by burning or blistering the tubes.

There are not a few so-called first-class plants where a complete cleaning of the outer surface of the heating surface of the boilers would result in decided increase of capacity, as well as desirable economy of fuel per h.p. of steam produced; *i. e.*, per 34.5 lbs. of water evaporated from and at 212° F.

A superintendent of a manufacturing establishment, where three water tube boilers of 350 h.p. each (rated capacity) are required to give a maximum of 1500 h.p. in daily work, recently told me that when he had managed to clean the outer surface of the tubes more thoroughly than by the usual method of "blowing," he found a saving of from three to five tons of coal per day of twenty-four hours.

Another instance is of increased economy and of increased capacity from attention to smoke flues and passages from furnace to chimney, of which I have personal knowledge. In a plant of twenty-four common horizontal tubular boilers, the manager found the coal and the labor bill had increased in much greater ratio than his product, and that it was with great difficulty that the necessary capacity was secured. On investigation, the blazeway back of the furnace was found to be badly choked with accumulated cinders, ash, etc., and, following up this revelation, found the flue passages from boiler to chimney also badly choked. After all had been thoroughly cleaned, they dropped off four of the boilers used and reduced the coal consumption from seventy tons per twenty-four hours to forty-five tons; dispensed with five men formerly employed in the boiler room, and had no difficulty about enough steam.

The coal had been wasted at the rate of about twenty-five tons per twenty-four hours (over thirty dollars per day) through negligence or stupidity, because the engineer in charge had not given proper attention to details in the boiler room. There is another engineer in charge now, and results are quite satisfactory.

Another case which recently came under my observation was in the case of a large steel mill using boilers aggregating about 8000 rated h.p.; I had some time previous recommended an increase of at least 1000 h.p. to obviate the necessity of crowding beyond the economic rate of duty, but cost of installation kept the enlargement in abeyance. At the time referred to, I chanced to be there with a pyrometer, and, at a time when the rate of duty was slightly below the usual maximum, I tested the escaping gases, and found the pyrometer registered 685 ° F. The point of insertion of pyrometer was fully three feet from where the gases left the boiler, and through the upper side of a flue having a down draft, and near where the downward turn toward chimney occurred. It is, therefore, certain that the flue gases leave the boilers when in full regular duty at not less than 700°. A test of one battery under, as nearly as practicable to determine, average rate of duty showed the boilers were being worked at from 80 to 100 per cent above the rating. As all but one battery, and at times all but one boiler, in that room of about 4000 h.p. were in constant use, no cleaning of the outer or fire surface more effective than "blowing" had ben attempted.

If 2000 h.p. were to be added to that boiler plant, which, with cost of necessary extension of boiler rooms, would require an investment of perhaps forty thousand dollars; the grate surface under the present boilers cut down to suitable proportion, and the outer, as well as the inner side of heating surface of all the boilers kept clean, the work now done could be more easily accomplished; the life of the boilers and of the furnaces prolonged, and a saving could be effected of at least forty tons of coal per day, which is now, and has been, daily thrown away in excessive waste of heat carried away with the escaping gases up the chimney.

The saving in dollars and cents in such a case depends on the price of coal, and I have not sufficient data to set it forth in detail, but have no hesitancy in venturing the assertion that in this plant a suitable increase of capacity, suitable proportion of grate surface and improved boiler room practice would result in a saving in the entire plant of from fifty to seventy-five dollars every day the plant is operated on the present average of steam consumption. This would, after making due allowance for the extra labor necessary to look after the extra number of fires or furnaces, and the lost time for "shut downs" for repairs, amount to not less than fifteen to twenty thousand dollars per year. This plant is by no means an exception. It is comparatively a new plant, and, in its mill or machinery equipment, and in general arrangement, the boiler plant so "modern" as to be considered a model by wideawake engineers and managers who contemplate new works or radical improvement of old ones.

## *Lessons in Practical Electricity*

### HOW TO DESIGN A DYNAMO.

In the preceding section the shunt coil was considered. The series coil now engages our attention. The coil must magnetize the field magnets sufficiently to overcome two factors tending to bear down the voltage, and must further raise the voltage at full load to 120 volts, an over-compounding of 10 volts, to compensate for line loss. The first of the factors tending to depress the voltage as the load comes on is the armature resistance, for additional volts are required to force the full load current through it. The other factor is armature reaction.

As to the first, we determined that the armature was to have 168 wires, that it was to be 6½ ins. in diameter and 11 ins. long. The wire was to be No. 8 B. & S. gage. It is evident that the total length of wire will comprise the following items:

168x11 ins. for the conductors.... 154. ft.
84x6.5 ins. for the back end connectors ..... 45.5 ft.

Digitized by Google

| | |
|---|---|
| 42x6.5 ins. for the front end connections | 22.75 ft. |
| 84x2 ins. for commutation leads | 14. ft. |
| Fifteen per cent for the end connectors, to enable them to avoid the shaft and each other | 12. ft. |
| Total | 248.25 ft. |

Two hundred and forty-nine and one-fourth ft. of B. & S. No. 8 will have a resistance of .1565 ohms. We must remember, however, that this wire is divided in two halves which are connected in multiple, and their joint resistance is one-fourth of the above figure, or .0391 ohms. The full load current is 55 amps., and hence we

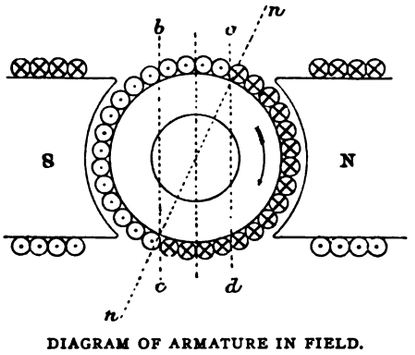

DIAGRAM OF ARMATURE IN FIELD.

need 2.15 volts to force this current through the armature.

The next factor, the armature reaction, can be determined only approximately, for before it can be computed a position must be estimated for the brushes. If we assume that the brushes are to be set opposite the pole tips, we shall have a margin which will not be too large.

Supposing the brushes to be set thus, it will be seen on examination that the slots between the pole pieces contain current-carrying wires, the magnetizing energy of which is directly opposed to the flux in the magnetic current. In other words, they are demagnetizing turns, and must be compensated for by additional turns on the series field. This will be better understood by reference to the accompanying illustration, in which is shown an armature between pole pieces. N N is the true line of the brushes, and the conductors from B to A and C to D constitute demagnetizing loops surrounding the magnetic circuit.

In the machine that we have designed there are seven slots between pole pieces. The polar gap is a little large, and as the field is quite strong, we will assume that the brushes are set only three slots away from the theoretical neutral line, making six demagnetizing slots. Each slot contains four loops, making twenty-four loops in all, and as each carries half the main current, we must wind half as many turns on the series coil to compensate for this factor.

We have a total of 12.15 volts to be generated by the series coil, and to the coil computed from this figure we must add twelve more turns for the armature reaction.

To generate 12.15 volts in an armature of 168 conductors revolving at 1500 r.p.m. there will be needed

$$N = \frac{E \times 100{,}000{,}000}{N\ C} = \frac{12.15 \times 100{,}000{,}000}{168 \times 25} = 289{,}000 \text{ lines.}$$

The flux due to the shunt field is 2,619,-046, and this, added to the series lines, makes a total useful flux of 2,908,046 lines and a field flux of 60 per cent more, or 4,652,,924 lines. The permeability at these fluxes must be determined, because it is at this magnetization that the 289,000 lines are forced through the magnetic circuit.

The calculation will evolve the following results:

| | |
|---|---|
| Density in field magnet | 84,600 |
| Permeability of field magnet | 1,200 |
| Density in armature teeth | 90,400 |
| Permeability of armature teeth | 860 |
| Density in armature body | 73,250 |
| Permeability of armature body | 1,550 |

We will also find it convenient to collect the following data for reference:

| | |
|---|---|
| Length of path in armature | 6.75 ins. |
| Area of path in armature | 39.70 ins. |
| Length of path in teeth | 1.39 ins. |
| Area of path in teeth | 32.19 ins. |
| Length of path in field magnet | 28.06 ins |
| Area of path in field magnet | 55. ins. |
| Length of path in air gap | .1 ins. |
| Area of path in air gap | 58.15 ins. |

From the foregoing we calculate the following:

Ampere turns necessary to force 462,400 lines through the field magnet at full load

$$\frac{462{,}400 \times 28.06 \times .3132}{55 \times 1200} = 61.6$$

Ampere turns necessary to force 289,000 lines through the gap space

$$\frac{289.000 \times .3132 \times .1}{58.15} = 155.5$$

Ampere turns necessary to force 289,000 lines through the teeth

$$\frac{289{,}000 \times 1.39 \times .3132}{32.19 \times 860} = 4.5$$

Ampere turns necessary to force 289,000 lines through the armature body

$$\frac{289{,}000 \times 6.75 \times .3132}{39.70 \times 1550} = 9.9$$

Total ampere turns ..... 231.4

The full load current is, as we know, 55 amps., and hence the turns necessary will be 4.2. To this we must add twelve turns to compensate for armature reaction, giving a total of sixteen turns. It will probably be found wise to use twenty turns, winding ten turns on each magnet limb. If this is found to be too much its magnetizing effect can be reduced by shunting; that is, by connecting a resistance across the terminals of the series coil. Most manufacturers are in the habit of placing several extra turns on their series coils and shunting, because one machine in this way can be made to answer for any given over-compounding percentage by simply varying the shunt.

It is also well to note that the shunt coil was calculated at an estimated total flux. Referring to the sections of this series published in the November and December numbers, it will be remembered that the shunt bobbin was to generate 2,619,046 useful lines. We determined the permeability of the basis of a maximum number of lines 4,950,000, which was estimated and not calculated. Having determined the additional flux the series coil must supply, we find the maximum flux to be 4,652,924 lines, and the total useful flux 2,908,046 lines.

The permeability as determined from these figures will be more accurate than those determined from the approximate figures, and might even change the size of the shunt wire a gage number. It would therefore be well to recalculate the shunt coil and see if the discrepancy is serious. At most it would only change the shunt wire from No. 22 Birmingham gage to the next size smaller. The size of the series wire should be determined on the basis of 1000 amps. to the sq. in. It is to carry 55 amps., and hence its area should be .055 sq. ins., which corresponds most closely to No. 2 Brown & Sharp gage. There will be a drop in these series coils which must be taken care of. This might be computed, but is best corrected by varying the shunt.

In calculating the series coil it will be seen at once that armature reaction plays a more important part than any other consideration, and as this can only be estimated approximately, it will not be well to follow the calculations too closely, for it is safer to leave a margin. In practice, series coils are determined by exciting the field magnets independently by what is known as an experimental coil, in which the number of turns are known. The current is measured both at no load and full load, and from this data the additional number of ampere turns which comprises the series coil can be readily determined.

## Letters on Practical Subjects

### An Electrical Paradox.

Of a number of letters on the above subject received after the December issue went to press, we select the following as giving the most general solution offered to the so-called paradox of Mr. Blake, printed in the November number:

*To the Editor of American Electrician:*

In your November issue I notice a letter, entitled "An Electrical Paradox," from Mr. C. D. Blake.

This problem may easily be solved by application of Kirchoff's laws, namely: The sum of all the e.m.fs. in a closed circuit is equal to zero, if the e.m.f. consumed by the resistance is also considered as a counter e.m.f., and all e.m.fs. are taken in their proper direction. The sum of all the currents flowing toward a distributing point is zero.

Let us take the general case represented by the following diagram, in which E and

Digitized by Google

e; R, r and r'; and I, i and i', are the e.m.fs., resistances and currents respectively in the three paths connecting the points A and B.

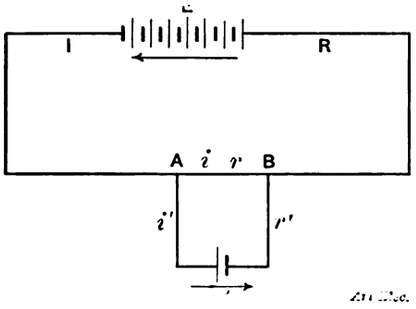

DIAGRAM OF CIRCUIT.

The directions of E and e are shown by the arrows. Then by the first law we have $E - I R - r i = o$ and $E - i R - r' i' + e = o$. And by the second law, $I - i - i' = o$.

Solving for I, i and i' we have

$$I = \frac{Er' + Er + er}{rr' + Rr' + Rr}$$

$$i = \frac{Er' + eR}{rr' + Rr' + Rr}$$

$$i' = \frac{Er + er + eR}{rr' + Rr' + Rr}$$

The condition that $i = o$ is that $Er' = eR$. That is, if $E : R :: e : r'$, there will be no current in the short wire A B. Also, if

$$\frac{E}{R} = \frac{e}{r}, \quad I = \frac{E}{R} = \frac{e}{r} = i'.$$

Mr. Blake will notice that it was necessary to make no assumptions in regard to the directions of the currents, but that they are evident from the equations. The secret of Mr. Blake's error is in the words: "If we apply an e.m.f. of 1½ volts to these terminals, opposed in direction to the direction of the current."

GEO. H. GIBSON.

## Transformers For Series Lighting.

*To the Editor of American Electrician:*

Sir—The kind of transformer shown in the accompanying diagram does away with two or more separate circuits, as in the usual constant-potential service, which in a great many cases is a saving through reducing complication and trouble to a minimum, and avoiding having to run part of the lights on separate transformers. I am operating street lights on this plan from a 350-volt and 700-volt two-phase machine till midnight; then, by the use of a double-throw switch and a terminal-change switch, I connect to a 1000-volt alternator, which alternator is loaded till this time, and then shut the two-phase motor circuit down until the usual starting-up time in the morning.

As will be seen in the diagram, one end of the primary winding goes directly to the middle binding-post of a double-throw switch, marked 1; terminal two goes to a two-phase machine, and has a ratio of 2.45 to 1, the voltage of the two outside wires being 612 volts primary, and 1500 secondary.

The ratio of this full primary winding to the secondary is 1.5 to 1, which corresponds to terminal three, and by changing switch S, from two to three, and changing the double-throw switch to the binding-posts leading to the 1000-volt machine, the street lights are placed on the high-tension machine and the voltage of secondary not changed.

SPECIAL TRANSFORMER FOR SERIES LIGHTING.

Terminals one and two on the secondary of one, two and three, are for a voltmeter connection, which throws the voltmeter in shunt to the current passing through the winding, and the loop can be thrown out for any voltage desired.

Another plan for indicating the condition of street lights is to have, for incandescent lighting, a lamp wired on the switchboard in shunt to a switch but in series with the street lights, or an ammeter in case of arc lighting.

I have been operating street lights on this plan for about a year, and find it perfectly satisfactory. V. E. HUNTER.

Auburn, N. Y.

## Constant Speed Regulation.

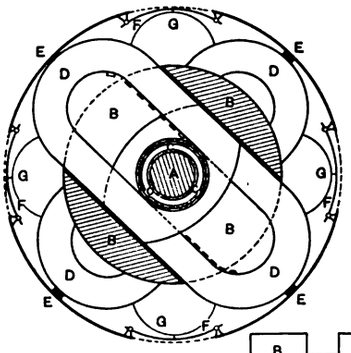
*To the Editor of American Electrician:*

Having read in a recent number of the AMERICAN ELECTRICIAN an article concerning the regulation of the voltage of dynamos under sudden variations of load, I have tried to solve the problem, and send to you the result of my effort. The device is based upon the principle that the voltage of a dynamo responds almost instantly to every variation of speed.

It consists of a pulley so arranged that if when carrying a normal load, the load be suddenly increased, the increased tension of the belt will cause the circumference of the pulley to be promptly decreased, which will result in a prompt increase of the speed of the armature, thereby maintaining the proper voltage. Under such conditions the dynamo must be driven by a heavy link belt, as the conditions it will have to meet will be severe. The engine should be powerful enough to carry, and its automatic regulating device should enable it to meet, the increased load at a constant speed.

Fig. 1 gives an end view of the pulley. A is the shaft upon which are keyed the two hub rims, B. Between the hub rims, and turning easily upon the shaft, is the regulating gear, C, upon the teeth of which work the regulating arms, D, which support the segments of the pulley rim.

FIG. 1.



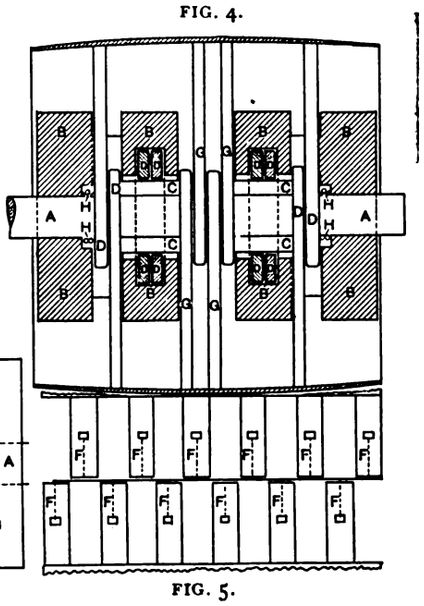


FIG. 4.

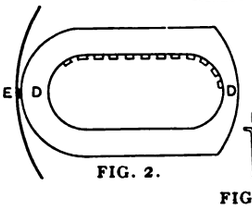

FIG. 2.

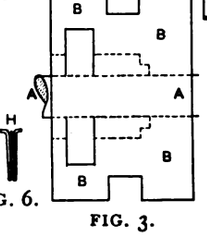

FIG. 6.

FIG. 3.

FIG. 5.

FIGS. 1 TO 6.—DETAILS OF PULLEY.

The ends of these segments are slotted as shown in Fig. 5, and are kept at their proper curvature by the devices, F, which

Digitized by Google

are controlled by the secondary pair of regulating arms, G, which work upon and are controlled by the regulating gear, C. This regulating gear is fastened at each end into the hub rims, B, by two coil springs, H. Under normal load they will be set to hold the pulley at its greatest tension. An accurate test of the springs can be made by varying the tension of the belt, until at normal load the springs just begin to yield.

In this condition the slightest increase of load would increase the tension of the belt, forcing the arms D together, rotating the gear C against the springs H, and decrease the diameter of the pulley, which would increase the speed to meet the conditions and keep the voltage where it ought to be. A decrease of load would result in the springs restoring the pulley to its normal state.

Portland Head, Me.

## Broken Circuit Indicator.

*To the Editor of American Electrician:*

The accompanying sketch represents a very simple arrangement for indicating when a circuit-breaker is thrown, or when a fuse blows. I have the solenoid mounted on a switchboard and connected to the bus-bars with two 110-volt lamps in series, as shown.

With current flowing around the solenoid,

BROKEN CIRCUIT INDICATOR.

the plunger, A, is held up, but if the circuit is opened in any way it drops down and comes in contact with the points, BB, and rings the bell.

G. W. HARROLD.

Philadelphia, Pa.

## Boiler Feeding Apparatus.

*To the Editor of American Electrician:*

Sir—In a recent issue, Mr. Jas. F. Hobart calls for a discussion of boiler-feeding mechanisms. He enumerates, and to some extent comments upon, five—exhaust injectors, live-steam injectors, return traps, steam-driven pumps and belt-driven pumps.

The exhaust injector, up to 70 lbs. working pressure, is a satisfactory and ideally economical apparatus. Above 70 lbs. it cannot be relied on. Below this, its only fault is a little trickiness about starting, especially in water carrying scale-forming material. Its low working pressure, however, puts it out of the question for any modern plant.

The live-steam injector consumes more steam to do its work than any other boiler-feed mechanism. In relation to this and to the return trap, Mr. Hobart says that practically all the heat in the steam used is returned to the boiler. This is, in one sense, true, but it is also true that if the plant is otherwise properly designed this heat is entirely wasted. A proper equipment of exhaust steam heaters will raise feed water from 60° to 200° F. before entering the boiler. This means that 140 heat units per pound of water are supplied to the boiler from a source exterior to itself and the fire. Now, with the injector and return trap the heat units in the steam consumed are absorbed by the water, and so returned to the boiler, the water being heated in passing through the apparatus. But if this water is sent through the same set of heaters as before, its temperature on reaching the boiler will be no higher than if it had entered the heaters at 60°. Since the feed water entering the boiler is no hotter by reason of the steam used in the injector, the boiler is the loser by the whole of this steam.

The return trap is nothing more or less than a steam pump, reduced to its simplest form. It employs directly for putting the water into the boiler, a volume of steam equal to that of the water. As compared to the steam pump, it removes the waste due to clearance, and piston and valve leakage on both ends; it introduces waste due to the contact of the steam and water. It cannot be true that the consumption of steam is as little as twice the volume of water.

After the trap is discharged, the external radiation must, with 150 lbs. working pressure and 15 lbs. pressure in the water main, condense 4/5 volume of steam before any water can enter. This same rate of radiation is maintained while the trap is filling and emptying. Also, while emptying, the steam at full boiler pressure is in contact with the water, and condensation from this cause must be rapid.

Were data at hand showing the rise in temperature of the water while passing the trap, the steam consumption could be immediately determined. Such data I have been unable to procure. I am, however, informed by the sellers of one make of these traps that with hot water and 70 lbs. boiler pressure the rise of temperature is about 15° F. This would indicate a consumption under these conditions of about five volumes of steam for each volume of water. This consumption will certainly not decrease with rise of pressure, and at 150 lbs. would make 1.8 lbs. of steam per cubic foot of water fed, or about 165 lbs. of steam per horse-power hour.

The steam-driven duplex pump has in its favor convenience, readiness of adjustment to varying load, and ability to stand abuse without absolute breakdown. Its drawbacks are, lack of economy and continual attention required to keep it up to maximum efficiency. The lack of economy is, of course, well recognized, but hardly goes as far as Mr. Hobart asserts. Of course, "coal" was printed by mistake for "water," but the pumps that consume from 250 to 400 lbs. of water per horse-power hour need, I should think, to have the repairs begin at the man in charge of the boiler room.

The belt-driven pump, for steady loads, undoubtedly stands at the head. Under any ordinary circumstances it should consume not more than 60 lbs. of water per horse-power hour. For variable loads it is troublesome or comparatively wasteful, according to the way it is regulated. It can be used only while the engine is running, and therefore must be an additional machine, not to be reckoned on as a relay.

The different mechanisms seem to rate as follows, in order of economy: Exhaust injector, belt pump, return trap, steam pump, and steam injector.

I think the reason why the two most wasteful of these are in most general use is, that either can be used whenever steam is up; either, if no attention be paid to economy, will keep running with very little attention, and the steam pump can be regulated in a moment to discharge any desired amount of water. It is simply another case where, in the mind of the man who has to take the trouble, simplicity and convenience outweigh economy.

JOHN WILSON BROWN, JR.

Philadelphia, Pa.

*To the Editor of American Electrician:*

Sir—The letter of Mr. Brown is to the point. I wish to ask Mr. Brown, however, if he has ever tested injectors by forcing a given quantity of water from one vessel to another, weighing the liquid accurately before and after, and noting the temperature in both tanks, the requisite pressure being gained by forcing through a safety valve in the delivery pipe, to maintain the head to be worked against?

After weighing and taking temperature, the "lost units," *i. e.*, those not accounted for by the increase of temperature of the water, will denote the actual work done in forcing the given quantity of water, while the increase in weight shows exactly the amount of steam condensed. It is a pretty experiment, and opens one's eyes considerably to the great cost of feeding boilers by the injector.

Regarding the cost—400 lbs. of water per horse-power hour—I quote the published catalogue of a well-known pump-making concern. The wastefulness of duplex pumps is stated from another and similar publication, coupled with my own observation.

It would, however, be cheaper for a concern to buy power from the nearest electric company, and run a special pump and motor for feeding boilers, than to use either a duplex pump or an injector. This would effectually lay that bugaboo always

Digitized by Google

brought up against the belt-driven pump, viz.: "That it can only work when the engine is running."

A large lighting company in Brooklyn recently put in electrically driven pumps for all purposes throughout their new station—feeding boilers, air circulating pumps, and for washing out, etc. They are so connected that should the entire station be shut down, storage batteries would drive the pumps during the limited time of idleness.

JAMES F. HOBART.

Brooklyn, N. Y.

## Electrical Catechism

*256. What is the principle of the "magnetic vane" instruments?*

The magnetic vane instruments have two soft iron cores, one of which is fixed and repels the other one, which is pivoted and free to move. The two iron pieces repel each other, since they are magnetized in the same direction; also since the repelling force is greatest when the two are closest together, the force moving the needle or pointer is considerable even with small currents, and the instrument may be calibrated from a point near the zero of the scale.

*257. Is an instrument liable to injury if not connected properly into the circuit?*

Usually instruments are not injured if the polarity is reversed so that the current flows in the wrong direction. If the instrument is intended for alternating currents, of course its readings are independent of the direction of the current. If the instrument depends upon the action of a permanent magnet, the pointer simply moves in the wrong direction and goes against a stop.

*258. How can one be sure that the current will not be too much for the instrument?*

In the first place he must exercise some judgment, as a knowledge of what load is on the circuit will ordinarily enable one to estimate the probable current or voltage to be expected. He must be careful that he does not try to use an ammeter for a voltmeter or a voltmeter for an ammeter, unless he knows exactly what he is doing. If the voltmeter has two scales, he should first try the circuit with the instrument connected for use with the higher scale to learn if he can safely use the lower scale.

*259. When a voltmeter has two scales, how can one tell which terminals to use to get the right scale?*

Voltmeters with two scales usually have three terminals, one on one side of the instrument and two on the other side. The single terminal is used for both scales. One of the two terminals on the other side is usually smaller than the other, and one can easily remember that the smaller terminal goes with the smaller scale.

*260. How can one tell whether an instrument is an ammeter or a voltmeter?*

Almost all instruments are marked. If the scale is marked to read amperes, or if the name on the plate states that the instrument is an ammeter, an amperemeter or a current indicator, one may be sure it is intended for measuring current and not volts. So, if the scale is marked to read volts, or if the name plate states that it is a voltmeter, pressure indicator or potential indicator, it is for measuring voltage and not current. If the instrument has no marks of identification, the size of the terminals or binding posts will be an indication, ammeters usually having comparatively large terminals, while voltmeters have small ones. One can generally get some idea of the size of the conductors in the coil either by looking through the glass front or by taking off the cover. If the wire is about the size of a coarse thread or smaller, the instrument is a voltmeter or a milli-amperemeter. If the wire is larger, the instrument is an ammeter. If the instrument has two large and two small terminals, it is a wattmeter, or possibly a combined ammeter and voltmeter.

*261. What would be the effect of sending too much current through an instrument?*

The pointer would be thrown violently against the upper stop, with so much force that it would probably become permanently bent. If the excessive current is allowed to continue through the instrument for any length of time, it is likely to heat the wire to a dangerous temperature and destroy the insulation or perhaps melt the wires. The same effects are also produced if a voltmeter is connected across a circuit of too high voltage, since that would send too much current through the coils. In the case of a static voltmeter in which no current flows, too high voltage is liable to jump across and short-circuit the instrument and the line.

*262. Is it better to close the circuit at an ammeter or at some other point in the circuit?*

The circuit should not be made or broken at the ammeter terminals, since it is not easy to close the circuit without making an uncertain contact, which causes arcing and burning the terminal. Also, it is not possible to open a circuit at the ammeter without drawing an arc which burns and disfigures the terminal. It is a good plan to have the ammeter near a switch, that one may see what current flows at the instant the circuit is closed, so that if anything is wrong he can open the circuit before considerable damage is done.

*263. Is the reliability of an instrument affected if the terminals are burned and blistered?*

The instrument itself might not be injured at the time, but a disfigured instrument is almost sure to be looked upon as being an old one and unreliable, hence it is more liable to abuse. The man using a disfigured instrument is also sure to think that, as the instrument is a poor one, it makes little difference whether he does accurate work, since he cannot depend upon the instrument anyhow. Thus the practice of using the ammeter as a switch for closing and opening the circuit is very apt to lead to poor work from those thus using it.

*264. In what way is an instrument liable to be abused?*

By careless use as a switch, by rough handling, and by its use with excessive currents or voltages.

*265. How does rough handling injure an instrument?*

The best voltmeters and ammeters are made much like a watch, with small pivots which rotate on jewel bearings. Rough handling is apt to crack the jewels or to dull the ends of the pivots, or to spring the parts. Rough handling is also liable to weaken the permanent magnet, if the instrument has one, which will make the instrument read too low or too high.

*266. What kind of instruments read too high if the permanent magnet is weakened?*

Instruments such as those formerly made by the T.-H. Company, in which the pointer is attached to an armature of soft iron that is held toward the zero point by a stationary permanent magnet and is deflected by a coil, whose magnetizing effect is at right angles to that of the magnet. When the magnet becomes weak, the relative pull of a given current through the coil becomes greater, and the pointer is then deflected too far, thus making the instrument read too high.

*267. What kind of instruments read too low if the permanent magnet is weakened?*

Instruments such as the Weston or Whitney, in which the coil rotates in the field of the permanent magnet. In such instruments the pull of the coil is opposed by a pair of springs. The pull of the coil is proportional to the product of the strength of the magnet and the ampere-turns in the coil. If then the magnet becomes weaker, the pull between the coil and the magnet becomes weaker for a given current, and since the strength of the opposing springs has not been affected, the instrument reads too low.

*268. Is an instrument liable to give incorrect readings even if it is in good order?*

Yes, to some extent. Most instruments are more or less affected by outside magnetic influences. Many instruments give correct readings only when approximately level or when vertical, according to the style of instrument.

*269. How does leveling affect instruments?*

Some instruments, such as the Siemens electro-dynamometer (see No. 224, "American Electrician," July, 1898, page 345) must be carefully leveled so that the moving coil shall hang exactly in the same position with reference to the stationary coil, for the magnetic field of each coil varies in different positions, as it is necessary for the two to occupy exactly the same relative positions as when the instrument was calibrated. In many instruments of a more portable form the moving parts are balanced for only one position, either for horizontal or for vertical use. If the instrument is placed in any other position, the pointer is liable to stop at some other place than at the zero point, and being wrong at the starting point, every other indication of the pointer is liable to be incorrect.

# Queries and Answers

**How many dry cells will be required to heat 1½ ins. of No. 32 platinum wire to a white heat for an instant?** C. E. F.

Try one dry cell, or two or more in parallel.

**Why is a booster connected in the positive lead of a dynamo charging a storage battery?** P. M.

It is entirely immaterial in which lead a booster is connected.

**I am desirous of constructing a Wheatstone bridge of the dial or Elliot pattern, but using switch levers instead of plugs. Would such a bridge be reliable?** H. H.

No, on account of contact resistance, which would not be constant with levers.

**What is the voltage and life of a Clark cell?** H. N. K.

1.435 volts. If properly used, and no appreciable current is drawn, the cell should last for years.

**What will be the effect on a transformer built to operate under 16,000 alternations per minute, if used on a circuit of 7200 alternations?** J. R. C.

It will overheat, owing to the larger current in primary, due to the reduced choking effect.

**How is the discharging current of a storage cell determined?** R. C.

Obtain the area of both sides of the positive plates, and allow from 8 to 9 amps. per square foot.

**Is there a mechanism for attachment to a dynamo in order to get its characteristic curve?** R. B. W.

No. All that is necessary for this purpose are simultaneous readings of a volt and an ampere meter.

**If I put rings on a direct-current motor, start it up with direct current and then switch on alternating current, will it continue to run?** J. J.

No, unless the direct-current speed is the speed of synchronism—that is, the alternations divided by the number of motor poles.

**What should be the resistance of the primary and secondary of an induction coil, to be used in lighting 3-c.p. lamps from constant current cells?** J. E. P.

As the loss in such an induction coil will be great, and as the voltage of such lamps is low, it will be far cheaper to buy more cells, and work direct from the battery.

**Are buildings more apt to be struck by lightning if telephone and telegraph wires are attached thereto?** J. J. P.

Theoretically an argument can be advanced either way. Practically, we have never seen any case recorded where a building having such wires was struck by lightning.

**I have a choke coil which "chokes" harder with the core out than when it is in. What is the reason?** C. A. K.

The fact mentioned is very peculiar, and might be due, if the core is solid and of large section, to eddy currents setting up lines that largely neutralize those tending to act on the coils.

**How much current from a 110-volt circuit will be required to heat a fair-sized room in ordinary winter weather?** L. A. V.

Anywhere from 10 to 40 amps. The test may be made with a bank of incandescent lamps as a heater, since 97 per cent, or practically all, the current supplied to such lamps is transformed into heat.

**Will a Shallenberger ampere-meter register correctly in a 2400-volt primary circuit?** H. C. P.

Yes, but if the circuit contains transformers the product of the volts and amperes will be the apparent, and not true, watts; to obtain the latter, multiply by the power factor or cosine of the angle lag, which must be determined.

**What are front and back pitch in armature winding?** W. W. B.

The front pitch is the angular distance, expressed in coils or slots, between the starting end of a given coil and the returning end of the connected coil; the back pitch is the angular distance, in similar units, between the two sides of a given coil.

**How much secondary and primary wire, and what diameter and length of core, will be required by one-inch induction coil for a 100-volt circuit?** C. M. H.

Two pounds of No. 36 wire for the secondary, and for the primary a single turn of No. 18 wi e, wound on a ¾-in. core 9 ins. long. Adjust the current by placing in series with the primary two or more lamps in parallel; the limit of current will be indicated by the heating of the primary.

**What size battery would be required for 16 16-c.p. house lights?** J. J. M.

Assuming that half of the lamps are burned on an average of two hours per night, the consumption is, for 55-watt lamps, 880 watt-hours. At fifty volts, this will correspond to 17.6 amp.-hours, or 70.4 a.-h. in four days; therefore, twenty-five 70-amp. hour cells will be needed if recharged every four days.

**1. How much current is consumed by a 16, 32 or 50-c.p. lamp on a 100-volt corcuit. 2. How much current is used by a series of twenty 32-c.p. 50-volt lamps in a 1000-volt circuit?** J. O.

1. The current is found by dividing the watt rating by the voltage. If the rating of a 16-c.p., 100-volt lamp is 50 watts, it takes ½ ampere; a 32 and 50-c.p. lamp of the same efficiency will take 1 ampere and 1.56 amperes, respectively. 2. Precisely the same as one of the lamps when connected in parallel.

**What advantage, if any, has a frequency of 60 over that of 133 for operating arc or incandescent lamps and motors?**

The higher the frequency, the higher the inductive line drop. Arc lamps can be constructed to burn equally well at both frequencies. High frequency are cheaper than low-frequency transformers. Low frequencies are most suitable for motors, on account of lower speed involved, and less so-called idle line current.

**How is aluminum tempered?** A. R.

Aluminum cannot be sensibly increased in hardness by the addition of any substance in small quantity. Casting will give it a hard surface, as will also rolling, but in no case has it been made harder throughout than very soft brass. A method of hardening aluminum without greatly increasing its specific gravity would prove a profitable invention.

**What is the resistance of a plate of mica 1-64 in. thick and 1 sq. ft. in area?** G. T. H.

Assuming the resistivity of mica (the resistance of 1 square centimeter 1 centimeter thick) to be 84 meg-megohms, the resistance of the plate named will be less in the ratio of 1 sq. ft. to 1 sq. cm., and of 1 cm. to 1/64 in., or 22,300; dividing by this gives 3767 megohms. It is the disruptive or dielectric, strength of mica that applies when used commercially; it is practically a non-conductor, as will be recognized from the figure calculated.

**How can I test the setting of the valves of an automatic engine without using an indicator?** L. A. S.

Place a pencil somewhere on the governor mechanism, and when the engine is running with the desired load, hold against this pencil a board, clamped securely to some solid foundation. The pencil will describe a mark upon the board. The engine should then be shut down, and the governor blocked out until the pencil reaches this mark once more. The cover of the valve chest may then be taken off, the engine turned over by hand, and the relative positions of the various events of the stroke determined.

**How can the rotary field be simply illustrated?** A. V. D. N.

Against two opposite sides of a square glass jar place zinc plates; fill the jar with blue vitriol solution, in which rotate three zinc rods, secured to a disk at equal intervals from each other; on the axis of the disk have three collector rings, to which connect the rods. If the zinc plates are put in circuit with a battery, and the disk revolved, three-phase currents may be taken from the rings. If these currents are led to three equidistant points of a closed winding on an annular ring, a rotary magnetic field may be obtained of a frequency corresponding to the rate of rotation of the disk.

**What is the e.m.f. of a nickel-iron couple?** G. T. L.

Between the temperatures of 480 and 590 degs. Fahr. the thermo-electric power of nickel is much higher than at lower or higher temperatures. The e.m.f. of a nickel-iron couple within this range is about .1 millivolt. At a low temperature the couple is .03 millivolt, or there is available .07 millivolt per degree Fahr. Assuming the range to be between 550 and 50 degs., a nickel-iron couple will give .035 volt, or one hundred couples will give under the conditions named 3.5 volts, being thus almost equal to a bismuth-antimony couple.

**What are the comparative insulating properties of glass, mica, gutta-percha, shellac, ebonite and paraffine?** G. T. H.

The resistivity of insulators varies greatly with temperature, duration of electrification, purity and physical state, and the condition of surface also greatly affects their insulating property. Glass, for example, has a resistivity over 70,000 times greater at 2 degs. F. than at 145 degs. F., and different experimenters give figures for the resistivity of glass, which vary from .7 meg-megohms for common glass at 140 degs. F., to 10,200 meg-megohms for flint glass at 140 degs. F. The following comparative numbers (from Everett) are therefore only approximate: Flint glass, 102; mica, 8.4; gutta-percha, 45; shellac, 900; ebonite, 2800; paraffine, 3400.

## STORAGE BATTERY, AUXILIARY AND OTHER IMPROVEMENTS IN THE CENTRAL STATION OF THE WILMINGTON CITY ELECTRIC LIGHT COMPANY, WILMINGTON, DEL.

The Wilmington (Del.) Electric Light Company has recently installed some interesting additions to its plant, of which a traveling staff correspondent sends the description which follows:

### STORAGE BATTERY.

In connection with its power plant, a storage battery has been installed of a size sufficient to carry half of the load of the station. The battery is of the Willard type, made by Sipe & Sigler, of Cleveland, O., and consists of 144 cells, each 22 ins. x 40 ins. x 34½ ins. Each of these cells has an ultimate capacity of 3750 amp. hours, but at present contains but 19 plates each, making a capacity of 2000 amp. hours.

The containing tanks are made from hard wood 1¾ ins. in thickness, and are treated outside and inside to two coats of insulating compound, after which they are lined with four-pound lead. Each cell complete weighs something more than a ton. The 144 cells complete contain something more than 1000 carboys of electrolyte.

The elements at present consist of 19 plates each, each plate 15½ ins. x 24 ins. x ⅜ in. The positive and negative plates are made in the same manner. A sheet of pure rolled lead is used, from which thin leaves are raised at an angle so that a cross section of the plate has a herring-bone appearance. By this method of construction, each plate is given about 6000 sq. ins. of surface contact between the active material and the conducting support. The active material is created by an advanced electrochemical process. No paste is used and no mechanical application of active material in any manner.

The chief merit claimed for this construction of the plate is in its enormous surface, which enables it to absorb and give forth an enormous current at high efficiency. The shape of the leaves is such as to hold the active material in position, and to admit of the expansion due to the growth of active material without any liability to buckle, bend or distort the plate.

The plates are separated from each other by means of glass tubes suspended by hard rubber insulating supports, which rest upon plates of like polarity only, thus avoiding leakage. The cells are insulated from one another and from the ground by means of large and thoroughly vitified and triple-petticoat glazed porcelain insulators, and are connected in series by means of heavy lead bus bars, to which the terminals of the plates are lead-burned by means of an oxy-hydrogen flame.

The station has recently been enlarged by an L-shaped brick addition, a portion of which is divided into two stories. In the narrowest portion of the L the cells are arranged on each side, with an aisle between, and in the other portion there are four rows of cells. An interesting feature of the arrangement is that all the copper and switch connections are located on the second floor, immediately over a portion of the battery, and individual lead bars lead from the terminals of each cell up through this floor, where the connections are made, and into the same room, from the individual terminals of the other portion of the battery a heavy cable delivers the current, so that all the copper is entirely protected from any of the deleterious fumes escaping from the battery.

### TRANSFORMING A SINGLE INTO A COMPOUND ENGINE.

The station changes include the making over of the single high-speed engines into a compound engine, and coupling the two cylinders direct to a 175-kw. generator of the General Electric type. The cylinders of the original engines were 14 ins. x 13 ins. On one of the engines this is replaced by a low-pressure cylinder, 21 ins. x 13 ins., and the two are placed side by side and coupled, as before noted, to the armature shaft of the generator, an additional framework being placed between the pillow blocks, which helps to carry the weight of the shaft, which is thus given four bearings. The valve gear remains about as before, and the governing is done on the high pressure cylinder. This is not an experiment in this station, as a pair of engines were made over in this manner some years ago, and, having given good satisfaction, the other four engines are being thus compounded.

The output of this station is reinforced by current generated by water power at a woolen mill, two miles out of the city. This current is generated by a 50-kw. machine, and delivered to a double Stanley rotary transformer in the central station at 2500 volts, and is transformed on one side to an alternating current of 1200 volts for the Edison three-wire system and into a direct current of 115 volts. The transformer is operated by two old type Edison generators, placed on each side of the transformer, with the armature shafts coupled direct to that of the transformer.

### BOILER EQUIPMENT.

The original boiler equipment has been replaced by three vertical water tube boilers of the Moran-Climax type. Two of these are 350 h.p. each; the third, quite recently installed, is of 600 h.p. The superintendent of the station, Mr. C. R. Van Trump, reports a decided increase in orders for current, both for lighting and power, greater than that for a number of years past.

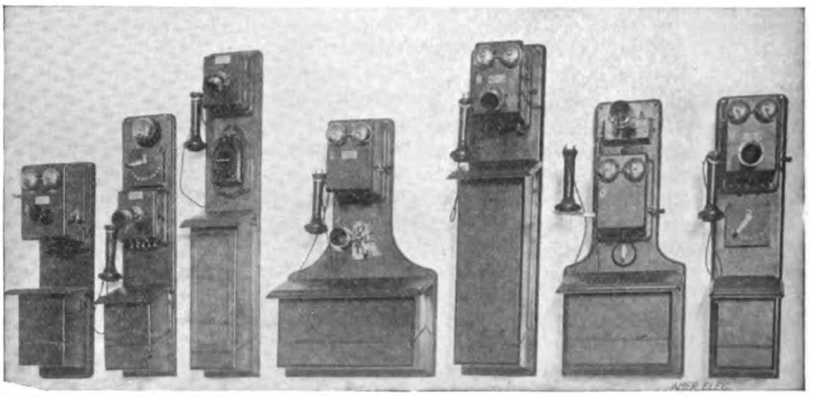
While making the rounds of the station a novel use for old oil barrels was noted. These were being used for shipping copper scrap. The old wire, after the insulation has been burned off, was coiled in bunches and then packed into the barrels by means of a heavy iron bar, which was used as a pounder, a very considerable quantity being thus packed in a barrel.

## THE MANUFACTURE OF TELEPHONES AND CALL MESSENGER BOXES.

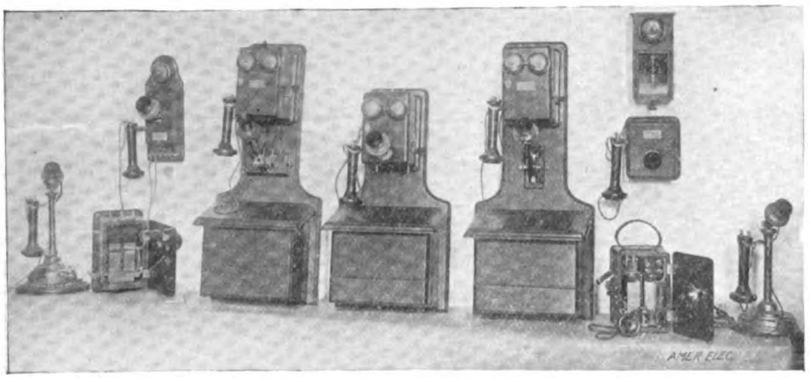
### THE VIADUCT MANUFACTURING COMPANY.

For the benefit of the novice in telephone instruments it may be stated that the principal parts of an outfit consist of a call bell, or magneto bell, a transmitter, receiver, one or two cells of battery, and a containing case or cabinet, with the necessary connections and switches. For desk use the case is omitted, while the call bell may be located at a convenient place about the desk, and the battery at any convenient place. The instruments which it is the province of this article to describe are manufactured in great numbers by the Viaduct Manufacturing Company, of Baltimore.

The instruments are made in great varieties, as shown by the types illustrated in the accompanying illustrations. Some of the special characteristics are found in the construction of the magneto bells—really small generators—which are constructed with four permanent magnets made from steel bars, 1¾ x ¼ in., and bent in horseshoe shape, the limbs being about 5 ins. in length. These are arranged in pairs, one of each pair being placed astride the other, and the pairs placed side by side and connected by horizontal pole pieces between which the armature revolves. The armature is made with a cast core of soft iron, so shaped as to receive two coils of magnetizing wire. The commutator is placed on the end of the shaft outside the bearing, and is connected by a lead through the hollow shaft, while the other conductor is attached to the case. The gear wheels are toothed, four to one, so that in ordinary ringing the armature makes about 800 revolutions per minute. The bars employed for the horseshoe magnets are permanently magnetized after being bent by being drawn by hand four or five times across the core of a strong electromagnet, the terminals of which are grooved and adjustable, so that magnets of different sizes may be treated from the same pole. The electromagnet is energized by means of a current from a 50-volt generator.



In the transmitters hard rubber insulation is employed in place of fibre formerly used, and coarser granules of carbon used in the chamber for receiving the diaphragm vibrations than formerly.



Among the new designs is a nickel-plated desk equipment in which the call bell is not cut out if the operator should fail to hang up the receiver. Another instrument is especially designed for use in warehouses, building exchanges, or in street railway offices, and which operate independent of any telephone exchange. These are made in two patterns, one a desk instrument, with a switch located in the base, the other a wall instrument, with a switch on the face of the case, by means of which calls can be made to the different rooms. In this instrument the calls may be received with the switch on any point, but in order to talk with the new call it is necessary to place the switch upon the home stud. The use of this instrument avoids the necessity of a switchboard and attend-

Digitized by Google

ant. A good many instruments are now made with an arm rest on which the operator places the elbow when talking, and by means of which the contacts are made, so that the contact is sure to be broken even should the operator leave the box and fail to hang up the receiver.

A profitable outfit is also made designed for use by street car conductors or others who are required to report to the starter or station from any point on the road. For using this instrument when no provision has been made contact is made by throwing a wire over the line wire, and making a ground connection, but where metallic circuit is employed contact is made with both limbs of the service. For street railway circuits, however, it is usually attached, cut-outs providing at intervals on the trolley poles, to which the plugs of the instrument can be attached. This outfit consists of a generator ringer, a receiver of hard rubber, a transmitter, and two-cell dry battery; this is all enclosed in a case and provided with a strap for carrying, and the outfit weighs only about nine pounds.

FIFTEEN TYPES OF TELEPHONES.

The output of the Viaduct works is not by any means confined to telephones, but includes different types of district telegraph signal or call boxes, of which thirty-five different patterns are made, some known as "Answer Back" boxes, which give a return acknowledgment signal when a call is received.

The output of the works in call boxes is from 8000 to 10,000 a year, and the capacity of the works for making telephones in addition to the call boxes is about 200 per day, complete, including the bells, transmitters, receivers and the cases. In addition to the above named products from the works they supply telegraph relays, lightning arresters and switchboards for central stations, and as a specialty an instrument known as a police fire alarm and trolley signal outfit designed for use on trolley lines or in outlying districts. This instrument is enclosed in an iron shell or case, which can be readily attached to poles, and in connection with those in use on trolley lines is a large vibrating gong, which may be sounded by a starter to signal the conductor of a passing car should he wish to communicate with him while on his trip.

The works of the Viaduct Company are located near the Relay Station, on the Baltimore & Ohio Railroad, nine miles from Baltimore, and near the end of a high arch stone viaduct on which the tracks of the railroad cross the river, and from which the company takes its name. The tract owned by the company embraces twenty-five acres of meadow and wild land, and the works include twelve buildings, some of them being residences for the employees. The average number of hands employed is 125, and some of them, as above noted, have been in the company's employ for many years.

The machinery of the works is driven by water power, four vertical turbine wheels of the Leffel type being employed. The water is conducted to the wheels through a race which leads out from the river some distance above the viaduct. It has a fall of about seven feet, or sufficient for about 200 h.p. The power is transmitted to the machines of the different buildings by means of shafting and belts. The power building is 100 x 140 ft., a part of which is used as a storeroom for supplies, and includes the nickel-plating and burnishing department, while the generators for lighting and other current purposes are also in this building.

The principal machine shop is 208x40 ft., and provides for the iron and woodworking departments, as well as for the packing and shipping departments. There is a very full complement of iron working tools, consisting of lathes, screw machines, radial and gang drills and punches. Some of the tools are equipped with an electric device which automatically rings a bell when a piece of work is finished, so that one man is able to operate three or four machines. An exhaust system for removing the dust and shavings from the machines in the woodworking department is provided, and all through the works are minor labor-saving appliances and means to facilitate the handling of material. Oak, black walnut and mahogany are chiefly used for cases, and a drying kiln is provided in which all the material is thoroughly seasoned before being cut up for use. The varnishing department occupies a building 60 x 48 ft., where the polishing and hinging is done by hand work chiefly.

The main office and storeroom are located on Howard Street, in Baltimore, and here the president and manager, Mr. A. G. Davis, can usually be found. Mr. Davis has had long experience in electric lines, having learned telegraphy in 1849 under the instruction of his cousin, Samuel F. B. Morse, the pioneer in message transmission. In his career he has had charge of the construction of a number of telegraph lines, including the original equipment of the Grand Trunk Railway in Canada.

## CAHALL WATER TUBE BOILER FACTORY.

Steam users are quite familiar with the phrase "Cahall's sales department," but for the uninitiated it is explained that this is a department located at Pittsburgh, Pa., for the control and sale of the Cahall water tube boilers, which are manufactured by Aultman & Taylor, Mansfield, Ohio.

On a recent visit to the works at Mansfield, the writer was agreeably surprised to find that they were among the largest and best equipped boiler works to be found in the country. The output consists of horizontal and vertical boilers, the former in general appearance being like the type of boilers turned out by other well-known makers of water-tube boilers. The main building is of brick, with high walls and high monitor roof, and the tool equipment in every department is of a high order, including almost every labor-saving device to be found in works of this character. Large electric traveling cranes serve to shift and handle the largest boilers, while many of the larger tools are operated by independent electric motors.

Among the special tools were noted a plate planer 22 ft. in length, a hydraulic flanging press, pneumatic riveters and reamers, drills and chipping tools. Special

Digitized by Google

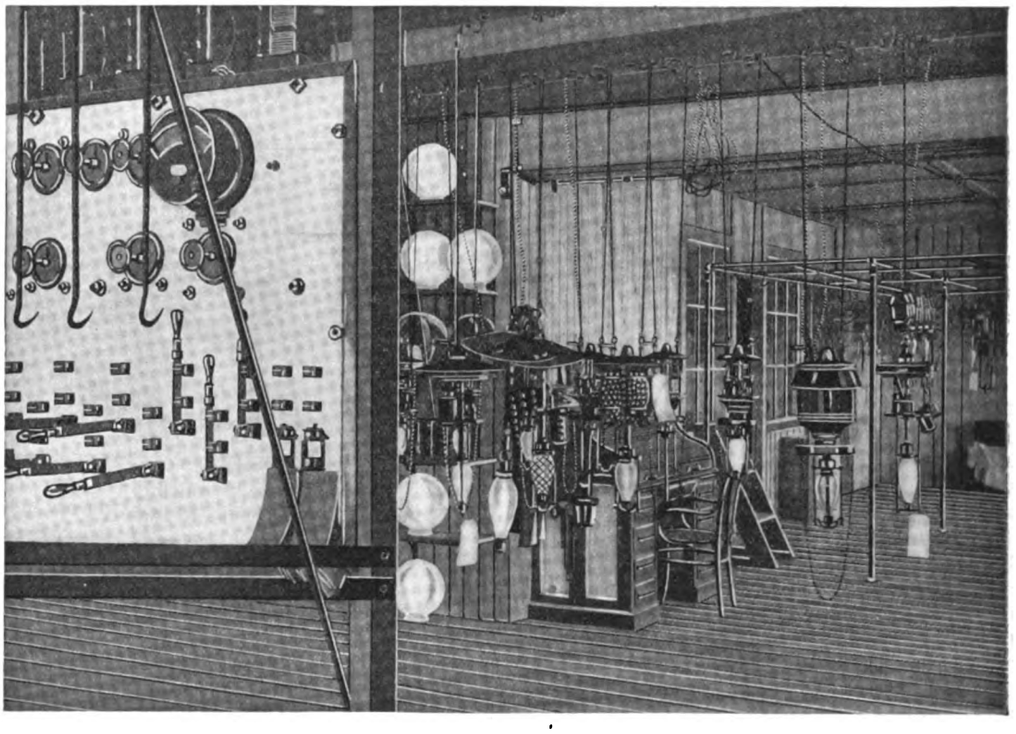
attention is given to the material used, the flue headers being made of cast-flowed steel. The testing department, in which every bank of flues is tested for leakage and strength, is very complete, and provided with trolley hoists, by means of which the groups of flues are readily handled and adjusted. The capacity of the works is almost unlimited, turning out the largest orders in from six weeks to two months.

The works have supplied one of the largest iron mills in Pittsburgh with boilers aggregating more than 30,000 h.p. The company also makes a specialty of designing and manufacturing boilers for street railway and electric lighting plants. Being within easy reach of coal and near the boiler-plate manufacturers, and with a reasonable market of skilled labor to draw on, the works are fortunate in their location, while their equipment, as has been noted, is such as to turn out work of the highest character in the most economical manner.

## AN ARC LAMP FACTORY TESTING ROOM

A casual glance at an arc lamp would give but a faint idea as to the amount and variety of work expended in its construction, or the extent of the plant required for its manufacture on a large scale. Neither is it well recognized that such a lamp embodies mechanism which, though simple, is required to keep the carbons in an adjustment that is micrometrical in order and most delicate in kind. Moreover, as a lamp when it leaves the factory must be ready to satisfy this requirement under the most adverse conditions, it will be seen that the testing department of an arc lamp factory is one of extreme importance.

Lack of space forbids giving in this number a description of the manufacturing plant of such a factory, and attention will, therefore be confined to the testing department. As a text, the factory, at Peabody, Mass., of the Standard Thermometer and Electric Company will be taken, which, notwithstanding the non-committal of the firm name in that respect, is one of the largest makers of arc lamps in the world. An idea of the extent of this plant may be gained when it is stated that the main building occupied is 50 x 60 ft. in ground area, and four stories and a basement in height. In addition, there is a two-story 20 ft. x 50 ft. annex.



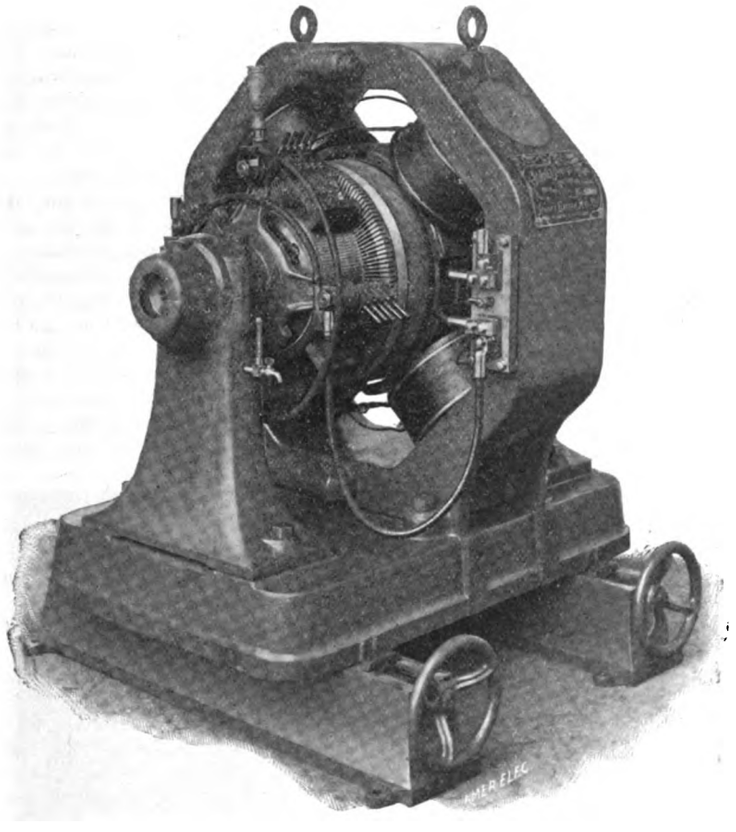
The arc lamp testing room, part of which is shown in the accompanying cut, is on the third floor. There are three separate switchboards in this room, one for alternating current, equipped with racks for testing open A.C. lamps, and with instruments for controlling the alternating dynamo in the basement. The second board, a corner of which is shown in the cut, carries the controllers for the multi-polar direct-current dynamo in the basement, used for lighting the shop and for testing the 110-volt lamps, either open or inclosed. For testing inclosed arc lamps there are ranges of drops, into which the lamps can be connected, and to which current can be run from either the A.C. board or the D.C. board, at will. This diversion of current, as well as the handling of the high-tension currents, is done by means of the third switchboard. This board is equipped with a complete set of throw-over switches, by which any of the lamps can be connected to the recording instruments or to the indicating voltmeters, ammeters or wattmeters at the will of the operator. The exact current consumption is thus determined and the necessary adjustments made very readily.

The company makes arc lamps, open and inclosed, for all sorts of currents—lamps for direct currents of 110 volts to 220 volts burning in multiple; for 220 volts to 550 volts burning in series-multiple; for constant current of 4 to 7 amps; for alternating current of frequencies of 7200 to 16,000 alternations per minute. All have to be tested, hence the need of the multiplied apparatus in the testing room. In addition to the current generated on the premises, wires from the town plant are led into the testing room, and a good many of the lamps are run on these circuits for continuous records and for testing. The currents being of 16,000 alternations on the one hand, and 6.8 amps. constant current on the other, the testing of lamps can be proceeded with at times when the rest of the factory is shut down, which in rush times is a great convenience.

The lamps are first tested until they run at the required current consumption without covers; they are then cased in, and run for several hours to develop any imperfections that would interfere with their good working after they leave the shop. The latest improvements in the construction of the lamps come from the developments of the past few years' experience of the users of the lamps. They meet all the weak points that have been shown to exist, which, as fast as discovered, have been studied and overcome. The constant trying of new devices suggested for doing this is another testing room job, and more or less new lamps are always burning there.

In the basement are located, in a room with glass slides, the dynamos furnishing current for testing. One is a 110-volt multi-polar machine for lighting the shops and lamp testing. Another is an alternating dynamo, rigged up for change of speed, in order to test out lamps of different frequencies. A third is a convertible 220-volt, or 550-volt machine, for testing direct-current lamps of these voltages, and the fourth is a series machine, for either 6.8 amps. or 10 amps., or anything between, used for testing and adjusting constant-current lamps. A feature worth notice is that the "spoolers" for winding the lamp solenoids are driven by individual motors from the 110-volt circuit, this method being adopted on account of the instantaneous speed control which it renders possible.

The principal personnel of the company and works consist of Mr. Roger Upton, president, an experienced man of affairs and an active official; Mr. Samuel C. Lord, secretary and treasurer; Mr. J. H. Hallberg, electrician and designer of the arc lamps manufactured at the works; Mr. M. L. Livingston, assistant manager and the traveling representative of the company, and Mr. Edgar Upton.



ARC LAMP TESTING ROOM.

# New Apparatus and Appliances

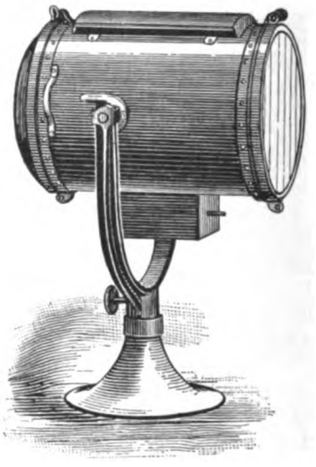
### FOUR-POLE JENNEY GENERATOR.

The accompanying illustration shows a new Jenney type of four-pole generator. As will be seen from the engraving, the armature is of the slotted core type, with a proportionately greater number of slots than is usually employed in the construction of armatures of this type, which results in extremely smooth running, and prevents heating of the magnet poles. The armature coils, or conductors, are wound in forms and thoroughly insulated before being placed on the core. The commutator is of generous proportions and insulated throughout with high-grade mica. The brushes used are of the improved Jenney sectional carbon type, and are reversible. In this form of brush, the carbon is rigidly bolted to the brass holder, insuring a positive connection at all times, resulting in much less heating than is usually experienced with carbon brushes.

JENNEY FOUR-POLE GENERATOR.

The field cores are made of the best quality of annealed wrought iron, and are forced by hydraulic pressure into the field frame. The pole shoes are of cast steel, and screwed over the ends of the field cores, after which the field is bored out. With this construction there are no "butt" joints in the magnetic paths. In all except the small machines the field frame is parted vertically, which enables either half of field to be slid out away from armature, making all coils easily accessible.

The bearings are both self-aligning and self-oiling, and all brasses are made of phosphor-bronze. The makers of these machines, the Jenney Electric Manufacturing Company, Indianapolis, Ind., claim a very low temperature rise in all parts when working continuously under full load.



---

### NEW ELECTRIC PROJECTOR AND SEARCH-LIGHT.

The accompanying illustration shows an improved type of electric projector and search-light, the latter only differing from the former in using in place of a mirror a silvered copper reflector and a set of condensing lenses, and being made in smaller sizes.

The apparatus consists of a cylinder of japanned iron or polished brass, in which is set the automatic focusing lamp, with carbons feeding horizontally and in such a position that the line of carbon is in the center of the cylinder, the lamp mechanism being in the box below. In the rear door of the cylinder is placed either a Mangin or parabolic mirror, as used in the English navy. Great care is exercised in the selection of these mirrors, which are ground and highly polished on both sides, and the silver is protected by a special backing of great heat-resisting power.

The lamp cases ride on a carriage in the box below the cylinder, and by means of a hand-wheel the entire lamp can be moved back or forward, so that the arc can be brought into the focus of the mirror, and thus the beams of light can be made convergent or divergent as occasion requires. The cylinder rests on its standard, and swings on its bearings, with a lock key to set the light in any desired direction. The contact between the base and standard allows the light to swing round the horizon without the twisting up of cables.

ELECTRIC PROJECTOR.

The apparatus for use on the roof of a pilot house, the light from which is entirely under control of the pilot, is of the same design as that above described, with the addition of a simple and efficient controlling device. This consists of a hollow tube running to the standard of the projector, through the roof of the pilot house; a wheel is attached to the end of this tube, through which runs a rod extending through the contacts, engaging with gears and sprocket carrying a chain over a second sprocket on the bearings of the cylinder. A lever handle at the end of the rod engages with a ratchet on the under side of the hand-wheel; thus, by turning the wheel, the light sweeps the horizon, and by moving the lever the gears are set in motion, and the light gets an up-and-down motion, from below the horizontal plane to the vertical.

These projectors are made by Chas. J. Bogue, 213 Center Street, New York, in all sizes, from the 8-in. diameter of mirror, taking 10 amps. and giving a beam effective at a distance of half a mile, up to the 32-in., with 100 amps., and throwing a light over six miles.

---

### PREPAYMENT ELECTRICITY METERS.

A new prepayment electricity meter is being placed on the English market that embodies several novel features, and which has recently been adopted for use at Norwich, England. The principle of the Long-Schattner meter, under which name it is known, is shown by reference to the accompanying diagram. A is a lever pivoted at X, having suspended to its far end a copper plate B, which is immersed in a solution of copper sulphate. The box D is also of

Digitized by Google

copper, and forms the negative plate, or cathode. C is a weight to balance the other side of the lever. K and E are cups to hold respectively the coins and the standard weights, the latter being placed in the cups to replace the coins removed by the collector. $F_1$ and $F_2$ are mercury cups, the former, or front one, being entirely filled with mercury, and the latter, or back one, half filled with mercury and having creosote oil on top. $H_1$ and $H_2$ are contact pieces, forming a bridge, across which

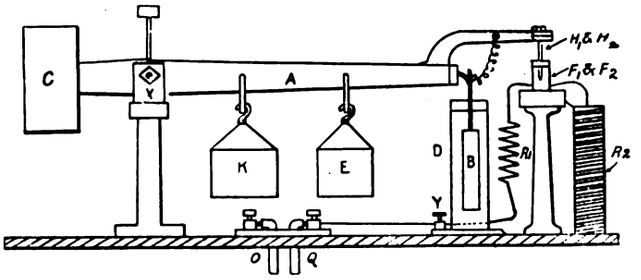


FIG. 1.—LONG & SCHATTNER METER.

the meter is shunted; and $R_3$ is a high resistance going from one mercury cup to the other.

The lever is overbalanced to start with, and when a coin is inserted it is brought down, thus establishing a short circuit across the mercury cups until an amount of electricity equivalent to the coin has been

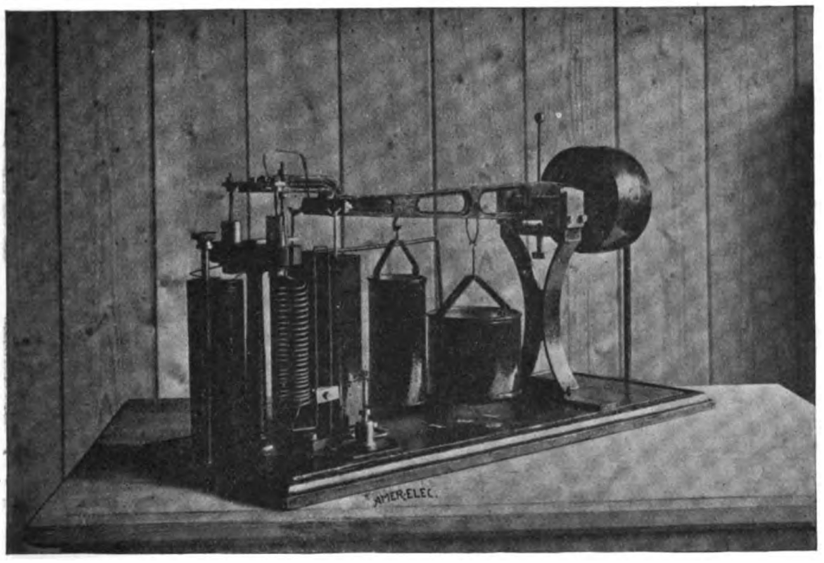

FIG. 2.—LONG & SCHATTNER METER.

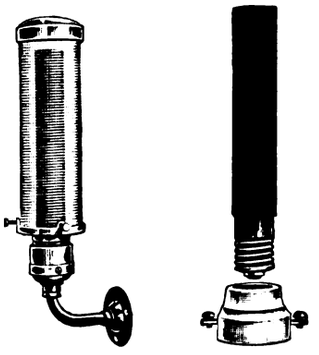
used; that is, until the cathode B has been sufficiently lightened by the meter current to cause the lever to again overbalance, when the contacts H and F are broken and the current is forced to pass through $R_3$. Thus the circuit is never actually broken, the lamps continuing to burn quite dimly, and thereby forcing the customer to insert another coin to get any appreciable light at all; he has also to pay for the light which burns dimly, as the current for it passes through the meter and is paid for by the next coin inserted.



The inventor states that the drop of pressure across a 5-ampere meter on a 110-volt circuit at full load is only .1 of a volt. The meter is very easily calibrated, it being only necessary to calibrate for one load. He states that the troubles which have been experienced with other voltmeter meters are avoided in this case by depositing away from the plate which measures the current used; by bringing the current in at the top of the plate and out at the bottom of the box, thereby getting a very uniform distribution of current through the liquid and a uniform deposit; and by using a very low current density, thus avoiding breakage. The manufacturers of the Long-Schattner meter are Schattner & Co., Timberhill, Norwich, England.

### BRACKET ELECTRIC HEATERS.

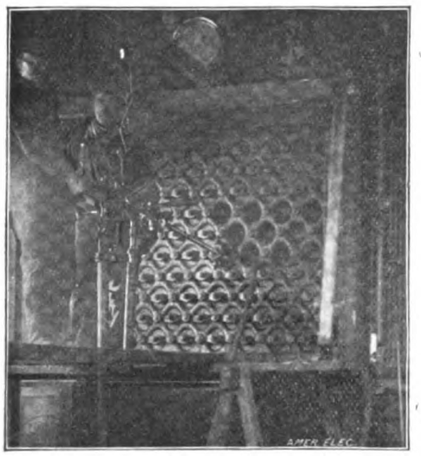
The bracket type of electric heater illustrated herewith is designed for either direct or alternating current, and can be controlled by thermostatic switches in groups, so as to keep a room at any desired temperature. They are recommended by the makers for use in heating large halls, theaters, conservatories, etc., and are specially adapted for warming show windows to keep the glass free from frost. The heaters are usually made for .9 amps. on 110-volt circuit, but are also constructed for any voltage and desired consumption of current. Their dimensions are 2½ ins. in diameter by 8 ins. in height. The manufacturers are the Girard Electric Company, Philadelphia, Pa.

### A DIFFICULT CASE OF TUBE CLEANING.

The accompanying illustration, Fig. 1, is a partial view of the boiler plant at the Union depot at Columbus, Ohio, and shows a device which, under the most trying and difficult conditions, proved successful in thoroughly cleaning the tubes. This case was a peculiarly interesting one, for the reason, primarily, that various cleaners were used entirely without success, and the contract was finally refused by several manufacturers of boiler-cleaning devices. The Chicago Boiler Cleaner Company, Monadnock Building, Chicago, finally undertook the work, and after a close study of the conditions, evolved a special cleaner for the purpose.

BRACKET ELECTRIC HEATER AND COILS.

The boilers to be cleaned were three in number and of the Edgemoor pattern, and each containing seventy-five tubes. In this plant the water for the boilers is first run through a purifier, which, being probably as good a one as there is manufactured, removed practically all matter from the water except the chemical properties, which were held in solution. A deposit consisting of a nearly pure flinty sulphate of lime, about one-quarter of an inch in thickness, and adhering tenaciously to the tubes, was the only deposit encountered. It will thus be seen that it was not the thickness or weight of the scale, but its extreme hardness and adherence to the tubes that made it so difficult to remove.



The Chicago Boiler Cleaner Company put into operation at this plant one of its cleaners modified to meet the special conditions. This consists of a steel barrel, 2⅞ ins. in diameter outside, and 2 7/16 ins. inside, with three slots cut in it 1 in. each in diameter and 2½ in. long, through which are set, in each slot, two boxes 1¼ ins. long, being admitted through the slot high enough to set snugly when inserted in the tube. In the center of these boxes are cutter wheels, with spiral knives running on a shaft. The core of the barrel is composed of a solid rubber spring, against which the base of these boxes rests, thus forming a cushion or spring, which gives way and allows the cutter wheels to pass any ordinary obstruction, or to clean a very crooked tube.

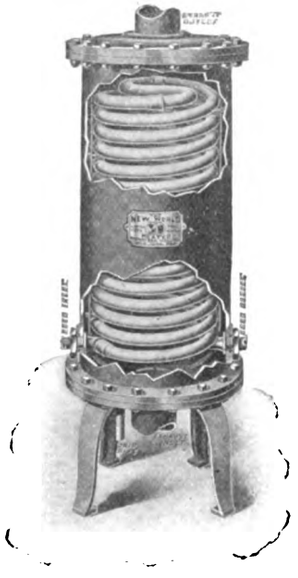
It will be noted from this that the cleaner has a flexible head. Screwed into each end of the steel barrel is a brass plug,

Digitized by Google

which has a nut end, into which a thread is run. This permits the attaching of a driving shaft in one end, and to the other a plow-shaped device, which keeps the broken scale from the cutter wheels.

In these boilers the scale did not come away in pieces, as is usually the case, but the resistance was so great that the cleaner had to literally grind the scale to a fine dust. As an instance of its hardness, the operator stated that he found he could not clean more than fifteen or sixteen tubes before the cutter wheels, which are made of the finest kind of case-hardened

TUBES IN PROCESS OF CLEANING.



steel, would become badly dulled. From each tube cleaned this instrument removed an average of 30 lbs. of pure flinty sulphate of lime. The tubes were left absolutely free from even a suggestion of scale, were, moreover, polished until they shone without in any way being scratched or damaged, and were altogether in even better shape than when they were first installed. This is, in the opinion of the parties concerned, one of the most interesting cases on record.

---

### RETURN COIL FEED WATER HEATER.

The new type of heater shown herewith, known as the New World return copper coil feed water heater, contains a number of departures from the old style of heaters, as can be seen from the engraving. It will be noticed that the water inlet and outlet are both located at the lower part of the shell, but on opposite sides, thus doing away with the many objections to the usual style of piping, where the outlet is generally at the top and on the same side of the heater as the inlet. The coil is made from seamless drawn copper tubing, and is of proper dimensions to give ample heating surface to heat the feed water to a temperature of 210 degrees Fahr., or to within 2 degrees of that of the exhaust under ordinary conditions.

The feed water is carried through this coil to the top of the heater; then, by means of an expansion return bend, which is so constructed that it does not in any way retard the flow of water or increase the friction, is passed down to the point of discharge at the bottom of the shell, meeting at that point the exhaust steam, and thus getting the benefit of the hottest steam as it enters and leaves the heater. The water in passing through this heater does not come in contact with any metal but

RETURN COIL FEED WATER HEATER.

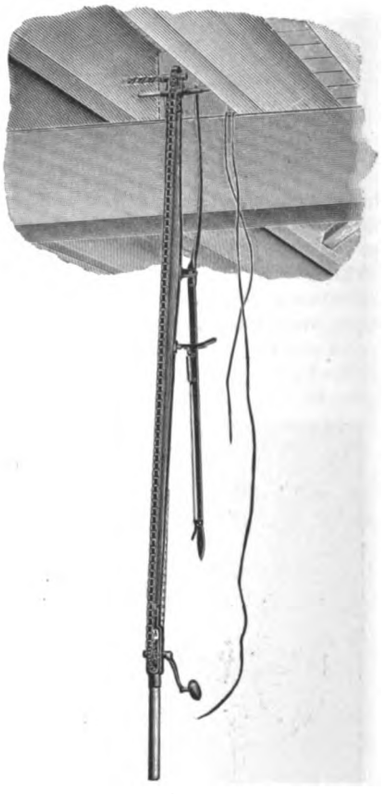
copper, and therefore there can be no rusting nor any of the galvanic action which is so common where the water comes in contact with two different metals.

Among other features that commend the new heater is the perfect freedom for expansion and contraction, both lengthwise and spirally, as the coil is not confined in any way at the inlet and outlet connections, or at the bottom of the shell. The coils are practically jointless from inlet to outlet. When necessary to join the tubing, it is done by expanding and lapping the tubes, then brazing with hard solder—by this means the chance of leaking being reduced to a minimum. All coils are tested by hydraulic pressure to 600 lbs. pressure to the square inch before being placed in the shell. The heater shells of all sizes up to 300 h. p., inclusive, are made from cast iron and in larger sizes from steel, and tested to 50 lbs. pressure to the square inch. Each shell is provided with a stuffing box and gland nut where the coil connects with it, the stuffing box being so arranged on the outside of the heater that it can be packed while the heater is in use. The manufacturers are the Robertson Manufacturing Company, 208 Fulton Street, New York.

---

### A SMALL DYNAMO.

The minature dynamo shown in the ac-



A MINIATURE DYNAMO.

companying cut has an output of 10 watts, but comprises all of the features of a large machine. The machine is wound for 2, 3, 5, 8 and 10 volts, and will light a 6-c.p. lamp, decompose water, charge storage cells, etc. The manufacturers are the T. & H. Electric Company, Elbridge, N. Y.

---

### ELECTRICIANS' BORING MACHINE.

The boring apparatus shown in the accompanying cut is made especially for boring through timbers for the insertion of porcelain tubes. As will be seen, it bores the holes laterally through the timbers; the pulling in of wires is thereby much facilitated and their insulation is preserved, as there is no bending from one joint to another nor scraping of the insulation. No step ladder is required for boring holes, and the bit is extracted very simply by means

ELECTRICIAN'S BORING TOOL.

of a spring, which in one operation feeds the drill, and, when reversed, extracts it. The manufacturers are the G. & E. Electric Company, Binghamton, N. Y.

---

### NEW TYPE OF SMALL GENERATING SET, WITH EIGHT-POLE GENERATOR.

Progression in the matter of the sizes of generating sets has been downward, as well as upward, and it is only recently that very small generating sets have come into the field. One of the latest is that illustrated herewith. The engine is single-cylindered, double-acting, with balanced piston valve. The frame is of such form as to practically inclose the running parts. Close regulation is secured by means of a shaft governor, which acts to change the point of cut-off from 0 to ⅞ of stroke.

The generator, which is attached to a common bed-plate with the engine, has a

Digitized by Google

wrought iron magnet frame, and is provided with eight poles. The armature is of the type shown in the accompanying illustration, and is built up on a spider, the interior of which is perfectly smooth, offering no opportunity for the collection of oil or dust. Ventilation is effected by specially constructed vanes, forming air ducts between the laminæ of the core. These convert the armature into a blower and create a strong draft through the winding. The series winding of the field coils is of flat copper ribbon, the shunt winding being of wire. Both windings are

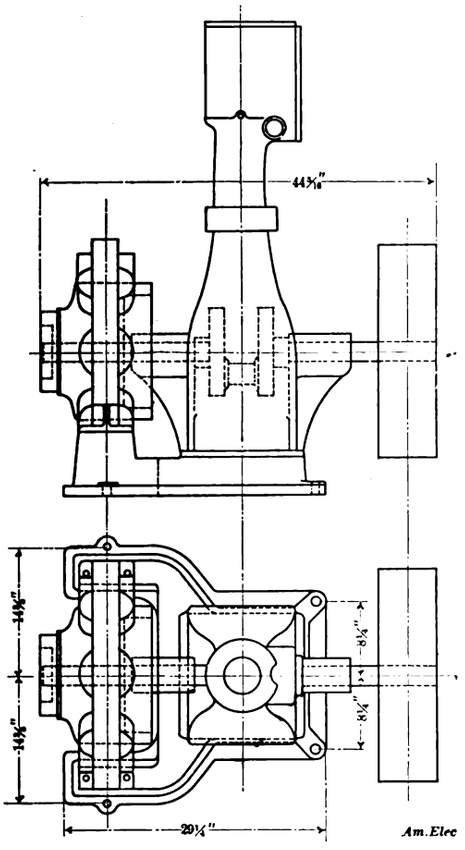


FIG. I. —SIDE, END AND PLAN VIEWS OF EIGHT-POLE GENERATING SET.

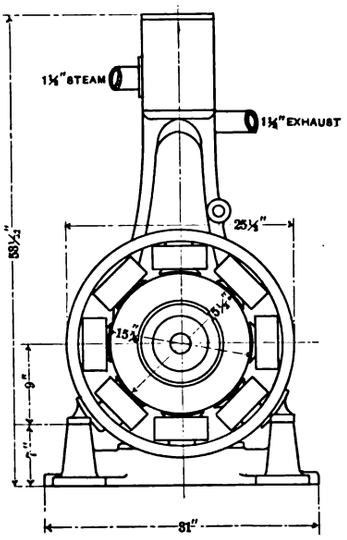
placed on the pole entirely independent of each other, and either may be readily removed. Both shunt and series winding have free circulation of air upon all sides. The generator is designed for sparkless operation under all changes of load, from no load to 25 per cent overload. The temperature rise for full load run of ten hours is limited to 90° F.

The set here shown consists of a 5 x 5 engine to run at 425 revolutions, and a 4½-kw. generator. The weight of the entire outfit is 1400 lbs. It forms one of a series designed and constructed by the B. F. Sturtevant Company, of Boston, Mass.

---



### SCARF PIN ELECTRIC LIGHT

The little novelty shown herewith, though not new in conception, is claimed to possess none of the defects which formerly so frequently gave dissatisfaction in the use of electric scarf pins. The lamp is of the high-efficiency miniature type and

ELECTRIC SCARF-PIN OUTFIT.

can safely be burned at a high brilliancy. The dry battery furnishing current is of the

"New Standard" Roche type, and is both efficient and convenient in size.

### A SMALL ARC LAMP.

The inclosed arc lamp, shown in the accompanying cut, has an extreme length of but 13 ins., and runs fifty hours on one trimming of 8 x 5/16-in. upper, and 2½ x 5/16-in. lower, carbons. In trimming, it is merely necessary to unscrew the small

ENCLOSED ARC LAMP.

nut shown at the bottom of the globe. The upper carbon is held in a contact bushing, which prevents it from feeding below a fixed point, at which current is cut off. The lamp illustrated, which is known as the "Tiney Lithian Lamp," is designed for connection on 110-volt constant-potential

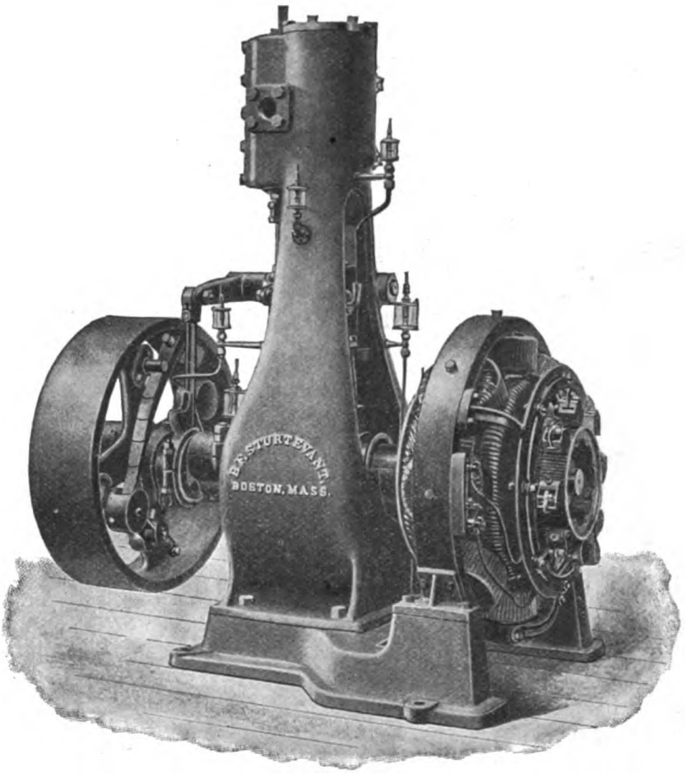


FIG. 2. —EIGHT-POLE GENERATING SET.

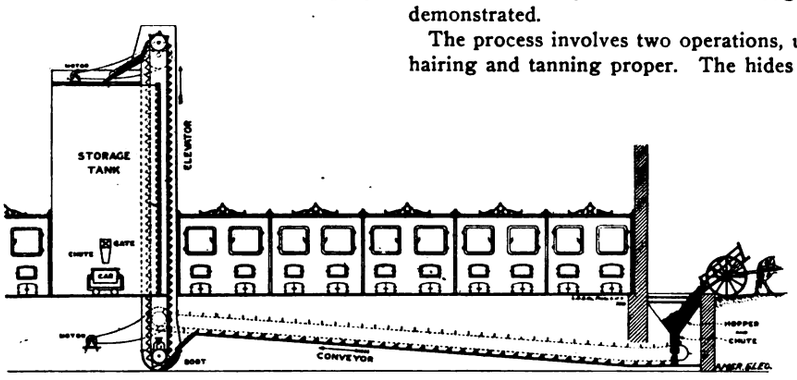

The manufacturer of the scarf-pin outfit illustrated is William Roche, 259 Greenwich street, New York.

circuits, and is made by the Safford Arc Lamp Manufacturing Company, 84 Terrace street, Buffalo, N. Y.

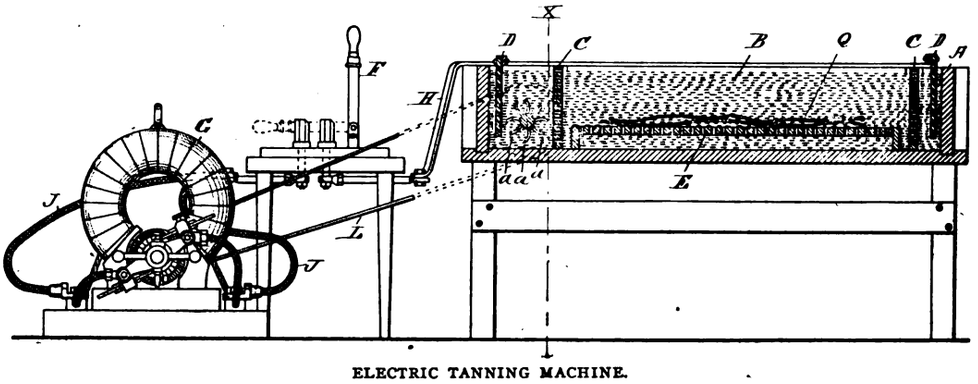
### COAL AND ASH HANDLING MACHINERY.

The accompanying illustration shows diagrammatically the coal and ash handling plant now being placed in the new Mt. Vernon Street power station of the Union Traction Company, of Philadelphia. The plant is being installed by the Link-Belt Engineering Company, from general plans furnished by Mr. W. S. Twining, chief engineer of the Union Traction Company.

COAL AND ASH HANDLING PLANT.

The coal as dumped at the street level will automatically feed itself through a regulating gate to a horizontal conveyor, employing Monobar chain and an improved form of suspended flight. The advantages of this new form of flight are, that it cannot come in contact with the trough under any circumstances, and that the trough may be made of such depth as to render it impossible for the coal to get beneath the wear-receiving blocks attached to the ends of the cross-bars of the flights. The conveyor will deliver the coal to a continuous steel bucket elevator, erected half on the outside and half on the inside of a 200-ton steel storage tank.



That is, the conveying buckets will ascend on the outside of the tank, and, after discharging their loads, will descend on the inside, a steel casing preventing the coal in storage from interfering with the returning line of buckets, and the side of the tank serving to hold the elevator rigidly in position. A track will be run in front of the boilers, and coal will be delivered to them by two Link-Belt one-ton side-dumping cars (one car for each half of the track), the storage tank being located alongside the middle of this track, and having its side fitted with a discharge gate near the bottom.

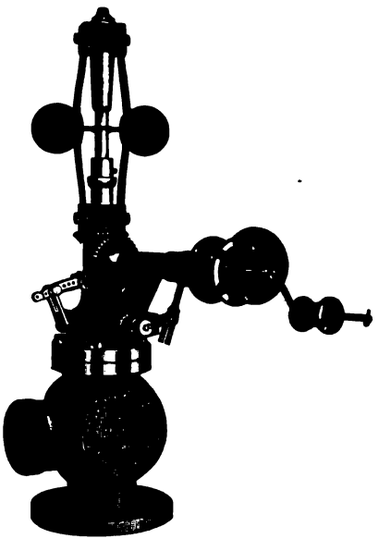
### ELECTRIC TANNING.

That electricity is of value in tanning has been known for some years from the investigations of German savants, but the practical application of electricity to commercial tanning is of recent origin. An apparatus for this purpose is illustrated herewith, being the first put on the market in this country, after, it is claimed, its commercial efficiency had been thoroughly demonstrated.

The process involves two operations, unhairing and tanning proper. The hides or skins are placed in an ordinary tank or vat containing a chemical solution, and while the skins to be unhaired are in the solution a proper current of electricity is passed through it and through the skins for a period of fifteen to twenty minutes. The current is then turned off, the skins still remaining in the solution for thirty minutes to one and a half hours, at the end of which time they are in condition to be removed and unhaired.

By the ordinary process from ten days to three weeks are required to prepare and unhair. After the hides have been unhaired and fleshed they are placed in a tank containing the proper bark extracts and a suitable current of electricity passed through the extract and the skins. The tendency of the current being to open the pores and allow the bark extract to thoroughly penetrate the skin, the tanning proceeds in a rapid and economical manner.

ELECTRIC TANNING MACHINE.



The illustration, which applies to both processes, makes clear the electrical connections and circuit, and shows the method of agitating the solution, the wheel, a, being in this case driven by belt from the dynamo furnishing the tanning current. This current passes between the electrodes, D, D, being controlled by the switch, F. C, C, are gratings, employed in order to obtain a proper distribution of the electrical current, and the hide is supported by a similar grating, as shown at E.

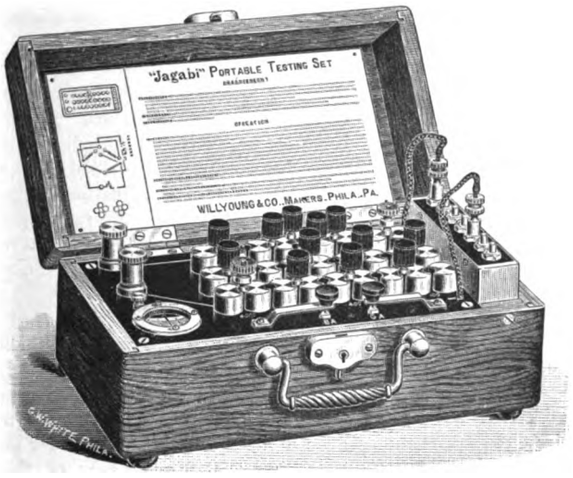
The manufacturers of the apparatus shown are the United States Leather Process Company, 138 Lincoln Street, Boston, Mass.

---

### MONARCH STEAM ENGINE GOVERNOR.

The throttling steam engine governor shown in the accompanying illustration is adapted to any type of steam engine, and in addition, by a special fitting, can be ap- in addition, by a special fitting, can be very simply applied to the throttling type of gas engines.

MONARCH GOVERNOR.



The valve throw of the governor is adjustable independently of the radial throw of the governor balls at normal speed of engine, thus enabling any desired closeness of regulation to be obtained on any type of engine. It includes an automatic safety stop, speed adjuster and valve lever, and all parts are standardized and fitted to gage.

The automatic stop device is positive and adjustable at any angle of the driving belt, from horizontal to vertical. The Monarch Governor and Machine Company, Indianapolis, Ind., is the manufacturer of this type of governor.

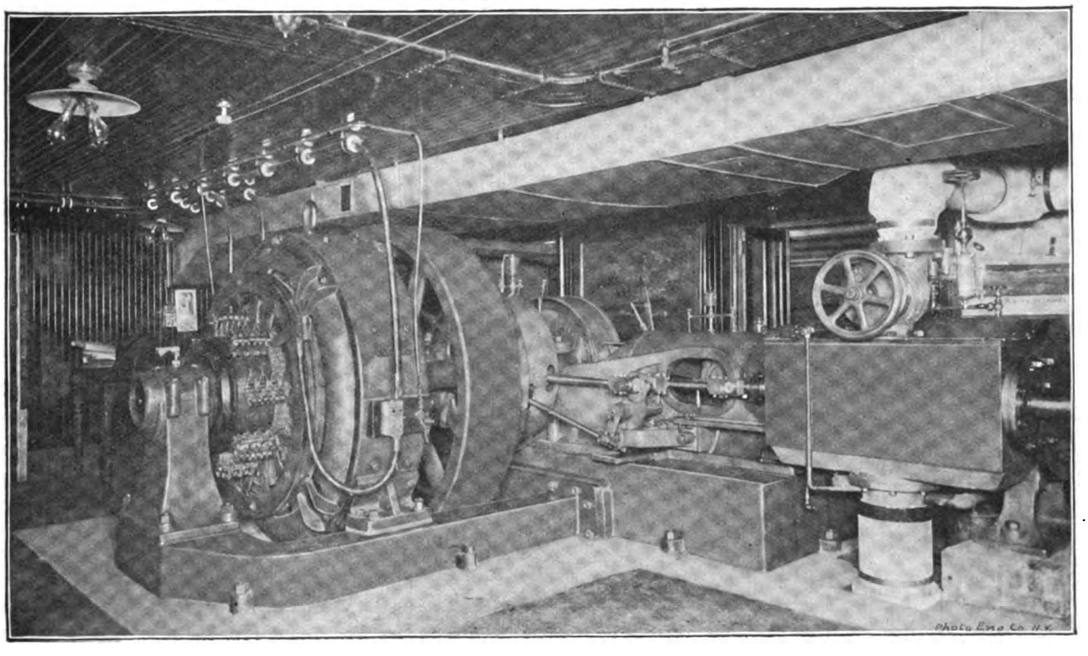
PORTABLE TESTING SET.

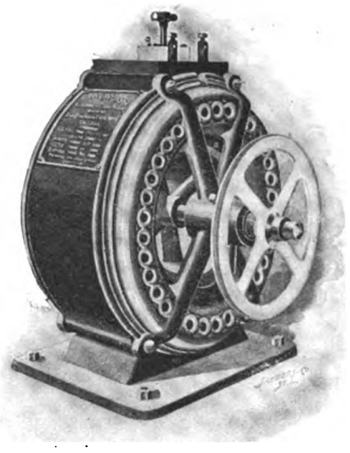
The "Jagabi" portable testing set for resistance measurements, shown in the accompanying illustration, has a theoretical range of measurement from .001 ohm to more than 11 megohms. The outfit comprises a D'Arsonval galvanometer of latest design; a set of resistance coils, with a total capacity of 11,110 ohms; a reversible arm Wheatstone bridge, with a ratio of 1 to 1000; keys for galvanometer and battery, and six chloride of silver dry cells. All these parts are mounted in a handsomely finished mahogany case with lock and handle. The total weight is 7 lbs., so that the instrument can be carried from place to place very readily. Mr. James G. Biddle, 910 Drexel Building, Philadelphia, is sole selling agent for the "Jagabi" portable testing set, which is manufactured by Willyoung & Co., Philadelphia.



PORTABLE TESTING SET.

100-KW. DIRECT-CONNECTED GENERATOR.

One of the largest of the isolated electric generating plants in New York City is that, in their mammoth wholesale house, of the H. B. Claflin Company, the present capacity of the installation being 300 kw.



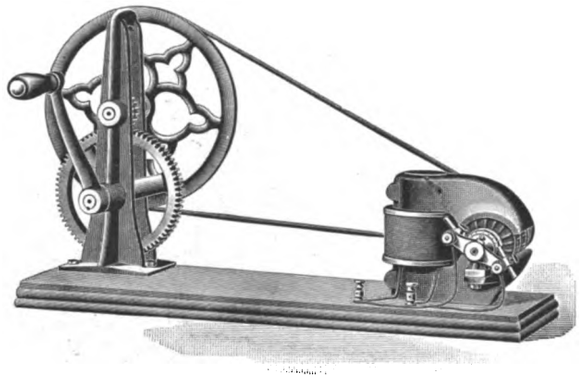
A recent addition to the plant has just been completed by the C & C Electric Company, of New York, and consists of one of its standard type eight-pole 100-kw. generators, direct-connected to a Buckeye engine running at 250 r.p.m. The generating set shown in the illustration herewith not only presents a very attractive appearance, but performs its functions in a most excellent manner. The compounding of the generator is so proportioned that it operates in perfect harmony with the other three older-type generators. The same company also furnished the very elaborate addition to the switchboard, and three iron-clad motors for operating freight elevators in the same building.

DIRECT-CONNECTED 100-KW. GENERATOR.

SPECIAL SLOW-SPEED LABORATORY MOTOR.

The laboratory motor shown herewith

SLOW SPEED LABORATORY MOTOR.



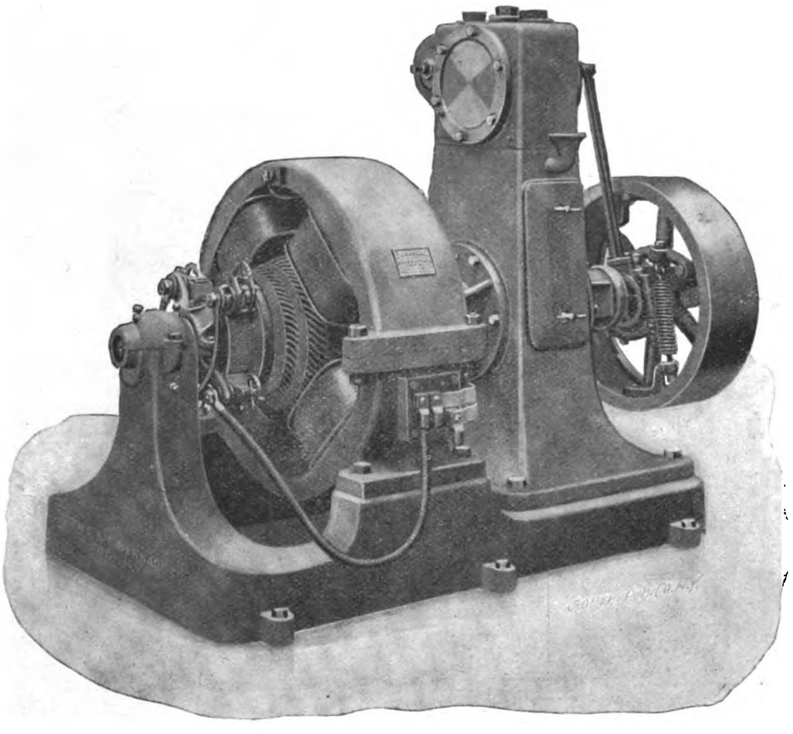
was designed, the manufacturers state, in response to a general demand for an alternating-current motor, giving more power than can be obtained from the small sizes of their ordinary induction motors, and less than their regular alternating-current motors of a ½-h.p. and upwards. The new type has speeds of 1200 and 1000 r.p.m. for 16,000 alternations, and 540 and 450 r.p.m. for 7200 alternations, the full load capacity in each case being 200 watts. The motor is intended for use on plate glass machines, dental work, small pumps and similar uses. Its extremely low speed gives it quite a strong torque at the pulley, and makes it much more convenient to arrange for di-

Digitized by Google

rect belting or gearing without the intervention of countershafts. The manufacturers are the Emerson Electric Manufacturing Company, St. Louis, Mo.

### A MODEL DYNAMO.

The small dynamo shown in the accompanying illustration, which was designed



HAND POWER GENERATOR.

especially for the use of schools and students of electricity, will decompose water, light an incandescent lamp, charge permanent magnets, electro-plate, drive small motors, etc. It can also be used as a motor to drive light machinery, such as a sewing machine. It weighs 20 lbs., is 5½ ins. high and 9¾ ins. long through the armature shaft, and has an output of 75 watts.

### MARINE TYPE OF MULTIPOLAR GENERATOR.

The direct-connected marine type of generator shown in the accompanying cut in a photographic representation of a set recently installed on the U. S. Coast Survey steamer "Blake," by the E. G. Bernard Company, of Troy, N. Y. The set is similar to one installed by the same firm on the U. S. light-house tender "Mangrove," and a duplicate will be put aboard the Coast Survey steamer "Pathfinder," now being built for survey work along the Alaskan coast. The plant for the Coast Survey steamers includes, in addition,

MARINE MULTIPOLAR GENERATING SET.

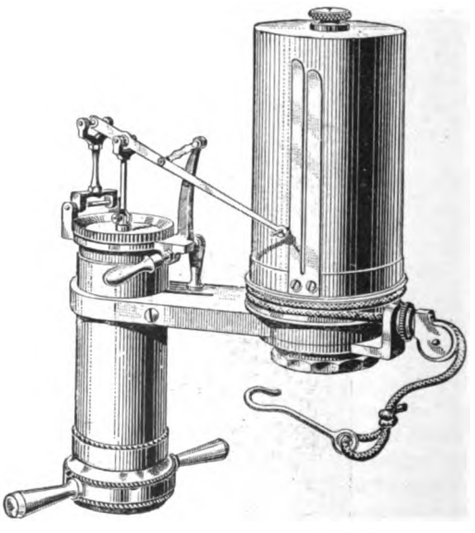
The machine was originally made by its designer for his own use in electrical experimenting, but at the suggestion of the New York State inspector of school apparatus it was placed on the market, and is now largely employed for educational work. The present manufacturers are the Elbridge Electrical Mfg. Company, Elbridge, N. Y., of which Mr. A. E. Doman, the designer of the machine, is manager and electrician.

a search light and other modern electrical appliances, such as ventilating fans for the cabin, ward room and state rooms. As many ship electrical plants by their noise and vibration largely nullify their convenience otherwise, the naval officials were particularly pleased by the noiselessness of this type, its operation not being recognizable ten feet away on account of the absence of sound and perfect balance of the armature.

### THE "STANDARD" INDICATOR.

In the present time of close competition, no subject is of more importance to the engineer and steam user than the economical generation and use of steam. In this connection, no instrument is of more pronounced benefit than the steam engine indicator. In the "Standard" indicator, illustrated herewith, all complicated features have been carefully avoided, but without omitting necessary adjustments. In the general appearance no radical changes have been made, as will be seen in referring to Fig. 1. The cylinder is of the standard bore, .7978 of an inch diameter, to which is carefully fitted a bronze or steel piston. The piston-rod is hollow, and threaded to receive a swivel rod by means of which the pencil may be raised, for use on condensing engines. The same object may be attained, even while the indicator is under steam, by loosening the clamp screw or the drum-supporting arm, after which this arm may be placed in a different position on the cylinder. This feature also permits turning the "blow-holes" away from the operator, a point the user will appreciate. These holes are of ample area, and open direct to the atmosphere, so there can be no accumulation of pressure above the piston. The spring and method of attachment to the piston is shown in Fig. 2.

The drum is made of solid-drawn tubing, turned absolutely true and cylindrical. The method of changing the tension of the drum spring is remarkably simple. The shaft is provided with a pin with projecting ends. The upper end of the spring is attached to the knurled head, Figs. 3 and 4, to which is attached a steel tube, with slotted end



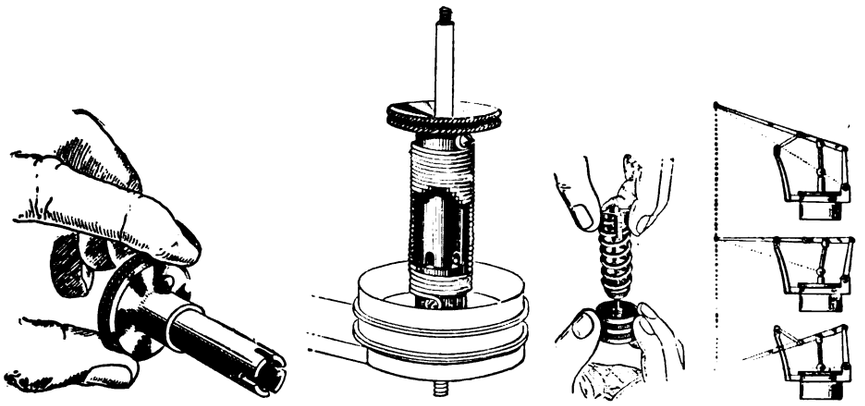


FIG. 1.—STANDARD INDICATOR.

to engage the pin. These slots are slightly wedge-shaped so that tension of the spring will hold it firmly in position without the aid of set screws or auxiliary springs. By raising the knurled head until the slots disengage the pin, any tension may be given the spring instantly. The style of spring used is shown in Fig. 4, and admits

Digitized by Google

of a perfectly even spring tension throughout the entire drum rotation. This style of spring is not liable to break with use, and may be quickly made by any engineer.

The parallel motion is mathematically correct, and gives a straight line as shown in Fig. 5. All joints are properly fitted, have wide bearings, and the entire movement is nicely polished and blued. The balance of the instrument is highly polished and nickeled, and is packed in a fine mahogany case with all usual fittings. The manufacturers are the Lippincott Steam Specialty Company, 169 Broadway, New York.

FIGS. 2, 3, 4 AND 5.—DETAILS OF STANDARD INDICATOR.

## NEW BOOKS.

Lighting by Acetylene. Generators, Burners and Electric Furnaces. By William E. Gibbs, M. C. New York: D. Van Nostrand Company. 141 pages, 64 illustrations. Price, $1.50.

A collection of memoranda rather than a systematic treatise on the subject of the title, this little book is nevertheless of much value to those interested in the subject of acetylene, its preparation and use. The information is practical in its character, and numerous forms of carbide furnaces are shown in well-engraved illustrations, as well as the present commercial forms of acetylene generators. An appendix gives a complete list of carbide furnace and acetylene generator patents. As showing the newness of the industry to which the book relates, it is interesting to note that the first of several hundred patents on these apparatus only dates from 1895.

Shop and Road Testing of Dynamos and Motors. A Practical Manual. By Eugene C. Parham and John C. Shedd. New York: The W. J. Johnston Company. 538 pages, 163 illustrations. Price, $2.

A long-felt want has been a book dealing with practical electrical measurements as applying to machinery and conducting lines. This need may be said to be fairly met with respect to direct current measurements by the book under notice, which besides gives instruction in the theory involved, both fundamental and as relates to testing work. The first section of the book, consisting of 55 pages, is devoted to fundamental principles. The testing and use of instruments form the subjects of the second section, occupying 124 pages. The more practical portion of the work is introduced by a chapter descriptive of the series, shunt and compound machines, with directions for their testing, both for efficiency and faults. One chapter is devoted to compounding and another to tests for core loss, eddy currents, saturation, distribution and brush contacts. There is a chapter each on line and motor testing, and an appendix of tables having reference to the text.

The A B C of Electricity. By Wm. H. Meadowcroft. New York: American Technical Book Company. 107 pages, 36 illustrations. Price, 50 cents.

That this little book has entered into its sixty-fourth thousand is evidence that it meets a real need. As a very elementary treatise on electricity, and one designed to answer the questions generally put by the uninitiated, its great success is well deserved.

Petroleum Motor Cars. By Louis Lockert. New York: D. Van Nostrand Company. 218 pages, 92 illustrations. Price, $1.50.

The importance which automobiles are assuming renders this translation from the French a timely contribution to the subject. The first six chapters treat of the future of auto-locomotion, motor-car races, direct-combustion engines, gas and gas engines, petroleum, and petroleum cars. The succeeding eleven chapters are given over to descriptions of the various types of automobiles. One chapter is on accessories, such as brakes, lubricators and pneumatics, and two others on acetylene and acetylene motors. The descriptions of the various types of vehicles are in full detail, with references to accompanying illustrations.

## OBITUARY.

MR. RONALD T. McDONALD, president of the Fort Wayne Electric Corporation, died at Dallas, Tex., Dec. 24, of pneumonia, after a short illness. With the death of Mr. McDonald the electrical field loses a forceful character, who has been a large factor in its development from early pioneer days. Commencing with the organization of the Jenney Electric Company in 1881, he has continued a leader in electrical development, and at the time of his death was at the head of the Fort Wayne Electric Corporation and the Fort Wayne Lamp Works, besides being interested in many town and city lighting plants. One of the personal characteristics of Mr. McDonald was his devotion to the interests of Fort Wayne, which led to his memorable contest with the General Electric Company, when it endeavored to move the Fort Wayne electric works to Schenectady, and resulted in the organization of the rival Fort Wayne Electric Corporation.

## PERSONALS.

HON. GEO. O. PROCTOR, president of the Anchor Electric Company, was elected Mayor of Somerville by a very large majority at a recent municipal election.

MR. M. J. MARTINEZ, Mem. Am. Soc. M. E., has received the appointment of resident agent at Havana, Cuba, for the Snow Steam Pump Works. The business will be conducted under the style of M. J. Martinez, consulting and contracting engineer.

DR. LOUIS DUNCAN has been selected as engineer by the company which recently purchased the Fifth Avenue stage franchise, in New York City. It is the intention of the company to replace the stages with some form of automobile vehicle.

MR. S. DANA GREENE, assistant general manager of the General Electric Company, has been appointed by Governor Roosevelt of New York as the naval aide on his staff. Mr. Greene served on the "Yankee" during the late war as watch officer, and at present is a lieutenant-commander in the New York State naval militia, and the chief of staff.

PROF. SIDNEY H. SHORT, of Cleveland, sailed for Europe Dec. 13, and will make an extended tour through Great Britain and the Continent. While the object of the tour is principally recreation, Prof. Short has been asked by several professional bodies to deliver addresses on heavy electric railroading and high-speed traction, on which subjects he is held an authority in Europe, as well as at home.

CHIEF ENGINEER WALTER M. McFARLAND resigned from the Navy to accept a position as assistant general manager of the Westinghouse Electric & Manufacturing Company. Mr. McFarland for some years has been the assistant to Engineer-in-Chief Melville, in which position, and in service aboard ship, he has not only established a reputation both in this country and abroad as an accomplished engineer, but has shown that he possesses administrative abilities of a high character.

MR. W. J. CLARK, well known as the manager for years of the General Electric electric railway department, has accepted the position of general manager of the foreign department of that company, with headquarters in New York. Mr. Clark is peculiarly well equipped for his new work, not only through an extended acquaintance with foreign countries, but also through the possession of the personal qualities necessary for success in a cosmopolitan field. As the author of one of the most important books of the year—"Commercial Cuba"—Mr. Clark has displayed a grasp of detail in dealing with foreign commercial matters that will be of immense value in his present position.

## TRADE PUBLICATIONS.

MECHANICAL DRAFT.—The B. F. Sturtevant Company, of Boston, Mass., has just issued a second edition of its very suggestive pamphlet, Bulletin E, entitled "Draft Without a Chimney," which will be mailed on application.

ROUND-HOUSE TURN-TABLE.—The Westinghouse Electric & Manufacturing Company has issued a brochure in a very artistic cover on the "Modern Round-House Turn-table." A number of

Digitized by Google

illustrations are given, accompanied by explanatory matter.

GAS ENGINES.—The New Era Iron Works, Dayton, Ohio, have issued a new catalogue, bound in an illuminated cover, and devoted to the "New Era" gas and gasoline engines. The text is both well written and instructive on the general subject of gas engines and their operation.

THE C. & C. ELECTRIC COMPANY, 143 Liberty Street, New York, has issued a new, enlarged and interesting issue of the bulletin, noticed here upon its appearance, treating upon its well-known iron-clad motors and dynamos. All those interested in this type of machines may obtain a copy of this bulletin (No. 127) upon request.

ANNUNCIATORS.—The Electric Appliance Company, Chicago, has made the Noxall annunciator the main text of a pamphlet, which also includes other house goods. The illustration of the Noxall drop shows that it contains but practically two pieces—the magnet and the needle—thus greatly reducing any chance of derangement.

PNEUMATIC TOOLS.—In a large-page catalogue, the Q. & C. Company, Western Union Building, Chicago, describes a long line of valveless pneumatic tools of its manufacture. Among the applications of those illustrated are to riveting, chipping, calking, beading flues, cutting stay-bolts, carving, lettering, etc.

IRON-CLAD DYNAMOS AND MOTORS.—Bulletin No. 127 of the C. & C. Electric Company deals with iron-clad dynamos and motors, generating sets, etc. Many applications of this type of machine are shown, and those interested in brush holders will find an illustrated description of the latest improved C. & C. reaction type.

ELEVATING AND CONVEYING MACHINERY.—The Aultman Company, of Canton, Ohio, has recently issued a catalogue descriptive of its various manufactures in the line of elevating and conveying machinery and other labor-saving appliances. The catalogue, which contains 136 pages, is very complete and is very carefully gotten up.

THE PEERLESS LAMP.—The Warren Electric & Specialty Company, Warren, Ohio, in a neat pamphlet gives an account of the recent unique prize contest instituted to bring forth a name for its incandescent lamp. Some hundreds of names were suggested, and that of "Peerless" was selected from these by a committee of three.

GRAPHITE.—The Joseph Dixon Crucible Company, Jersey City, N. J., has commenced the publication of a neat-looking periodical called "Graphite," whose object is to promote the use of the material from which its name is derived. Though thus frankly a trade publication, the matter contained is both interesting to the general reader and well written.

TELEPHONES.—In a new edition of its catalogue of telephones and telephone equipments, De Veau & Company, 27 Rose Street, New York, give some pages of practical information of value. The subjects are "Some Faults and Some Causes," "Telephone Line Construction," "Metallic Lines," "Ground Wires," and "Installation of Telephones." Another commendable feature is data on the e.m.f. and internal resistance of some of the primary cells listed.

CABLE TESTING APPARATUS.—The new catalogue of electrical measuring instruments recently issued by Mr. James G. Biddle, 910 Drexel Building, Philadelphia, describes a series of apparatus for testing resistance, insulation and capacity of aerial, underground or submarine cables. Portable outfits, as well as equipments for station use, are described. A copy of this catalogue (B) will be mailed to any address upon receipt of ten cents in stamps.

POCKET CALENDAR AND DIARY.—Mr. Henry L. Shippey, manager of John A. Roebling's Sons' Company, New York, is sending his friends with wishes for a happy and prosperous New Year a box containing a morocco case with twelve monthly diaries, the latter being so made that one can be removed and another easily secured in the case. The book also contains a miniature morocco-bound calendar scarcely larger than a postage stamp.

WESTINGHOUSE COMPOUND ENGINE.—The Westinghouse Machine Company, Pittsburgh, has issued an edition de luxe pamphlet, descriptive of its compound engine. In cover, binding, printing and illustration this beautiful production will compare favorably with the most pretentious of the holiday books put forth by the art publisher. The numerous half-tone illustrations are splendidly executed, and the text has more the character of a technical treatise than a trade publication.

AN ARTISTIC CALENDAR.—The H. T. Paiste Company, of Philadelphia, is issuing to the electrical trade a very artistic calendar for 1899. Many of our readers will recall a calendar which this firm distributed several years ago, illustrating a girl putting up her hair (A Switch?). Their 1899 subject is "Good Night," by Grust, and is a beautiful reproduction of the lights and shadows which make this painting famous. This handsome calendar will be sent upon receipt of four cents in stamps to cover expense of mailing.

THE M. O. ELECTRICAL LEATHER PROCESS COMPANY, 138 Lincoln Street, Boston, Mass., sends us a bright conceit in the shape of a post card having on the back a representation of a goose in a coop. Closer inspection shows that the neck of the goose is separable, and when pulled brings with it a sheet that had been concealed behind the coop. The latter contains the quotation: "The goose is not considered the bird of wisdom, yet the cackle of geese once saved Rome," with the comment, "If you will send for our illustrated catalogue it will show you how much we can save you."

TRANSFORMER DESIGN AND OPERATION.—From the General Electric press comes another fine specimen of the printer's art in the form of a pamphlet with the above title. The text includes a reprint of the Institute paper on "Alternating Current Transformers, from the Station Manager's Viewpoint," read by Mr. W. F. White, and a reprint of the paper read by Prof W. E. Goldsborough before the 1898 meeting of the National Electric Light Association. Another interesting feature is a description of the alternating current distribution system at Pueblo, Col., accompanied by plans.

TRANSFORMERS AND THEIR PROFITABLE USE.—Under this title the New York & Ohio Company, Warren, O., publishes a pamphlet, handsome in printing, paper and cover, and written by Prof. Dugald C. Jackson. Though professedly a trade publication, it is also an excellent technical treatise on the practical aspects of the subject. While the accompanying illustrations refer to the Packard transformer, the text has a general bearing, and will be found both useful and interesting by all users of transformers. In addition to the tests given by Prof. Jackson, a further section on this subject is contributed by Mr. Henry W. Wiswell.

INCANDESCENT LAMPS.—In a well-printed pamphlet bound in a cover of clean and artistic design, the New York & Ohio Company, Warren, O., illustrates and describes the various styles of its Packard lamps. A valuable addition to the catalogue consists of several tables containing lamp data, some of which is difficult to find in print. One of these gives the efficiency and life of lamps of various watt ratings at voltages above and below the normal, but within the range of commercial variation. Three other tables give the current in amperes taken by 3.1, 3.5 and 4-watt lamps of different candle-powers and voltages. An introductory section explains the bearing of these tables on the selection of lamps.

## BUSINESS NEWS.

W. G. NAGEL & CO. is a new firm, recently organized for the purpose of conducting a general business in electrical machinery, supplies and construction, in Toledo, O.

MR. HOWARD N. PATTEN, formerly with the Boston Edison Company, has accepted the position of electrical engineer with the Merrimac Manufacturing Company, Lowell, Mass.

THE ELECTRIC APPLIANCE COMPANY, Chicago, is calling particular attention to the Jenkins switch, which is the latest arrival in the field of snap switches and is sold at a low price.

PLUG SWITCHES.—The American Electric Heating Corporation, Cambridge, Mass., is making a plug switch containing a double-pole fusible cut-out, which is not only quick to install, but is claimed to be better for many wants than small knife or snap switches.

GEORGE WILLIAM HOFFMAN, Indianapolis, Ind., manufacturer of "U. S. Infallible Metal Polish," has opened a branch office in St. Johns, Newfoundland. Mr. Hoffman has branches in New York, Chicago and San Francisco, and is now reaching out for foreign trade.

THE SKINNER ENGINE CO., Erie, Pa., has recently shipped to Japan, for use in the Yokahama steel railway plant, a 9 x 17 x 15 tandem compound center-crank engine, equipped with the New Skinner self-oiling system. The engine will be direct connected to a Walker generator.

RHEOSTATS.—Mr. Charles Wirt, 1028 Filbert Street, Philadelphia, is making a specialty of field rheostats and also building a number of heavy and special designs. A searchlight rheostat recently shipped by Mr. Wirt is believed to be the largest constructed for this work, and has a capacity for continuous duty of 14 kw.

RED SEAL BOILER COMPOUND.—The Cherry Chemical Company, 1215 Filbert Street, Philadelphia, is much pleased with the business done during the past year with the "Red Seal" boiler compound. They anticipate, moreover, for the coming year even a heavier increase of business than met with in 1898.

MACHINERY AND MOTOR SPRINGS in large quantities have been turned out recently by the Cary Spring Works, 240 West Twenty-ninth Street, New York, on orders. The company reports that its customers express entire satisfaction with the springs furnished, which, it is stated, are of an especially high grade.

HENRY G. ISSERTELL, former manager of the Boston office of the Walker Company, has recently accepted the position of manager for the Middle Atlantic States of the Anchor Electric Company, of Boston. Mr. Issertell has opened an office in the Havemeyer Building, New York City, where he will be glad to receive his friends.

THE PHŒNIX IRON WORKS COMPANY, Meadville, Pa., has recently received an order from Laughlin & Co., Ltd., of Pittsburg, for three 300-h.p. tandem and one 600-h.p. cross compound engine. All these engines are of the condensing type, and will be direct-connected to electric generators in the new plant of Laughlin & Co.

MR. T. F. AHEARN, general superintendent, and Mr. S. P. Grace, electrical engineer, of the Detroit Switchboard and Telephone Construction Company, are in New Orleans attending to the construction and equipment of the People's Telephone Company, of that city. The new company has, it is stated, a list of nearly 3000 subscribers thus far.

THE SIOUX CORLISS ENGINE at the Omaha Exposition was awarded the gold medal over its competitors. This engine was built by the Murray Iron Works Company, of Burlington, Ia., and it was in continuous operation, twenty-four hours per day, during the greater part of the exposition, furnishing all the power used on the grounds.

THE UNITED STATES CARBON COMPANY, Cleveland, Ohio, reports a large increase in business, their mammoth presses being kept constantly busy on carbons for electro-metallurgy and electro-chemistry, which branch of trade is constantly demanding larger and more difficult carbons. Its carbons for inclosed arc lamps are also meeting with great success.

FEED-WATER HEATERS.—The Stewart Heater Company, Buffalo, N. Y., has received from the Bickford & Francis Belting Company a warm commendation of the Otis feed-water heater. One of these heaters installed seven years ago is stated to work entirely satisfactory at the present day, and with a cleaning once a year, continues to give the same excellent results that it did when new.

HAIR SPRINGS FOR ELECTRICAL INSTRUMENTS.—F. N. Manross, Forestville, Conn., has made a specialty of the manufacture of delicate springs for electrical indicating and recording instruments. The material used is a special bronze which possesses all the good qualities of steel and, of course, is not affected by magnet-

Digitized by Google

ism. Orders from Japan and England have lately been received for these springs.

A NEAT POCKET CONVENIENCE.—The Standard Underground Cable Company, Pittsburgh, Pa., is presenting to its friends a combination foot-rule and wire gage for the pocket. One side of the rule, which is of celluloid and in three hinged parts, has two scales of inches, one divided into eights and the other into sixteenths. The other side gives the diameter and circular mils of wires from No. 4-0 to No. 22 B. & S. gage.

THE SHAWMUT FUSE WIRE COMPANY, of Boston, Mass., reports a large demand for its Monadnock knife switch. This switch is now much used by engineers and contractors who are looking for a high-grade article at a reasonable price. The company has recently supplied switches for some of the largest boards now being built in the West, and at the present time is working its factory night and day to fill rush orders.

THE FARR TELEPHONE AND CONSTRUCTION COMPANY, 357 Dearborn Street, Chicago, is congratulating itself on both the volume and profitable nature of its business during the past year. It has been patronized by the independent telephone companies of the United States and Canada in a flattering manner, and looks forward to the coming year as the most successful for the electrical trades that has ever been experienced.

OIL FILTERS.—The Columbus Filter Company, Columbus, Ohio, reports a very gratifying number of sales of their filter recently. Among other orders was a large shipment to the United States War Department for use at Fort Warren and at Indian Head, which order was secured only after a very severe test had been made of several types of filters. The Government has also placed an order for filters for the new Washington postoffice.

THE CHICAGO RAWHIDE MANUFACTURING COMPANY, 75 East Ohio Street, Chicago, reports that its business for 1898 shows a gain of at least fifty per cent over that of 1897, both in domestic and European orders. They believe that the users of rawhide beltings, pinions, etc., realize they make a saving in using rawhide goods, and so are just learning that a rawhide belt adheres to the pulleys so closely that it makes it a great saver in power.

THE COMMERCIAL ELECTRIC COMPANY, Indianapolis, Ind., reports the year just closing as one of the most successful in its history. The demand for its iron-clad type of motor has steadily increased, and the field it is now covering is a very wide one. The past year has seen its motors shipped to not only nearly every country of the American Continent, but also to Japan and other foreign countries. The company reports the prospects for 1899 as very bright indeed.

THE ROCKWOOD MANUFACTURING COMPANY, Indianapolis, Ind., is busier than ever. They have been working overtime for some weeks past. The many tests made in the past by power users generally have so thoroughly demonstrated the superior efficiency of the paper pulley manufactured by this company that it is universally recommended, and the manufacturer can rest assured that with this pulley in his plant he has secured the acme of known excellence in pulleys.

A NEW SWITCHBOARD will be furnished to the Providence central station by the Hope Electric Appliance Company, Providence, R. I. The switches to be used are the new type of Hope generator and feeder single-pole, double-throw jaw switch, which stop midway in the throw at the will of the operator. The switches will range from 200 to 1200 amps. capacity, and are from new and original designs, showing a decided advance in the development of switchboard construction.

THE KEYSTONE ELECTRICAL INSTRUMENT COMPANY, 1 Montgomery Avenue, Philadelphia, is daily receiving gratifying evidence of the growing favor with which its electrical measuring and indicating instruments are meeting from engineers and others most qualified to judge. The high place which these instruments are rapidly taking is due not only to the correct principles upon which they are based, but also owing to their excellent workmanship and their constant reliability.

THE WHEELER REFLECTOR COMPANY, 18 Washington Street, Boston, Mass., has had a gratifying increase in the volume of its business for 1898 over any previous year, and anticipates a still better record for 1899. The success with which the well-known Wheeler reflectors have met is the logical result of first-class workmanship, the best of material, ability to make prompt shipments, and the courteous treatment extended to the customers of this company by its salesmen and executive officers.

THE LOMBARD WATER WHEEL GOVERNOR COMPANY, Boston, reports that the demand for its governors is constantly on the increase. During last month orders were received for upward of twenty generators to regulate forty-one water wheels, which will develop 15,750 h.p. More than half of this machinery will be used in electric stations—principally in power transmission plants—and railway power stations, the balance being in textile and other manufacturing plants driven by water power.

MONTAUK MULTIPHASE CABLE.—The superintendent of the fire alarm department of Boston has made to Mayor Quincy a flattering report on the merits of the cable made by the Montauk Multiphase Company, 100 Broadway, New York. In his report the superintendent states that the multiphase cable is a valuable adjunct for use in any automatic fire alarm service depending on the action of thermostatic devices for its operation, and superior to the isolated thermostats used in the present automatic systems.

BOILER INCRUSTATION AND CORROSION.—Thomas N. Warley & Co., Philadelphia, Pa., give evidence of their confidence in the boiler compound of their manufacture by offering to send a half barrel anywhere in the United States subject to approval, and if the results are not satisfactory it can be returned without cost to the customer. This compound is claimed to not only remove and prevent the formation of scale, prevent pitting, corrosion in steel boilers, but has shown an actual saving of coal of from 15 to 70 per cent.

MACHADO & ROLLER, 203 Broadway, city, inform us that their business is showing a marked and very steady increase in volume. Their new dead-beat Whitney portable and switchboard instruments are being used and specified by a large number of the most prominent consulting engineers, and reports of very flattering character on the performance of their A. E. G. lamps are being received almost daily. They are always glad to have their friends call to see them and inspect the various new appliances that they bring out from time to time.

GORDON PRIMARY BATTERY.—We are informed that the business of the Gordon Battery Company, of New York City, is rapidly increasing, and friends of the company will be pleased to hear that it will declare immediately a semi-annual dividend of 4 per cent on the preferred stock from the net earnings of the six months ending January 1, 1899. The Gordon cells are being fast introduced into the telephone field and fire alarm service of the country. A majority of the railroads have adopted the Gordon cell for the operation of signals, and thousands are daily in use.

THE ANCHOR ELECTRIC COMPANY, Boston, Mass., has opened an office, for the greater convenience of its numerous patrons in New York City, in the Havemeyer Building, Cortlandt Street, telephone No. 3831, Cortlandt. Mr. H. G. Issertel, formerly of the Walker Company, is in charge of the office, and will be pleased to see all of his old friends at this office. It is the purpose of the Anchor Electric Company to carry a small stock in New York for emergency orders, and to do everything needful for the convenience of their customers in New York City and vicinity.

THE ORIENT ELECTRICAL COMPANY, of Youngstown, Ohio, is offering 1899 purchasers a new lamp (not a new name) which they guarantee to possess all the dsirable features to be expected in a first-class lamp. This company has recently equipped its factory with the latest and most improved instruments and appliances for the manufacture and thorough testing of the high-grade incandescent lamp referred to, which is manufactured by new processes and when put to the most thorough and practical tests has without a single exception given entirely satisfactory results.

CLIMAX STEAM JOINT CLAMPS.—Jas. McCrea & Co., 11 South Canal Street, Chicago, have received a flattering letter from the manager of the Warden Power Building, Philadelphia, concerning Climax steam joint clamps purchased a year ago, and which have been in constant use since that time. In every case, it is stated, where these clamps have been put on they have promptly stopped leaks, and the leaks have not opened up again. In some cases the clamps stopped leaks which otherwise it had been impossible to make tight on account of the vibration of the building.

BALL ENGINES IN THE NAVY.—Among recent sales of engines to the Navy Department by the Ball Engine Company, Erie, Pa., are two 180-h.p. tandem compound, each direct-connected to two 60-kw. G. E. generators, for the Norfolk Navy Yard, and an engine of the same size for the naval station at Bremerton, Wash. Also, a 300-h.p. vertical compound engine, direct-connected to two Siemens & Halske 300-kw. generators, for the New York Navy Yard.

THE COLUMBIA INCANDESCENT LAMP COMPANY, of St. Louis, has completed a number of important improvements in its factory and office, with which it hopes to be able to catch up with its orders and resume its usual prompt shipment in a short time. Mr. A. C. Garrison is the secretary and manager of the company, and these additions are another evidence of his vigorous policy, which leaves nothing undone that will contribute to the success of his company and to the satisfaction of its customers.

THE CENTRAL ELECTRIC COMPANY, Chicago, is in receipt of a great many flattering comments from the trade on their new general catalogue, of which the following is a sample: "We beg to acknowledge the receipt of a copy of your new general catalogue, and thank you for the same. It is a very complete and fine production in every respect. Kindly send us discount sheet." As the catalogue contains a quantity of valuable data outside of the merchandise illustrated, it is well worthy of careful examination and preservation.

INDUCTION SEWING MACHINE MOTOR.—The Emerson Electric Manufacturing Company, of St. Louis, calls attention to the fact that its improved induction sewing machine motors, having no wearing parts except the shaft, are particularly adapted for use by inexperienced persons, and the entire device is easily attached to any make of family sewing machine. The sewing machine is started, stopped and speed is regulated by a slight movement of sewing machine treadle. They further state that this is not in any sense an experiment, but is thoroughly practicable and fully guaranteed.

EXCELLO GRAVITY BATTERY.—For charging storage batteries the Excello Gravity Battery, manufactured by the Burnham Electric Company, 146 Franklin Street, Boston, is claimed to be superior to the ordinary bluestone cell by reason of its higher internal resistance. It is explained that this feature results in an economy of operation when the storage cell becomes partially charged, which the low resistance gravity battery does not possess. The manufacturers have on file a number of strong testimonials from users of Excello batteries, thorough satisfaction being expressed in each instance.

IDEAL ENGINES.—Recent sales by A. L. Ide & Sons, Springfield, Ill., of "Ideal" engines aggregate twenty-three in number, ranging from 8 x 10 to 16 and 26 x 20. Among the States represented are Michigan, Nebraska, Illinois, South Dakota, Oregon, Wisconsin, Minnesota, Missouri, Arkansas and Iowa. The list includes eleven direct-connected to electrical generators, and a large engine for a United States Government dredger. The Chicago & Great Western Railroad appears as a purchaser of two direct-connected compound engines, one 14 x 22 x 16, and the other 12 x 20 x 14.

CARBON BRUSHES.—The Le Valley Vitæ Carbon Brush Company, 45 Broadway, New York City, commences a new year with the confidence which success alone gives. During the past year its brush has not only met with large sales, but has established a favorable reputation far and wide that serves as a guarantee for the future. Among recent testimonials received is one from the manager of an important street railway, stating that the Vitæ brush had been run nearly 19,000 miles on one of its cars. As the life of the ordinary carbon brush is only about 2500 as a maximum, the weight of this statement is evident.

Digitized by Google

VENTILATION OF BOSTON SUBWAY.—The thorough ventilation of the Boston subway, as well as the prevention of any possible moisture, is receiving the careful attention that it deserves. A thorough circulation of air is necessary, and it is to be secured by the operation of four special electric fans recently constructed and installed by the B. F. Sturtevant Company, of Boston. These are of the cone type, two of them 7 ft. in diameter and two 8 ft. in diameter. Each is driven by a special direct-connected motor, and operating together they have a capacity equivalent to changing the air in that portion of the subway which they connect once in fifteen minutes.

THE MASON vitrified, salt glazed, terra cofta conduit made by the Potomac Terra Cotta Company, of Washington, D. C., is salt glazed inside and out, and offers but little friction to the drawing in of the cables. The standard length is 30 ins., and they are made in two and four way patterns, with ducts of 3 and 3¾ ins. in diameter, capable of carrying the largest size cables. The sections are made and registered accurately by means of iron dowels. They are used extensively by the Postal Telegraph Company, the Chesapeake & Potomac Telephone Company, the United States Electric Light Company and the Potomac Electric Power Company, all of Washington, D. C.

TREATMENT OF BURNS.—Electricians well know that an electrical burn is apt to resist the usual remedies and require a long time to heal. There is, however, a remedy known as Vitogen, which, it is claimed, will quickly cure such burns, and as this claim is substantiated by many testimonials from reputable physicians, and put forth by one of the leading drug manufacturing firms of the country—the G. F. Harvey Company, of Saratoga Springs, N. Y.—it is well worthy of attention by those apt to be thus afflicted. The AMERICAN ELECTRICIAN for May, 1898, contains a report from the "Medical Journal" of a severe case of electrical burn which was successfully treated with Vitogen.

ELECTRICITY IN CUBA.—The Krajewski-Pesant Company have opened a wholesale and retail electrical establishment at O'Reilly 15, Havana City, Cuba, the manager of which is Mr. Norman H. Schneider, who was in the export department of the Western Electric Company, of New York, for a number of years. They are prepared to handle all kinds of machinery and electrical materials, and are sole Cuban agents for a number of prominent American manufacturers, and also represent the General Electric Company in London. Mr. Schneider will be pleased to hear from any of his old friends. He reports that they have several plants near Havana which they are overhauling and putting into going order.

THE CENTRAL TELEPHONE AND ELECTRIC COMPANY, St. Louis, Mo., calls attention to the fact that they are removing from 1123 Pine Street to 909 Market Street, St. Louis, at which place they will occupy the entire building, and will be prepared to give their customers even better service than in the past. Mr. J. S. Cuming made a flying trip to Chicago last week, and called at the Western office of the AMERICAN ELECTRICIAN. He stated that they had done an unusually large business during the past year, and that they were never better prepared to handle large orders with facility and promptness than they are now in their new quarters. The many business friends of this concern will be pleased to learn of its growth and progress.

A LAMP NOMENCLATURE CONTEST.—The Warren Electric & Specialty Company, Warren, Ohio, as a result of a prize contest to suggest the most appropriate name for the high-grade lamp of their manufacture, has adopted the word "Peerless." Several hundred different names were suggested, and from these the committee to whom the suggestions were referred, decided upon the word "Peerless," and a prize of $50 was divided among the three persons who suggested this name. The second prize of $30 was divided among seven persons who suggested the word "Wesco;" a prize of $20 among five people who suggested the word "Liberty," and a fourth prize of $10 divided among four contestants who suggested the names of "Aladdin," "Aurora," "Eclipse" and "Encore," respectively.

A GERMAN P. & B. FACTORY.—Owing to the great increase in its foreign trade, the Standard Paint Company, of New York, decided some time ago to build a branch factory at Hamburg, Germany. This factory was begun in July, 1897, and completed in 1898, since which time all the compounds and apparatus manufactured by the Standard Paint Company in this country have been supplied by the branch factory at Hamburg. These include not only the P. & B. paint, tape, varnish, and other goods which pertain directly to the electrical trade, but also P. & B. rubberoid roofing, P. & B. building sheathing and insulating papers, and P. & B. preservative roof and structural paints. It is a good indication of the standing of this company's products that material which has proved so popular in this country is equally popular abroad.

PENBERTHY INJECTORS.—An injunction, with cost, has been granted to the Penberthy Injector Company, Detroit, Mich., against a concern which has been offering for sale an injector under the name of the "Penberthy injector." The court decides that the defendants by the formation of a company under a similar name, their location on the same street, and their persistence in using the word "Penberthy" upon their goods and in their business and corporate name and in all their advertising matter, thus leading buyers and people dealing with the concerns to think that the defendant corporation was a continuation of complainant's business as successor or otherwise, all led to the conclusion that they intended to appropriate a portion of complainant's good will and good reputation, and to divert the complainant's business to the defendants.

CLING-SURFACE.—The great extension of the business of the Cling-Surface Manufacturing Company, now at 146 to 152 Virginia Street, Buffalo, has compelled it to move from its former quarters in Court Street to the above address. Although the new factory is ten times as large as the former establishment, all available space therein, including a spacious laboratory, is used for manufacturing the daily output. That the sphere of usefulness of "Cling-Surface" is a large one is further attested by the fact that the output is being daily shipped to all parts of the globe, orders being received from South America, Europe, Asia, South Africa and Hawaii. Engineers who realize the tremendous loss of power every day and every hour in the day must necessarily be interested in a product which not only allows belts to run so slack that they almost touch, but secures an increase of power.

STORAGE BATTERY SUPPLY COMPANY.—Storage batteries and accessories have been manufactured by Theodore D. Bunce, of 239 East Twenty-seventh Street, New York, for the past seven years, and the business has assumed such proportions as to cause Mr. Bunce to form the Storage Battery Supply Company for the purpose of handling the increasing trade. Mr. Bunce is president of the new company, and states that a larger stock of cells for rental will be carried than heretofore, and that the company will extend the lines of manufacture previously conducted by him, which include storage cells and repair parts of every description, medical and dental outfits, carriage lighting outfits, etc. A seasonable specialty to which attention is particularly called is a complete outfit for lighting Christmas trees and for table decorations on special occasions.

AMERICAN ELECTRIC VEHICLE COMPANY, Chicago, announces that the contract and agreement heretofore entered into between it and the Indiana Bicycle Company, whereby the latter company undertook to build the electric vehicles for the American Company, was canceled and terminated Oct. 4, 1898, and that the Indiana Company has now no authority to build or sell the American electric vehicles, or vehicles made in accordance with the patterns or under the patents of the American Company, and has no right to deliver said vehicles, although contracted for or commenced during the continuance of said contract. The announcement states that the vehicles of the American Electric Vehicle Company are covered by letters patent owned by that company, and that purchasers of such vehicles from unauthorized parties will render themselves liable for infringement.

A "STERLING" SPECIALTY.—The beautiful white enameled dial of the Sterling Supply & Manufacturing Company, of New York, is coming to be seen more and more often on the cars of American street railways, small, as well as large, though hitherto a favorite among the larger companies chiefly. Its exclusive use by the Metropolitan Street Railway Company, of New York, is, of course, almost in itself a guarantee of its excellence and satisfactory qualities, since it is well known that every possible "leak" is avoided on the Metropolitan system, and no leak is so important as that of earnings. The Sterling trip and totalizing alarm registers are made with either the plain white disc referred to, or the dial indicator, as may be preferred, and are arranged for either cord or rod connection, as desired. All of the auxiliary equipment devices are of the finest quality and most carefully made.

MOTOCYCLE STORAGE BATTERIES.—J. K. Pumpelly, manager of the Crofton Storage Battery Company, Chicago, who has had sixteen years' experience in storage battery work, has produced two types of batteries especially designed for motocycle work. In one the plates are very thin and light but strong and tenacious, excelling in endurance the noted French "Fulmen" battery and equaling it in efficiency. The other is a battery of an entirely new type, in which the negative electrode forms the containing jar, thus doing away with the expensive rubber jar. This battery is very strong and light, and can be set up in any wooden box or frame suitable to go into the motocycle receptacle made for the purpose. The battery electrode consists of only two elements, is 4 ins. in diameter and 11 to 12 ins. in height. The two electrodes, positive and negative, of this surface and weighing 13 lbs., has a capacity when fully charged of 100 ampere hours. Machinery is now being made to make these batteries.

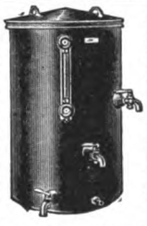
STREET RAILWAY SUPPLIES.—The Sterling Supply & Manufacturing Company, New York, has recently enlarged that portion of its plant devoted to the manufacture of insulating material and commutator bars, and large quantities are being turned out to meet a greatly increased demand. This insulation is a special compound molded while in a plastic state under hydraulic pressure. It is hard, tough and impervious to weather, and has high insulating qualities. In addition to these specialties, the Sterling Company also manufactures a large line of street railway supplies of various kinds, including the Sterling sand box, conductors' badges, the Sterling counter for counting reciprocating or rotary movements, including revolutions of wheel axles, machinery, etc., a wire-measuring machine, and a winding machine for recording revolutions of spindles and armature bobbins. With so large a number and variety of specialties, it goes without saying that the Sterling Company is of great use to street railway purchasers.

MURPHY AUTOMATIC SMOKELESS FURNACES, made by the Murphy Iron Works, Detroit, Mich., are to be attached to the twelve 375-h.p. Wickes vertical boilers for the Armour Company's new central station plant at Chicago Stock Yards. The Raritan Copper Company is now installing at its new works at Perth Amboy, N. J., a boiler plant of 1400 h.p., equipped with Murphy automatic smokeless furnaces. Coal and ash handling machinery will be attached in both the above cases. Other recent orders are for eight furnaces for the National Carbon Company, four of which are for new boilers and four displace another type of furnace; three for the Lakeside Hospital and three for the Upson Nut Company, all at Cleveland, O.; two for the J. C. Hubinger Co., Keokuk, Ia., for their plant at Quincy, Ill.; six for John Morrell & Co., Ottumwa, Ia.; six for the Cincinnati Street Railway Hunt Street Station, and four for the Cambria Company's works at Johnstown, Pa., making its twenty-seventh order and a total of 144 furnaces sold the latter company since May, 1890.

TELEPHONE EXCHANGES ABROAD.—L. P. Smith, of the Ericson Telephone Company, 20 Warren Street, New York, who has just returned from an extended business trip through Europe, states that the telephone system of Sweden, equipped with the Ericson telephones of Stockholm, is unquestionably the best in the world. Stockholm has the largest and most complete single telephone exchange in the world, there being 21,600 subscribers. In the principal hotels in Stockholm each room has a telephone directly connected with the exchange. The expense to each subscriber is from $10 to $16.60 per year. In

Digitized by Google

Copenhagen is an exchange of 12,000 subscribers lately completed and equipped with the Ericson telephone. The Ericson Company, of Stockholm, is also building an exchange in St. Petersburg for the Russian government. They are also filling an order of 10,000 telephones for the National Telephone Company, of London. After visiting the principal countries of Europe Mr. Smith is of the opinion that the telephone system in this country stands next to that of Sweden in completeness and efficiency.



CORRESPONDENCE INSTRUCTION.—It is safe to say that there is no system of education, aside from a university course, so well suited to the wants of all connected with the electrical profession and of those desiring to enter it, as correspondence instruction. This system has been gradually improved and developed until the present high standard has been attained. The courses in the United Correspondence Schools, 154 Fifth Avenue, New York, now represent the perfected result of seven years' experience in instructing by this method. The public has not been slow to recognize the advantages to be obtained by enrolling in these schools, and vast numbers of mechanics, engineers, attendants, superintendents, salesmen, firemen, motormen and others testify to the benefits which they have received from their scholarships. Special courses are offered in electrical engineering (complete), electrical station engineering, electric lighting, electric railways, telegraphy, telephony and electro-plating. Mechanical drawing and machine design, including the design of dynamo electrical machinery, are also taught.

LORD'S BOILER COMPOUNDS.—A recent number of the "Boot and Shoe Journal" contained a very interesting article giving percentages of failure in the wholesale boot and shoe trade, and concluded by stating that only one firm in a thousand can point with pride to a record of thirty years in that line of business. This percentage may also apply to many other staple trades, and makes the record of Mr. Geo. W. Lord, Philadelphia, Pa., of Lord's boiler compound fame, seem phenomenal. Mr. Lord has devoted his entire time and ability for the last thirty years to the one business of chemically treating feed-water for steam boilers, and as the result is now recognized by nearly all authors on steam engineering as an eminent authority on the subject. From the appearance of his general offices, mill and shipping rooms, one would judge that his life-long labors have not been in vain, as everything seems to be pushed to its full capacity. Mr. Lord stated, in a recent interview, that his business has increased year by year, not even decreasing in the late hard times, but has been greater in volume in 1898 than in any previous year.

THE MICA INSULATOR COMPANY, of New York, Chicago and London, manufacturers of "Micanite" materials for high-grade insulation, reports a gratifying demand for its commutator rings. The company makes a specialty of manufacturing molded insulation, and is now turning out for some of the large manufacturers of electrical machinery molded rings all in one piece. This pattern of ring is the most difficult insulation to manufacture, but as it comes from the machinery of this company it is as perfect as a stamped piece of steel ware, and has the same metallic ring. Electrical manufacturers will do well to write the company, sending their blue-prints for estimates. Another form of insulation of which this company has made a specialty is the armature trough or slot, which is now in use by many of the manufacturers of motors for crane work and by those who require a heavy insulation which will stand at very high voltage. While this form of insulation is a trifle more expensive than the common red paper and "mica," yet those concerns manufacturing machinery which receives such rough usage have found it necessary to get the best possible insulation for their armatures.

THE LARGEST VOLUME OF BUSINESS ever taken in a similar period by the C & C Electric Company, of 143 Liberty Street, New York City, is reported by that company as having been transacted during the first week of November. The company states that this business did not consist of comparatively few large orders from large centers, but was made up of orders of average size from nearly every quarter of the globe. An order, the history of which is rather interesting, was one from the R. H. Hood Company, of New York City, for two 120-kw. belted generators, with all switchboard equipment, and iron-clad, back-geared motors, aggregating about 100 h.p., for use in connection with apparatus for removing all the ashes from Greater New York to Riker's Island for the purpose of raising the level of that island. The C & C Forbes marine generating sets, comprising a C & C generator (either open or closed type), direct connected to a Forbes vertical en-

gine, are meeting with a steady demand for lighting yachts, ferryboats and other small and medium-sized craft. These sets are made in sizes ranging from 2½ to 17 kw. output, and are fully described in circulars published by the C & C Electric Company.

BROADWAY BRAKES.—Nearly every one who rides on the Broadway cars in New York City wonders at the power and delicate adjustment of the brakes in use thereon, by means of which a car may be run in a crowded street at considerable speed, almost to the point of touching a wagon or another car in front, and yet may be instantly brought to a complete stop by a slight movement of the gripman's hand. The brake which accomplishes this result is the invention of Thomas Millen, master mechanic of the Metropolitan Street Railway Company, and is made by the Sterling Supply & Manufacturing Company, New York. It is a simple hand brake, with one essential peculiarity, namely, that the usual movement of the brake rod is multiplied in power through a gear and pinion working in the ratio of 5 to 2. On the gear axle is a double sprocket wheel, which operates the brake levers by means of a chain. Another feature of the entire brake apparatus is that the brake shoes are run very close to the wheel, so that a slight motion only is necessary to bring them to full bearing, and the wear in the brake shoe is taken up in the chains connecting with the brake rod. Another well-known device made by the same company is a street car fender, also in use in New York and other cities. This is a track fender, not a dashboard fender.

THE PELTON ENGINEERING COMPANY has been incorporated at Cleveland, Ohio, by W. H. Pelton, H. H. Holding and Allan Bassett, and has acquired all the available assets of The Cleveland Electric Trading Company, formerly doing business at 806 The Cuyahoga, and of The Cornman Company, assigned. It is the purpose of the new corporation to act as contracting engineers in the erection of steam and electric plants and as manufacturers' agents for a few first-class lines of apparatus. They have already some very good agencies, and have considerable work on hand. They will also carry a full line of station supplies, making a specialty of repairs and supplies for Brush arc apparatus. The company expect to locate very shortly at 1076 Hamilton Street in the buildings now occupied by The Parish & Bingham Company, and will be exceptionally well located for the handling of general electrical business. Regarding the personnel of the firm, Mr. Pelton has had some years of active experience handling electrical machinery, and in the design and erection of power station work, and is well fitted for handling very heavy erection. Mr. Holding, the vice-president of the company, graduated from Rose Polytechnic Institute in '87 and entered the engineering department of the Thomson-Houston Electric Company, remaining with them until their consolidation with the Edison interests. He then entered the engineering department of the General Electric Company, remaining with them for several years as an expert, during which time he installed several very large plants. Mr. Bassett, secretary of the company, who will take the sales department, is a young man who has already an exceptionally wide acquaintance among central station men and the electrical trades. He is thoroughly familiar with the principal systems of light and power distribution, and has also had considerable experience pioneering electrical enterprises. Manufacturers who are not now represented in the central section are invited to correspond with this company.

**CAN YOU SOLVE THIS PUZZLE VERSE?**

"A simple go-between am I,
Without a thought of pride;
I part the gathered thoughts of men,
And liberally divide.
I set the soul of Shakespeare free,
To Milton's thoughts give liberty,
Bid Sidney speak with freer speech,
Let Spenser sing and Taylor preach.
Though through all learning swift I glide,
No wisdom doth with me abide."

If you can solve the foregoing, and send the correct answer to George H. Heafford, General Passenger Agent, Chicago, Milwaukee & St. Paul Railway, Old Colony Building, Chicago, together with a two-cent stamp, he will send you what it calls for.

**Greatest Fuel Saver on Record.**

THE
**MASON HYDRAULIC DAMPER REGULATOR.**

Will control one boiler or a battery. Guaranteed to change the damper on the slightest variation in steam pressure.

# American Electrician.

Vol. XI. New York, February, 1899. No. 2.

## ELECTRICITY IN A MEDICAL CLINIC.

### ELECTRICITY AT THE POLHEMUS MEMORIAL CLINIC.

The average isolated electrical installation partakes of a certain sameness, which makes descriptions in this day of enlightenment on engineering matters of this nature somewhat tedious, but in the case of the plant which has been chosen as the text of this article, the writer believes that the exceptional thoroughness of the installation, the unique applications of electricity which are employed and the numerous and highly ingenious methods of convenience and economy which are incorporated into its construction, will render a description interesting to those who are in search of something new.

The building in which this plant is installed is located on the corner of Amity and Henry Streets, Brooklyn, N. Y. The cost of erection was defrayed from funds donated by the widow of Henry Ditmas Polhemus, and is wisely managed by Mr. Wm. B. Davenport, attorney of the estate and president of the Clinic. The generous donation was sufficient to enable the highest grade of electrical and mechanical engineering to have a free field.

The building is an imposing structure of eight stories high and is thoroughly fireproof. The architecture is French Renaissance. The frontage on Henry Street is sixty-eight feet and the Amity Street frontage is ninety-two feet. The walls, floor, roof, and many of the partitions are constructed of steel girders with masonry enclosure. A complete system of ducts is provided for steam and water pipes, for ventilation and for electric cables.

The boiler room of the plant is located under the sidewalk on Amity Street, and the sidewalk under Henry Street is devoted to a coal bunker of 300 tons capacity. From the bunker to the boilers runs an overhead trolley (Fig. 4), similar to that used by wholesale handlers of beef. Instead of sides of beef this trolley enables the ready movement of a dumping bucket which will easily carry 500 lbs. of buckwheat coal. This bucket is readily filled from the coal bunkers by an appropriate chute, and before its contents are finally dumped on the boiler-room floor, it is weighed, for the track is provided with a section which is connected to a Fairbanks scale. A record is made of the weight of every bucket of coal that is delivered to the furnace.

A similar trolley system is used for the removal of the ashes. These are placed in cans, and by means of a trolley are transferred to a little hydraulic lift which raises them to the level of the sidewalk.

The ashes are weighed as well as the coal, a limiting ratio of the weight of the ashes and coal is set, and the fireman is expected to keep close to these figures. With the coal that is now in use, which is a good grade of the buckwheat variety, the ashes from three tons of coal must not exceed

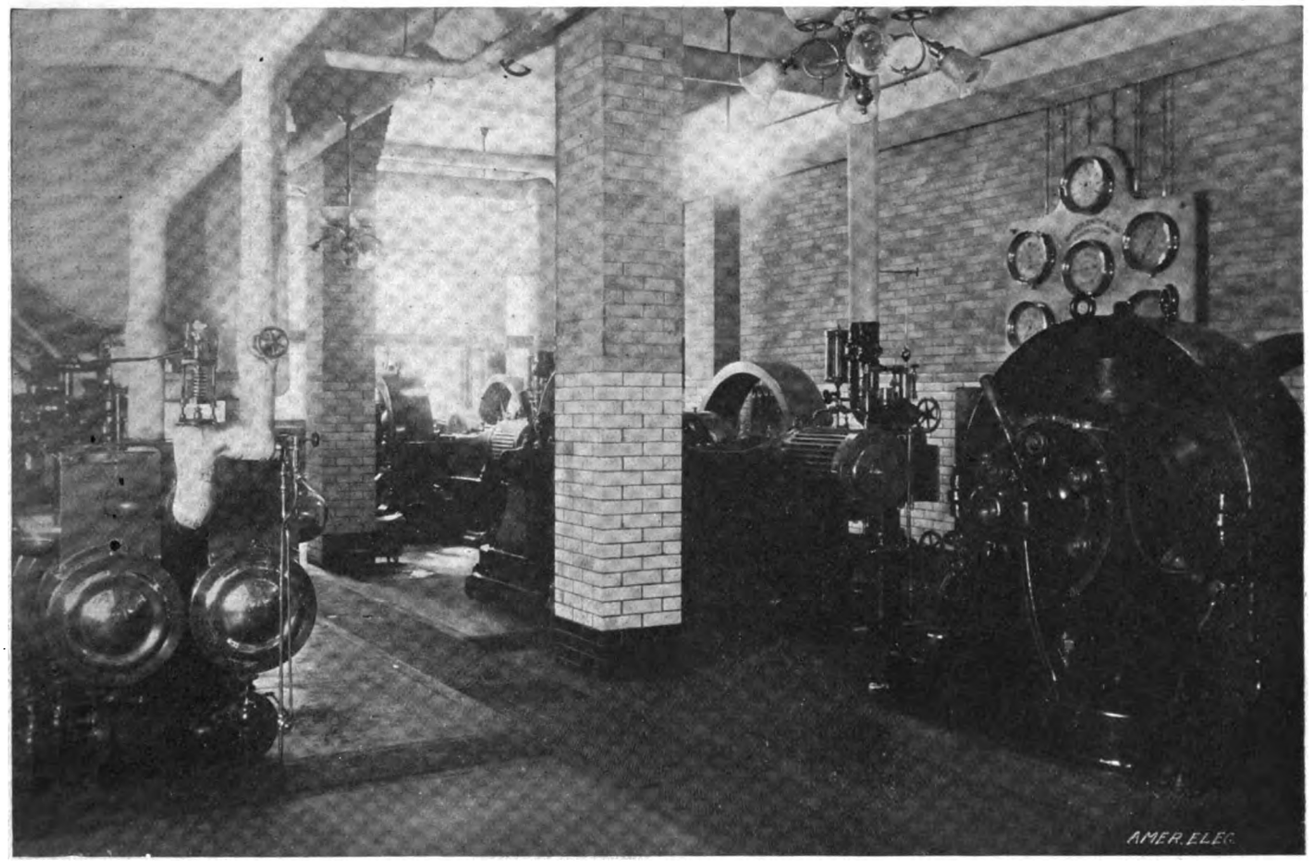

FIG. I.—VIEW OF GENERATING ROOM.

Digitized by Google

900 pounds. The average coal consumed during cold weather is 3½ tons per day.

In order to keep up to the ratio which has been set, it is necessary for the fireman to keep a thin fierce fire under the boilers and to fire frequently. The fire carried is scarcely more than four inches thick and the "spread firing" method is used. This is essential, for a thick fire of fine coal offers great obstruction to draft as it tends to pack closely.

The boilers are of the Babcock & Wilcock type. There are two of them, rated at 150 h.p. each. They are provided with a brick setting and the grate surface underneath each of them is 35 square feet. The fires are cleaned twice a day, and this operation is much facilitated by means of a dumping grate. An argand blower is fitted for one of the furnaces, which is pressed into service in cold weather, since the present boilers are now taxed to their fullest capacity.

The flue gases pass to a breeching at the back of the boilers, which takes a downward drop of about 6 ft., and then passes to a 145-ft. stack, 48 ins. in diameter. The breeching is covered with magnesia, and it may be added that insulating covering is profusely used throughout the plant, and that even the water supply pipes are thus covered, the idea being to stop annoying drips from pipes sweating and also as a matter of appearance. A general view of the boiler room is given in Fig. 4.

The pressure carried in the boiler is 100 lbs. It is fed with city water, which has proved very satisfactory. Brooklyn water is said to be softer than New York water, but it contains more material in suspension. This water is passed through a filter which removes a great deal of foreign matter. The filter used is very satisfactory and was

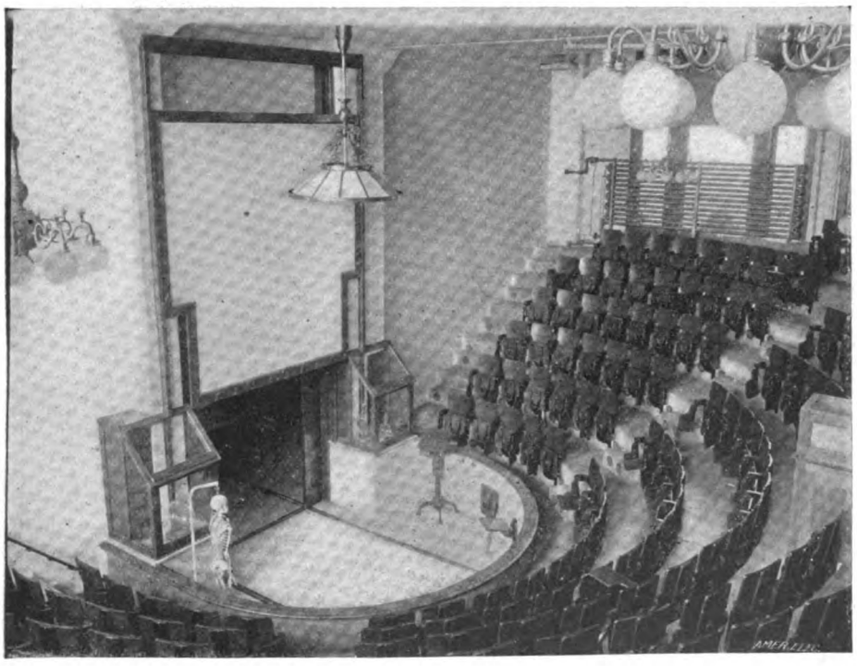

FIG. 3.—OPERATING AMPHITHEATRE.

furnished by the Ward & Upright Engineering Company of Brooklyn.

After passing through the filter the water enters a Berryman heater which receives the exhausts of the engines, and its temperature is thereby raised nearly to the boiling point. Two feed pumps are supplied, either of which can easily feed both

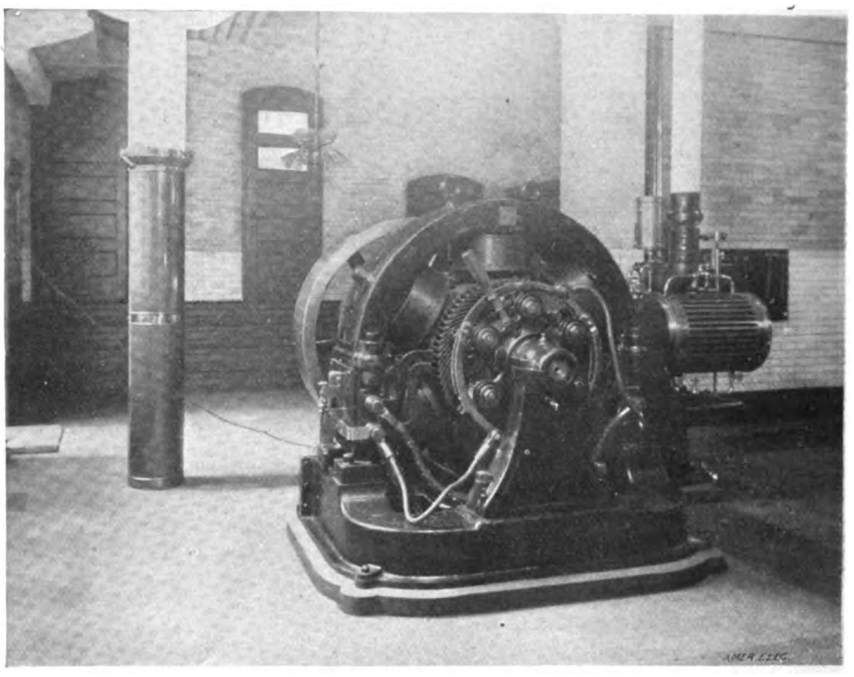

FIG. 2.—ONE OF THE GENERATORS.

boilers. Besides these feed pumps there are two compound elevator pumps, a pump for fire and house purposes, two pumps to return water from heating stacks to the boiler, a pump to take care of the drips from traps, etc. The latter three and the feed pumps are governed by Kieley pump governors. A moving injector is also provided, and in this way the boiler may be fed from five different sources, which practically renders a break-down of the feeding system impossible.

A feature of this plant is the great economy which has been effected in saving heat and hot water. The returns from the steam heating system are taken care of by the pump governor already mentioned. A refrigerator system which uses heating coils for evaporating the ammonia, disposes of its condensation in two ways; a portion of it is used for making ice, and as it is distilled water very pure ice can be manufactured therefrom—in fact, the very action of freezing tending to remove foreign substances of all kinds. The remainder of the condensation from the refrigerator heating coils is delivered to the pump governor and returned to the boilers. Even the heat in the blow-off tank is largely abstracted before its contents are permitted to run into the sewer. The building must be supplied with very hot water, for it is very necessary in surgical work, and the blow-off tank contains a system of coils through which water is passed and thereby heated for this purpose. So effective is this device that an automatically controlled heater which was installed for the purpose of heating this water and which employs live steam, is never used. This arrangement has the further advantage that it reduces the temperature of the waste drips to such a degree that they may be safely pumped into the sewer. Without this arrangement it would be necessary to use cold water from the meters to pass through the coils in the drip tank in order to reduce the temperature of the waste sufficiently to comply with the law.

The refrigerator system is provided with a condenser which uses a considerable volume of water from the city service. A tank is provided for the accumulation of this condenser water and fitted with ball cocks to supply it without overflow when the re-

Digitized by Google

frigerator is not running. This tank is connected with the house pumps which supply the tank on the roof, and also with the feed pumps, by means of which its contents can

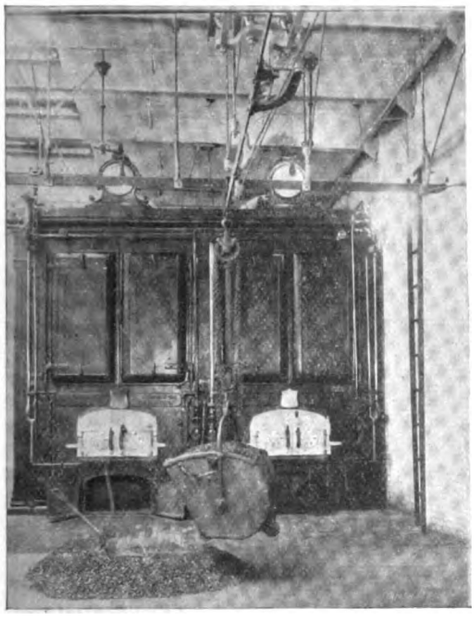

FIG. 4.—FIRE-ROOM, SHOWING COAL CONVEYOR.

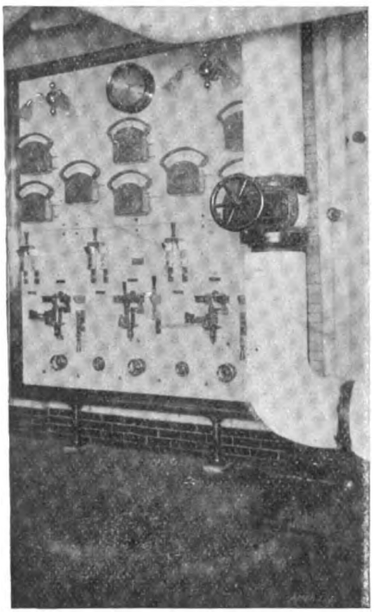

FIG. 5.—SWITCHBOARD.

be fed to the boiler if that is desirable. These economies are very effective and materially reduce the cost of operation.

The boilers generate an excellent quality of steam which they deliver to a 10-in. header. This header is fitted with appropriate valves which are in many cases in duplicate and with a 4-in. bypass. The valves are all Jenkins' make with the exception of the back pressure valve and the reducing valve, which are of the Kieley type. The system is thoroughly drained at every pocket by Kieley traps and no separators are necessary. The steam pipe system is covered with asbestos, which has been put on with great neatness. The general effect is very pleasing, and once a week, or as often as may be necessary, all discolored spots are painted with James Clark's special preparation.

The steam is delivered to three small Ball & Wood engines. These engines have cylinder dimensions of 13 x 12 ins., a speed of 275 r.p.m., and develop 90 h.p. at 100 lbs. of steam. They are equipped with the new Rites governor, which has been recently improved by the Ball & Wood Company. The moving parts are inclosed in such a way as to effectually prevent danger or damage and to readily permit inspection of bearings and slides.

The performance of these engines is highly satisfactory. They run almost noiselessly, the only sound that can be heard being that of the steam passing through the ports, while the absence of all vibration can be effectually demonstrated by the old-time test of balancing a nickel on the valve chest. This performance is partly due to the excellent foundations, which are 14 ft. deep.

The engines exhaust into a long header which passes up through the flooring and, returning above the engines, enters one side of a Berryman heater of appropriate capacity. The riser to the upper system of exhaust piping resembles a supporting pillar of the structure, and appears at the left in a picture of one of the units. Fig. 3 gives a general view of the engine room.

The heater into which the engines exhaust is connected in a unique manner. The engines do not exhaust through the heater but into it, for the other side or outlet is closed. Thus the heater is connected like a condenser and the condensation which accumulates in the bottom is pumped into the drip tank. In spite of this unusual method of connection, it remains to be said that the heater most efficiently accomplishes its purpose of heating the feed water to a high temperature.

Back pressure valves are provided on the exhaust system, which enable the engines to exhaust into the atmosphere if the back pressure should exceed a certain amount, and this amount is fixed at from 2 to 4 lbs., according to the state of the weather.

Besides the heater, the exhaust of the engines also enters the steam radiator system of the building. This system is arranged on the double pipe plan and consists of three parts, the direct, the indirect and the direct-indirect methods of heating being practiced. The direct-indirect system is used in corner rooms, where the dust from the blast wheels could not very well be carried; the air in this case is taken from the outside through registers in the walls.

Double pipe radiators distributed throughout the building and provided with automatically controlled valves, comprise the direct system. The indirect system consists of 7000 ft. of pipe, which is constructed into an appropriate radiator, and installed in a chamber through which air is forced into the ventilating ducts. Both of these radiator systems drain to the pump governor, as before mentioned.

The lubricating system of the plant is very complete and effective. Two large cylinder lubricators are provided, and either one is capable of lubricating all of the cylinders in the entire plant. These lubricators are piped to the various cylinders, and at each of them the oil passes through a suitable sight-feed indicator, delivering oil to the entering steam pipes. The indicators are each provided with a little wire passing through the cylinder of the tube, which serves to guide the bubble of oil straight upward and prevent its fouling against the sides.

A central distribution of oil in this way is much to be desired, for in the first place it requires less care than a multiplicity of small lubricators, and in the second place less oil is wasted, for as is well known, ordinary lubricators are filled to overflowing and the surplus oil is wiped off with a piece of waste, both of which are undesirable in a station.

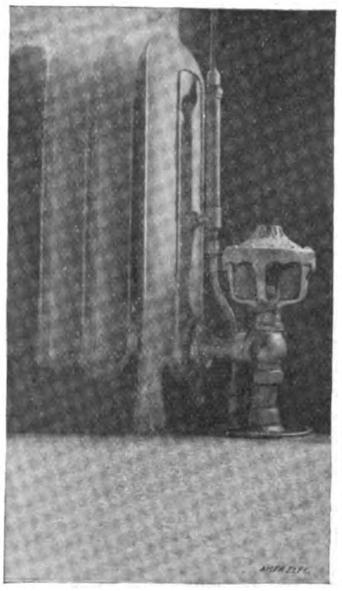

FIG. 6.—THERMOSTATIC VALVE FOR RADIATOR.

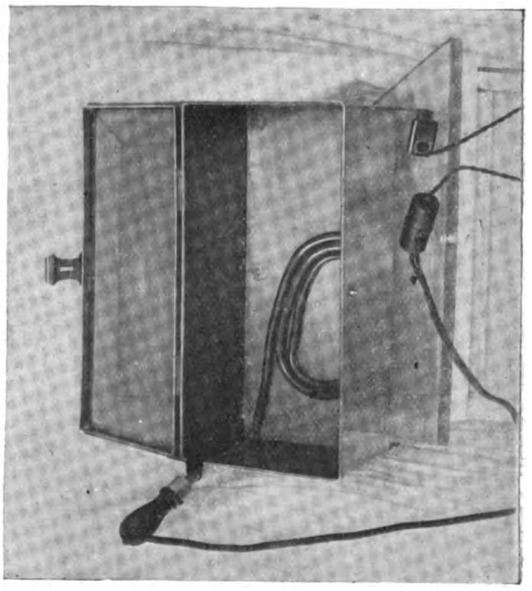

FIG. 7.—HEATING COIL FOR STERILIZER.

Digitized by Google

The engine lubricators are supplemented with a small cylinder lubricator, which may be operated in case both of the large lubricators should fail, and they are also provided with a hand oil pump which serves the double purpose of an additional reserve and as a means of injecting Dixon's graphite into the cylinders. The management are great believers in this material as a cylinder lubricator and supply it to all of their high-speed pistons.

The lubricating system of the high speed bearings, which require a thin oil, is also centralized and consists of a purifier and two reservoirs. The oil is forced from the reservoir to the engine bearings by means of compressed air, and is delivered in a steady stream on each bearing. It is drained from the ends of the bearing by appropriate troughs and passes back to the purifier, by means of which it is thoroughly cleansed and returned to the reservoirs once more. The two reservoirs are used alternately, as it is believed that the oil improves on standing for a period. Compressed air has been found vastly superior to water pressure as a means of forcing oil to the bearings. Water is likely to contain ingredients which might cause the oil to saponify, and in addition, means must be provided for periodically removing the accumulated liquid. Connections, however, are made to use the water pressure in case the compressed air system should fail.

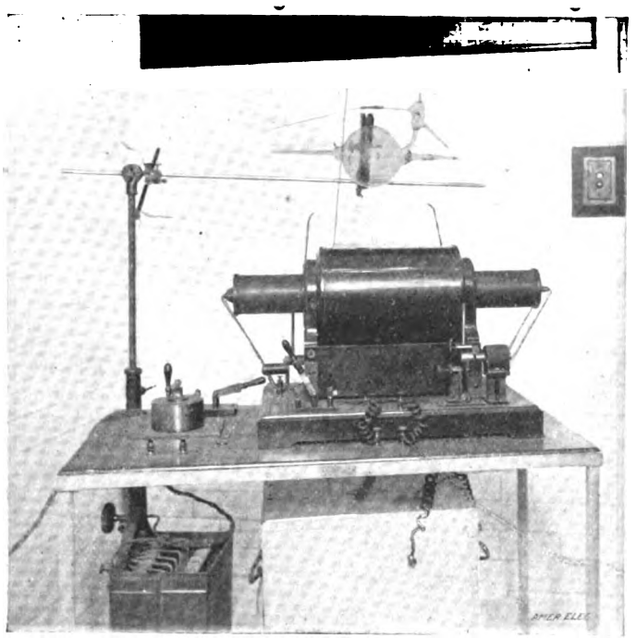

FIG. 8.—RONTGEN RAY OUTFIT.

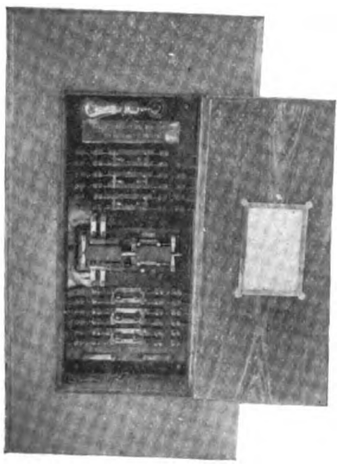

FIG. 9.—CAUTERY TRANSFORMERS.

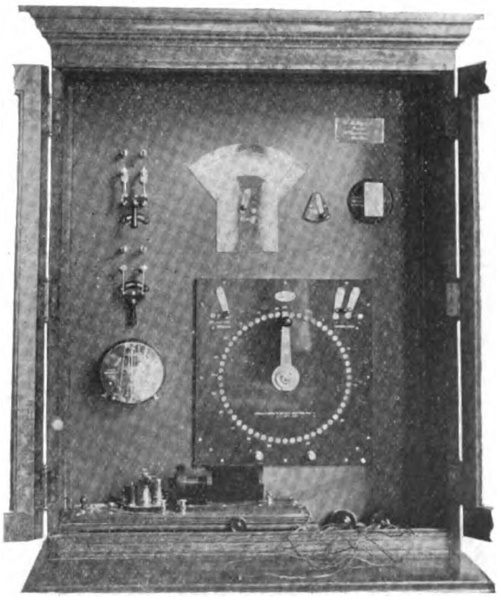

FIG. 10.—ELECTROTHERAPEUTIC CABINET.

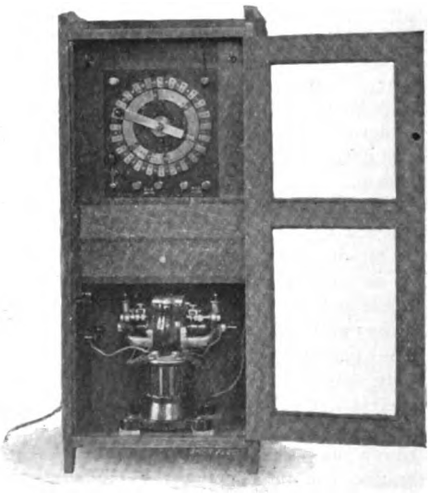

FIG. 11.—DISTRIBUTING CABINET.

The compressed air system is a feature of the plant and is worthy of special description. A small pressure tank is provided, which is kept at 15 lbs. by a little double cylinder pump. When the pressure drops below this figure, a little piston in a suitable cylinder is forced inward by means of a spring and thereby actuates a small valve which admits compressed air to the various automatic valves necessary to control the pump, which immediately starts up and quickly raises the pressure to the required amount, when the little piston is forced out, turning air on the diaphragms and the valves promptly close.

This compressed air is used for operating the automatic valves of the radiators, which are controlled by thermostats. All of the automatic valves of this class are of the Johnson make. In addition, compressed air is also used for the oil reservoirs as already indicated, and for the embalming of dead bodies, which are frequently received at the Clinic for scientific purposes. The embalming fluid is placed in a two-necked bottle, the delivery tube of which is sufficiently long to reach to the bottom thereof. Compressed air is forced into a tube, which is tightly sealed into the other neck of the bottle, which forces the embalming fluid out and injects it by means of suitable connections into the veins and arteries of the body to be embalmed.

The radiators and the thermostats controlling them are interesting and are shown in Figs. 6 and 15. The thermostat consists of a little arm made of two strips of brass and steel sweated together. This arm is bent into a U shape, and under the influence of lower temperature, tends to bend still more by reason of the unequal contraction of its component metals. In the act of bending it presses a little leaden cap over a minute orifice and thereby permits compressed air on the backs of diaphragms of steam and return valves to escape, a spring under the diaphragm then opening the valve controlling the radiator. Should the temperature change a sufficient amount, the leaden cap opens the minute orifice in the thermostat, the operations are reversed, the radiator valves are closed. A little screw at the base of the thermostat enables

Digitized by Google

its adjustment for a considerable range of temperature.

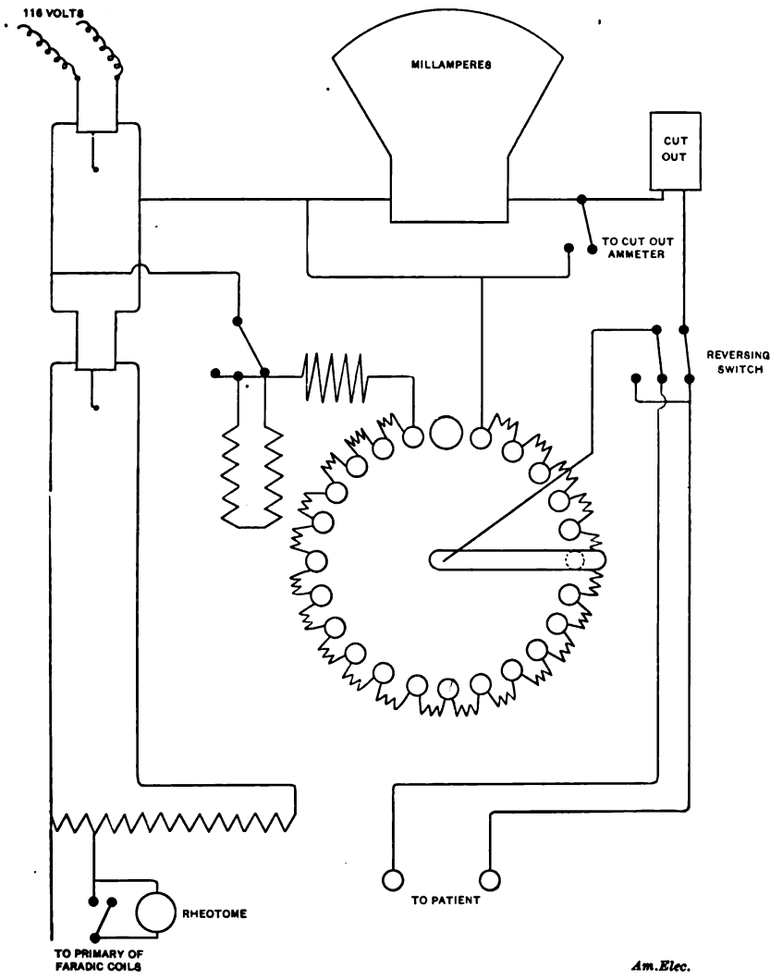

FIG. 12.—DIAGRAM OF MEDICAL SWITCHBOARD.

The source of electrical power in this building consists of three Western Electric dynamos. These machines, which are of 50-k.w. capacity are provided with 6 poles and directly connected to the Ball & Wood engines. They are arranged to operate in multiple and for this purpose are provided with equalizer connections, the equalizing switches being on the machines. They deliver their current to a switchboard, furnished by the Western Electric Company, on which are placed suitable instruments and switches for measuring and controlling the output. Each machine is provided with a main switch, a circuit-breaker, ammeter, voltmeter, and ground-detector, with switch to each machine, bus bar and to ground. A differential voltmeter is also provided and is found very convenient. All of the instruments are of the Weston illuminated dial type. An illustration of the switchboard is given in Fig. 5.

The system of wiring is on what is known as the cabinet plan. Each floor is provided with risers which pass to a cabinet which becomes the center of distribution. These cabinets are well designed and are of excellent workmanship. Each circuit is provided with a baby knife switch and fuse.

One of the cabinets is shown in Fig. 11. It is lined with slate, which is painted and grained to resemble woodwork. On the door of the cabinet is placed a panel containing a typewritten sheet explaining the various circuits that the switches control. To facilitate the explanation, the switches are all numbered.

A feature of interest in the cabinet shown is the automatic switch which appears in the center of the panel. This consists of a double solenoid which acts on an iron core. When the core is in one side of the solenoid, it completes the circuit for the other half. The plunger is attached by a suitable system of levers to a double pole knife-switch, which it is thus enabled to operate. The chandelier which this switch controls is located in the lecture room, and at a suitable point two buttons are provided, one in each solenoid circuit. Thus controlled, the plunger can be made to move to the right or to the left and close or open the switch as desired. There is also another point where two controlling buttons are installed, and there could easily be as many as might be desired. The chandelier and similar lights are controlled by means of Cutter flush switches in addition to their control at the distribution box. The building is wired throughout in iron armored interior conduit. There are many plug sockets in the building which are of the flush type.

The ventilating system of this building is very complete, and it is interesting, for electricity plays an important part in its operation. A large space in the basement is set apart for a ventilating chamber. Into this the air enters and is drawn through screens by two large engine-driven Sturtevant fans, 7 ft. in diameter. They force the air into a large chamber into which is placed the heating coils before mentioned, and from thence air is distributed by suitable ducts into every room in the building. The exit of the air is provided for by another system of ducts, and on the roof of the building are installed three large electric motors, two of which drive fans for the purpose of drawing the air out of the building and are connected to these exit ducts. The third fan is 54 ins. in diameter, driven by a 7½ h.p. motor, and employed for forcing air into the dissecting room through automatically controlled heating stacks. The air is drawn out of this room by the same system of ducts that serve to remove the air from other parts of the building. The dissecting room, from the nature of the operations carried on there, requires special ventilation and the

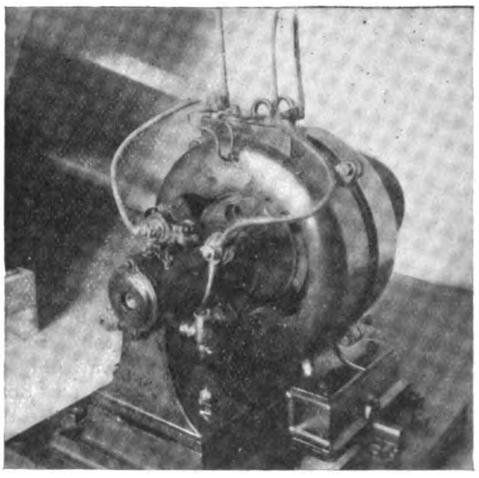

FIG. 13.—VENTILATING MOTOR.

FIG. 14.—CAUTERY TRANSFORMER.

Digitized by Google

air is changed in this department very frequently.

In Fig. 13 is shown a view of the Lundell motor, which is typical of those used for driving the fans in the upper part of the building. The two fan motors which are used in forcing the air out of the building are of 20 and 30 h.p., respectively.

The applications of electricity to surgery and medicine, though very diverse as far as the actual methods of treatment are concerned, do not employ such a large variety of apparatus as has been supposed. For the direct application of electricity to the human system a combination board is provided. On this board are arranged a main switch, a milli-ammeter and an adjustable resistance through which current from the lighting circuit is passed. This resistance is tapped off to many points arranged in a circle on the switchboard and over these points swings a contact arm. One electrode is connected to one terminal of this resistance, and the other to the contact arm. As the latter is swung over its points, the potential between the electrodes rises. By throwing in additional resistance in series, the current in the main circuit is reduced, and the difference of potential between sections thereon is correspondingly reduced. In this way the patient can be submitted to from zero to thirty volts in steps of one volt, and from thirty to eighty-five volts in steps of two volts. The milli-ammeter is connected in series with the patient and the current that is used can thus be determined. The instrument has two scales, one reading 50 milli-amperes and the other 500 milli-amperes. There is also in series with the patient an automatic cut-out which can be set to break the circuit should the current by any accident reach a dangerous value.

A faradic coil of the Dubois-Raymond type is employed. Two secondaries are provided for this instrument, one of fine and one of coarse wire, and the intensity of shock is regulated by varying the position of this coil with reference to the primary winding, a rack serving to drive the secondary coil back and forth over the core. There are two circuit breakers, each of which has certain advantages. One of these is for low frequencies, and is built on the metronome plan. The circuit is broken by means of a clock-driven pendulum with an adjustable bobbin, and can give interruptions from 6 to 600 per minute. More rapid interruptions are provided by means of an ordinary vibrator. The contact of this vibrator is mounted on a swinging arm, which can be moved so that its position relatively to the point where the spring of the vibrator is fastened varies. In this way a considerable range in the rapidity of interruption can be obtained, and the circuit-breaking devices enable the use of any frequency within wide limits. A photograph of this board is shown in Fig. 10, and a diagram of the connections appear in Fig. 12, and from them the method of operation of the apparatus can be easily understood.

Another interesting adaptation of electricity to surgical uses are the cautery instruments. These consist of a rotary and a static transformer. The rotary transformer takes current at 118 volts, and from two collecting rings which are tapped into the armature winding at equally distant points, it delivers alternating current to a static transformer, the secondary coil of which is adjustable. Taps lead from various points of the secondary winding to a series of contacts arranged in a circle, and an arm swinging over this contact varies the amount of secondary in circuit. The range of pressure obtainable is from zero to 8 volts in 48 steps, and the quantity of current is sufficient to heat the largest part of the electrodes to full working temperature. This current may also be used for lighting miniature incandescent lamps for dental and surgical purposes.

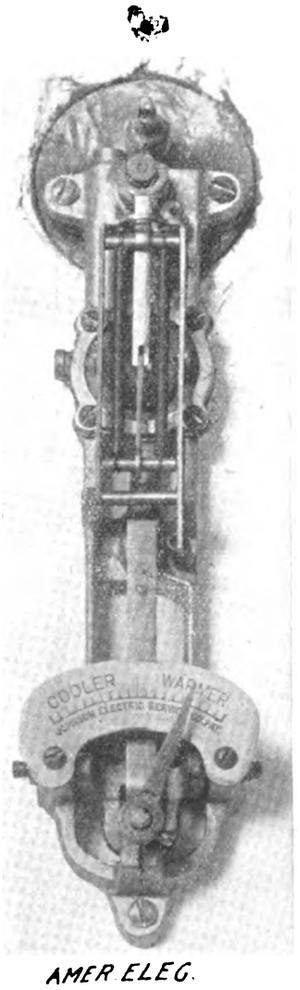

FIG. 15—THERMOSTAT.

There are four equipments at the Clinic, which have different types of transformers. One of these complete is shown in Fig. 9, and the other is shown in Fig. 14. Both of these transformers were made by the Holtzer & Cabot Electrical Company. The ironclad machine shown in Fig. 14 has in addition an extension on its shaft to which may be coupled drills and other appliances for cutting bone. The machines are capable of delivering 1/6 h.p., either in mechanical power for the bone-drilling devices, or alternating current for the static transformer as may be desired.

The Clinic is provided with an excellent Röntgen ray equipment which is shown in Fig. 8. It consists of a Queen induction coil which is capable of striking fully 10 ins., a large condenser for minimizing the spark at the circuit-breaker, a fluoroscope and a supply of tubes. The tube shown in the photograph is of the self-regulating type, and is said to maintain a very constant degree of vacuum. The current is supplied to the apparatus from the lighting circuit, across the terminals of which a resistance is connected. The coil is connected across a suitable section of this resistance, and in this way receives the necessary low voltage. The condenser used with this coil is of very large capacity, and when charged at full dynamo pressure, contains enough electricity to run the vibrator for an appreciable period of time and discharge several sparks across the terminals of the secondary.

Electric lights are largely used in the building for illuminating devices for examining the eye, and electric lamps are used for the laryngoscope and similar devices for examining the mouth and throat. About 1000 incandescent lamps and 26 enclosed arc are installed in the Clinic and in the laboratories, lecture-rooms, etc., of the teaching department of the endowment.

It may be safely said that this building is one of the best of its kind in the world. Every pains has been taken to render it so, and money has not been spared. The corners of the wainscoating and the walls are rounded to prevent the accumulation of dirt and dust. The doors are built up without panels and present a perfectly smooth surface without trimming or moulding of any kind, and are veneered with ¼ in. solid oak. Everywhere in the various departments the flooring is of tile or mosaic, the walls are of enameled brick and the furniture of glass-enameled iron or the smoothest quartered oak. It is a most discouraging structure for a microbe in which to find lodgement, and it is very easy to keep clean.

The design and execution of the electrical and mechanical equipment of this building is largely due to the present superintendent, Mr. J. G. Ould, who has since its inception exercised the most scrupulous care and attention in its construction, operation and maintenance.

## American Electrical Market Abroad.

The United States Consul at Brussels reports that the electric lamps, as well as nearly all other electrical supplies used in Brussels, are principally of German origin, Holland supplying a few, and England a fair percentage of the electrical wires employed. American lamps and other electrical goods are exposed for sale on this market, and are conceded to be superior to those imported from Germany, France and England. The Consul believes that with proper effort the trade in this line could be greatly increased, especially in copper wire, insulated wire, large cables and arc lamps.

# Induction Motors.

## POLYPHASE AND SINGLE-PHASE ALTERNATING CURRENT INDUCTION MOTORS.

BY ERNST JULIUS BERG.

In the first part of this article was discussed the construction of synchronous motors, their similarity in general constants and appearance to ordinary alternating current generators, and the necessary field adjustment to operate them at various power factors; their use as phase controllers, that is, for compensating for lagging currents incidental to other loads; their use to obtain a constant potential point in any part of the distribution, and, finally, the conditions which govern their starting torque.

### POLYPHASE INDUCTION MOTORS.

The greater number of this type of motors are also of the polyphase type; although a great many more single-phase induction motors are installed than single-phase synchronous motors.

The characteristic features of induction motors compared with synchronous motors are that they are self-contained units; that is, they do not require any exciters, and they start with considerable torque—in fact, can be made to start with any torque. Although they do not run at exact synchronous speed with the generator, their speed is nevertheless practically synchronous. It can, however, be varied, yet they are not well suited for efficient operation at the variable speeds. They will operate with as high efficiency as synchronous motors and direct current motors, but necessarily have a lower power factor, thus introducing lagging currents into the system on which they are run. Their overload capacity is, as a rule, large, although not so large as that of synchronous motors.

Regarding their mechanical construction, one part, the primary, has a winding similar to that of the direct-current machine. The secondary winding, however, is often extremely simple, consisting in one type of motors simply of copper bars projecting through the iron laminations without any insulation whatever, and connected together by copper rings at each end.

They are built on essentially two different lines— one type with regular winding on primary and secondary, the other with regular winding on the primary and squirrel cage winding on the secondary. Depending upon the use intended for the motor, one construction or the other is preferable. Indeed, the starting conditions of the motor in almost every case decide the type.

Motors with definite winding on primary and secondary can be made very efficient and still start with any desired torque and with reasonably small starting current, by the use of a resistance in the secondary. Motors with squirrel cage armature can be made to start with considerable torque, but are then necessarily less efficient, or take in starting a larger current.

The first type of motors may be recommended and used wherever considerable starting torque is desired, and where the current taken by the motor must be limited. The second type has the advantage of greater simplicity, and may be used where less starting torque is necessary, and then in connection with the compensator, so that the motor is started at a reduced voltage, and therefore with a reasonable current.

In places where motors have to operate in damp atmosphere, and, in general, in places where they are exposed to considerable hard usage and subject to little care, the squirrel cage type should be used, even if the starting torque has to be large.

The characteristics of a polyphase induction motor are essentially those of a direct-current shunt motor; that is, it is an approximately constant speed motor. Speed

TABLE I.—CONSTANTS AT VARIOUS SPEEDS.

| | Eff. | P. F. | App. Eff. | Torque App. Eff. |
|---|---|---|---|---|
| At rest..... | 0. | 90 | 0 | 80 |
| ¼ speed.... | 22.2 | 90 | 20 | 80 |
| ½ " .... | 44.5 | 90 | 40 | 80 |
| Full speed.. | 89 | 90 | 80 | 80 |

control can be obtained by varying the secondary resistance or the impressed electromotive force, or by changing the connections of the field winding whereby the motor speed is reduced or increased by reducing or increasing the number of poles.

The first method, that of varying the resistance of the secondary, is the most efficient, but necessitates the use of a specially wound secondary.

The efficiency is proportional to the speed, and the power factor is constant at all speeds, so that, for instance, a motor with 89 per cent efficiency and 90 per cent power factor at full load would have the constants at rest, one-quarter, one-half and full speed, which are given in Table I. The current is proportional to the torque.

The second method, that of changing the speed by means of impressed voltage, can only be made as good at one particular speed, and is always very much inferior at others. Depending upon the shape of the torque curve, the efficiency and power factor of such a motor changes over a wide range.

It is always advisable to make the sec-

TABLE II.

| | Eff. | P. F. | App. Eff. | Torque App. Eff. |
|---|---|---|---|---|
| At rest..... | 0. | 48 | 0. | 23 |
| ¼ speed.... | 10.5 | 50 | 19.5 | 29 |
| ½ " .... | 32.5 | 60 | 19.5 | 39 |
| Full " .... | 87. | 90 | 78.5 | 78.5 |

ondary of comparatively high resistance and of lowest possible reactance; therefore, if the motor above mentioned were built for compensator control—that is, speed control by change of impressed voltage—the efficiency would probably not be more than 87 per cent to give the best all around conditions.

Assume, furthermore, that the motor is built for a maximum of 50 per cent more starting torque than rated torque at rated voltage, it would have the constants given in Table II. The power factor is practically the same at the same speed, regardless of impressed voltage.

In Table II. the heads of the several columns have the following definitions:

$$\text{Efficiency in this table} = \frac{\text{Mechanical Output}}{\text{Electrical Input in Watts}}.$$

$$\text{Power Factor} = \frac{\text{Electrical Input in Watts}}{\text{Electrical Input in Volt-Amperes}}.$$

$$\text{Apparent Efficiency} = \frac{\text{Mechanical Output}}{\text{Electrical Input in Volt-Amperes}}.$$

$$\text{Torque Apparent Efficiency} = \frac{\text{Power at Synchronous Speed for Given Torque.}}{\text{Electrical Input in Volt-Amperes}}.$$

The third method, that of changing the number of poles, even disregarding the feature of a complicated mechanical construction, would not permit of a gradual change of speed. For instance, by changing the number of poles from six to four, the speed of a 60-cycle motor would be changed from 1200 to 1800 revolutions, which is rather a large step.

The constants of such motor at its possible speeds would, however, be better than that of the compensator controlled motor; in fact, the efficiency would even be better than the rheostatic controlled motor. The power factor, however, is necessarily very much lower, so that the torque per ampere—that is the apparent torque efficiency—is about the same.

In discussing the starting conditions of induction motors, it was stated that in order to get a reasonable efficiency the armature resistance has to be low. In general, the lower the resistance in the primary and secondary, the higher is the efficiency and the less the drop in speed; also, though to a small extent, the larger the output for a given impressed voltage.

The slip of the induction motor—that is, the drop in the speed—is directly dependent upon the armature resistance. For a given load by doubling the armature resistance the slip will be twice as great, etc. By varying the primary resistance the speed is not changed, but the heating is increased and the output of the motor decreased.

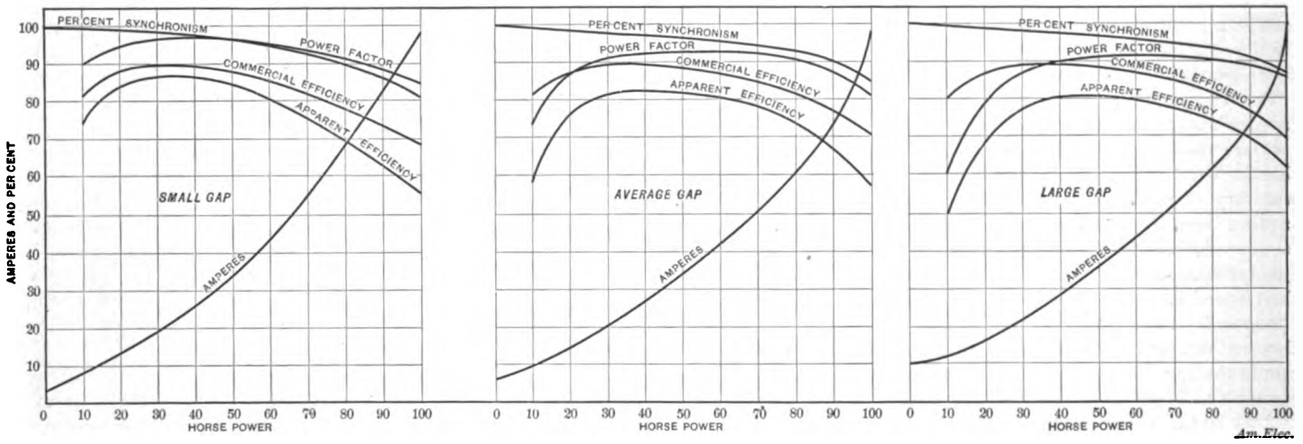
The self-induction of the motor is of greatest importance. By using very few and large slots in the primary and secondary, the self-induction is decidedly higher than by subdividing the winding in many slots; consequently, wherever low self-induction is necessary, the primary and secondary are wound with a great number of coils in different slots.

The power factor of the motor depends upon the self-induction and magnetizing current. The relative effect of self-induction and magnetizing current on the power factor of a motor is such that at light load or up to three-quarters and full load, the magnetizing current is more predominant, while at full load and particularly at overloads, the self-induction is predominating.

Digitized by Google

In motors operated on low-frequency circuits, such as 25-cycle, the self-induction with distributed winding is extremely low, so that the power factor at full load and even some overload, is practically entirely determined by the amount of magnetizing current; and since this magnetizing current is almost proportional to the lengths of air gap, it is possible to obtain motors of extremely high power factors by making very small air gaps. It is rather a delicate point to decide where to limit the lengths of gap. One manufacturer, for instance, may consider it better to have a motor of 95 per cent power factor and 1/16 in. clearance, and another consider that a motor of 90 per cent power factor and double as long an air pay would be preferable. As a rule, it is well worth while to consider the question of mechanical clearance, and rather sacrifice power factor a little to get a motor which will need less attention as to the bearings.

Should the power factor of a motor with large clearance be 2 or 3 per cent lower, it means only that the current taken by the motor for the same load is 2 or 3 per cent larger, which, in most cases, is not objectionable, because it does not represent more power from the generator or more coal from the coal pile. It simply consists of "wattless" current.



To illustrate the dependence of power factor on lengths on air gap, in Figs. 1, 2 and 3 are plotted three characteristic curves of the same induction motor, a 40-h.p. 25-cycle being chosen. The constants with normal air gap are shown in Fig. 2, the constants with one-half of this air gap in Fig. 1, and with 50 per cent larger than normal air gap, in Fig. 3. As is readily seen, the efficiency is not much changed by this modification in air gap. It is but ½ per cent higher at full load in the two motors with smaller air gap, than in that with the largest gap. The power factor, however, is greatly different. With the shortest air gap, the power factor is 97 per cent, with the average gap it is 92½ per cent, and with the longest gap, 90 per cent. The maximum output is not affected.

The apparent efficiency, which is directly noticeable in the current input for a given output, is proportional to the power factor. As a rule, motors with large magnetizing current give a large margin in output. This is not on account of the large magnetizing current itself, but is caused by the low self-induction incidental to the large magnetizing current and the lesser number of turns.

Two different types of induction motors are built, one of which has high light load constants and a maximum output of approximately 50 per cent more than rated output; the other has lower light load constants, but gives a large margin in output—from two to four times the rated output before stopping.

TABLE III.—CONSTANTS OF 10-H. P. 60-CYCLE MOTORS

| | Load. | A | B |
|---|---|---|---|
| Efficiency ..... | ¼ | 74 | 69 |
| | ½ | 85.5 | 80.5 |
| | ¾ | 88 | 84.5 |
| | Full | 86 | 86 |

| | Full | 71.5 | 73 |
| | 1¼ | 67 | 76 |

FIGS. 1, 2 AND 3.—CHARACTERISTIC CURVES, 40-H.P. MOTOR.

The advantages of the latter type of motors are apparent in circuits with greatly varying voltage, since the torque of a motor is proportional to the square of the impressed voltage; therefore, if, for instance, the voltage for some reason or other drops 20 per cent, a motor of the first type would be liable to stop, whereas one of the other type would still have a margin of from 50 per cent to 100 per cent of rated output.

To illustrate the constants of the two types of motors, the characteristic curves of two 10-h.p. 60-cycle motors running at 1200 r.p.m. are given. Column A represents the first type and Column B the second type.

### SINGLE-PHASE INDUCTION MOTORS.

These motors are essentially identical with polyphase motors in their mechanical construction and characteristics. While running, they give the same characteristics as polyphase motors, but have slightly lower efficiencies and power factors, which, however, can be greatly improved upon by the use of condensers connected across one of the windings.

Electrically, however, the single-phase induction motors run under quite different conditions than polyphase motors. For instance, a polyphase motor running light has no current in the secondary, and consequently no loss in the secondary winding, whereas a single-phase motor, even when running light, has considerable current in the secondary—approximately half that of the primary current.

The speed regulation of a single-phase motor is better than that of the polyphase motor; for example, the drop in speed of a certain motor run on a single-phase circuit is half of that when operated on a polyphase circuit at the same output.

The rating of a single-phase motor for the same heating is less than a polyphase motor. Roughly speaking, they can be given a capacity corresponding to about 70 per cent of the three-phase capacity and are then operated at about 30 per cent higher voltage, provided the same winding is used; or, which is equivalent if a certain motor is designed for multiphase work and for single-phase work at the same voltage, the multiphase rating is about 40 per cent higher than the single-phase rating, and the multiphase winding has about 30 per cent more turns in series than the single-phase winding.

They are mostly used in connection with some starting device, generally consisting of a reactance in series with a non-inductive resistance, some times of a condenser, and some times of a combination of the two. They can be made to start with practically any desired torque, but take in starting 50 to 100 per cent more current than multiphase motors for the same torque—that is, if no condensers are used. By the use of condensers the starting current can be reduced and good torque can be obtained with very reasonable currents. The condensers may conveniently be left in circuit all the time, since they will act as a compensator for the lagging currents and thus reduce the input to the motor for given output and raise the power factor and apparent efficiency. Since the condensers are inserted in a separate circuit and the charging current supplied therefrom, the wave shape of the generator is immaterial.

## CONSUMPTION OF STEAM BY WARSHIP AUXILIARY MACHINERY—A FEW FIGURES.

BY F. W. ROLLER, M. E.

In a paper by Mr. W. D. Weaver, read recently before the New York Electrical Society, on the employment of electric motors for power purposes on war ships, mention was made of the gross inefficiency of the steam pumps and other auxiliaries that are at present there used. The actual extent of the waste occasioned in this way is realized by but few, and in connection with this point it is thought that some actual figures may be of interest.

The writer had occasion a short time since to make a careful investigation of the steam consumption of the auxiliary machinery in common use on the U. S. S. "Nashville," one of our modern gunboats. A distinguishing feature of this vessel is the very large amount of coal she carries in proportion to other vessels of her class, and by virtue of this fact, she is supposed to be capable of making very extended cruises or of remaining on port duty for great lengths of time.

To further this end her equipment comprises two different types of boilers, Scotch and Yarrow water tube, the former being of course the more economical and the latter furnishing the steam required for higher speeds and quick steaming with a minimum of bulk and weight. The main engines are quadruple expansion, with independently adjustable cut-offs and steam-jacketed cylinders designed for low steam consumption and with all details worked out for the same end. Her auxiliaries, consisting of two dynamo engines, two circulating pump engines, the steam anchor and boat winches, ash hoists, blower engines, work-shop engine, steering gear and numerous pumps, were in general of standard navy patterns and good representatives of their types, so that the results reached may also be taken as fairly representative.

The test was determined on because of the fact that it had been calculated in the design of the vessel that one of the Scotch boilers should be ample to run all of the auxiliaries and the evaporator under normal conditions, whereas experience showed that two were constantly required. The water that the boilers were called upon to furnish in port was, therefore, to be determined by test, the amount including only that called for by the group of constantly used machinery specified below and not for the total.

As the radiation losses in the auxiliary piping had also to be made up by the boilers, these were not deducted. Further, as the tests were not specially desired to be of more than ordinary accuracy, the cylinder diameters and strokes were measured only to the nearest sixteenth of an inch in figuring the horse power, and the indicator springs were checked only by substituting different ones of the same strengths in the same indicators and comparing the cards obtained under like conditions. The total steam consumed in each case was determined by running the apparatus for a sufficient length of time for the condensed exhaust to fill a large feed tank, the capacity of which was carefully determined by actual measurement and checked by calculation from its dimensions.

All the machinery had been overhauled and, with the exception of the larger of the two generating sets in which one of the two piston rings in one cylinder was broken, found in good order. The most interesting of the results found are given in the accompanying table:

| Apparatus. | I.H.P. | Steam per I. H. P. |
|---|---|---|
| Fwd. aux. feed pump (2 cylinders).. | 1.2 | 335 lbs. |
| Water service pump (2 cylinders).... | .67 | 348 " |
| Air and circ. pump eng. (1 cylinder). | 8 | 172 " |
| Small generating set (2 cylinders)... | 7.7 | 142 " |
| Large generating set (2 cylinders) .. | 14.9 | 96.6 " |

We had here then a total of 3679 lbs. of steam per hour to furnish less than 27.5 h.p. in nine different cylinders, which work was then transformed into light or directly applied by the apparatus.

The steam required by the evaporator, its combined pump and another small pump plus the boiler feed pump, added approximately another 5000 lbs. per hour for a good portion of the day.

From the enormous quantity of steam thus required the reason that a second boiler was needed under ordinary circumstances was at once made evident, and the object of the test, as far as this was concerned, attained. As the pistons and valves were all tight and properly set, and there were no piping leaks to be corrected, there remained nothing to be done, but the figures obtained certainly furnished food for reflection.

Let us make a short calculation of how we would have gotten along had there been an electric equipment instead of what was actually furnished. In the first place, the average amount of current required during the day to supply the lights in use and drive the electric ventilating sets and fans, was about 80 amps. at 80 volts or 8.6 e.h.p. The i.h.p. required to drive the pumps and engines above mentioned averaged, including everything, 5.3. This horse power may be figured from the known efficiency of small direct-current motors and the reducing gear through which they would drive, and allowing for the fact that they would be working much below their rated power, as no less than 10, and perhaps as high as 12 e.h.p. at the dynamo terminals.

Taking into consideration the fact that the boat winch, fire pumps or bilge pumps might be called on to run at any time, we would have to provide in our minimum capacity day unit for at least 15 e.h.p. additional, this amount being amply sufficient when we take into consideration the liberal safety margin allowed in all navy generating sets, and the ease with which they could carry 100 per cent overload till another unit or units could be started up and coupled in. Our total e.h.p., therefore, figures out as about 35, for which we would use a 25, or, as 24 is standard, a 24-kw. unit, which would ordinarily work at two-thirds load.

Allowing as high as 45 lbs. of steam per e.h.p. under these circumstances, a liberal figure considering that we would always be operating condensing, and that the machinery would be designed for a maximum economy at about this load, we have a total of 900 lbs. of steam called for per hour against 2339, or a saving of 1339 lbs. per hour. As the boilers were, as determined during the same test, evaporating about 9.5 lbs. of water per pound of coal, we have 141 lbs. of coal saved per hour, or 3384 per day. As our total daily consumption averaged about four tons, this 1½ tons saving means a clear 37.5 per cent from this cause alone.

This, however, is only one of the direct savings in coal consumption that would be effected. It will be noticed that the evaporator and distilling apparatus is charged with a very large proportion of the steam ordinarily consumed. Now of the fresh water supplied, that quantity required for cooking, drinking and washing purposes of course remains constant, but the make-up feed is decreased in nearly the same proportion that the steam drawn from the boilers is decreased under like conditions, and far more so where, as in this case, we reduce the total number of steam cylinders in operation. The amount of steam required for the evaporator is, therefore, again reduced and another source of saving in coal found.

See now what could be done if electrically-driven auxiliaries are used. In the first place, to provide for the space required for the extra generating units we should have to sacrifice some coal-bunker space. It happens that on the "Nashville" there were two bunkers, one of seventeen and the other of nineteen tons capacity, situated on either side of the passage connecting the forward and after fire rooms, either of which would make a splendid dynamo room. Say that the larger of these two was selected; we then have a total amount of coal carried of 381 tons instead of 400 tons as at present, but taking a case where a prolonged stay at a given port was to be made, and assuming that we start with full bunkers, it would take only fifty days to get down to 200 tons with the present machinery and consumption, whereas 72.4 days would be available with the electric equipment, a difference that would be nearly doubled were the coal on hand nearly exhausted before the bunkers were replenished. In addition, we would have the dynamos below the protective deck instead of above it as at present, a point of the greatest importance.

It is not the purpose to enlarge here on the numerous other advantages, such as flexibility, ease of repair, gain in weight and safety, temperature and so on, that would accrue from the use of electric power. These points have been gone over before in other places, but this matter of economy is alone most important. The data from which the consumptions under the proposed circumstances were figured was all taken from the daily performance of apparatus aperating under ordinary conditions and is in no way theoretical. The apparatus is likewise in no sense special, so that

Digitized by Google

there would be no experimenting to do and no factors that could only be determined after extensive trials. Let us hope that the advantages so plainly offered will be taken advantage of.

## TYPES OF AMERICAN LIGHTNING ARRESTERS.

BY H. E. RAYMOND.

In types of lightning arresters the General Electric Company have followed lines different from those which most of the other concerns have chosen, and this difference lies in two distinct features. They do not pretend to prevent a rush of current in the direct-current devices, but make use of this momentary flow to cause its own destruction without injury to the dischargers and without the use of movable devices.

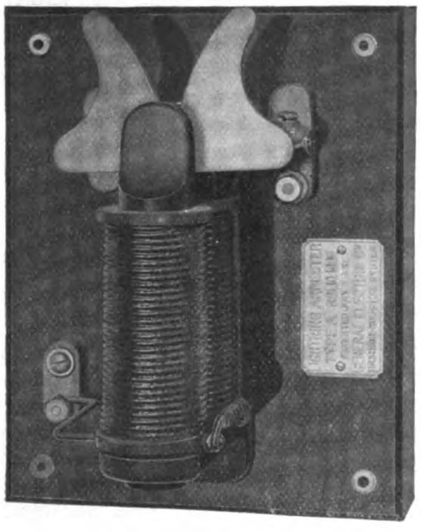

FIG. 1.—ARC ARRESTER FOR STATION USE.

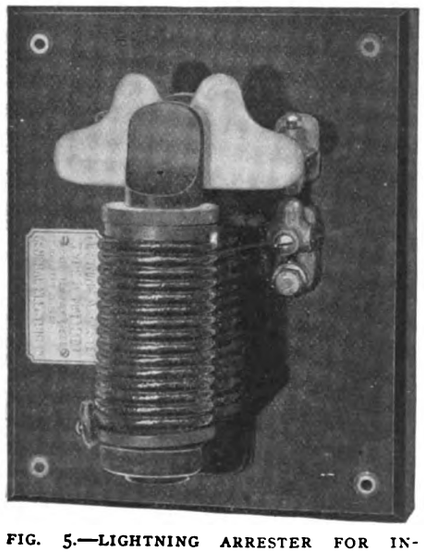

FIG. 5.—LIGHTNING ARRESTER FOR INCANDESCENT CIRCUITS.

The General Electric Company makes use generally of the Thomson method of arc suppression by means of a magnetic blow-out. This is based on the principle that a current flowing through any medium in a magnetic field in a direction crossing the lines of force is acted upon in a manner tending to move it in a direction approximately at right angles to the lines. It is precisely the same idea that is embodied in the rotation of a motor armature. The arc is simply current flowing through air and a metallic vapor of such high resistance that the arc, which is a visible indication of the $C^2R$, is a result. The arcing terminals and the poles of the magnet are placed at four quarters, and so arranged that the line of the arc will be at right angles to the lines of force in the section of greatest density. Where practical they are also so placed that the arc will be forced upward, the blow-out action being reinforced by the upward curvature caused by the current of hot air.

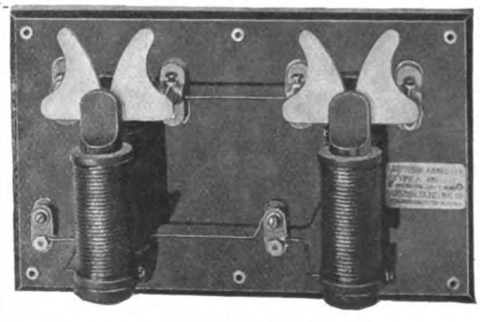

FIG. 2.—ARC CIRCUIT ARRESTER FOR HIGH VOLTAGE.

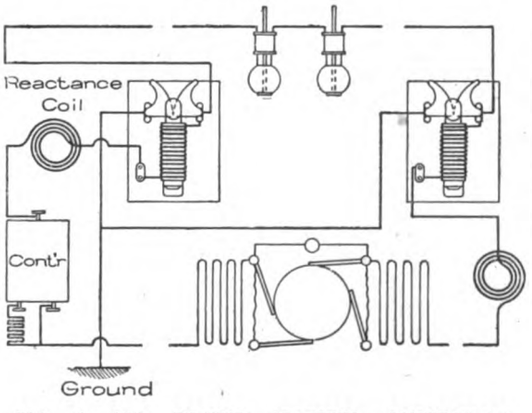

FIG. 4.—ARC CIRCUIT ARRESTER CONNECTIONS.

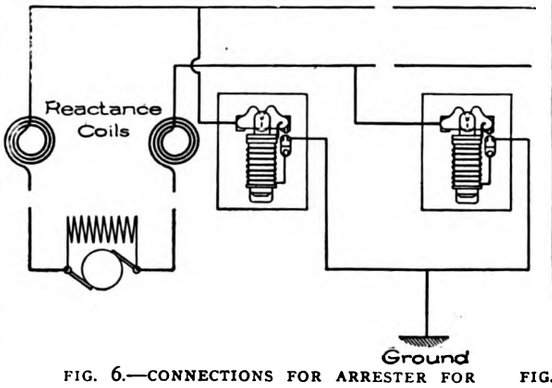

FIG. 6.—CONNECTIONS FOR ARRESTER FOR INCANDESCENT CIRCUITS.

Direct current lends itself with peculiar readiness to the use of this magnetic rupture, and the idea is involved in the design of all their arc breaking devices using direct current. On the other hand, the suppression of an alternating current arc is a problem of very different aspect. The voltages of this system at the present day are so much higher than in any other use of commercial electricity, and the inapplicability of alternating currents to the establishment of a strong magnetic field render it necessary to employ other methods of protection to the apparatus per se.

In order, therefore, to avoid the use of magnetic rupturing methods there is employed in their alternating current arresters a number of large metal dischargers in series with which is a resistance. The number of dischargers, with their adjacent gaps and the amount of ohms resistance, are proportioned to the voltage of the lines which they are to protect. The resistance cuts down the possible flow of current succeeding a discharge, and prevents an absolute short-circuit. This limited current is unable to heat the cylinders to the temperature necessary to the maintenance of an arc before the reversal of e.m.f. in the dynamo circuit brings the current to zero, at which point it ceases to jump the gap. The large mass of the metal, with its proportional radiating surface, dissipates the heat

FIG. 3.—ARC ARRESTER FOR LINE USE.

FIG. 7.—THE LIGHTNING ARRESTER FOR RAILWAY CIRCUITS.

Digitized by Google

to such an extent that no amount or frequency of operation probable in practice is able to cause a sufficient temperature to render the "cooling effect" inoperative.

In both direct and alternating current apparatus their arc rupturing and preventing methods permit the use of a very small air gap. This is very essential, as the striking voltage of any arrester is to a very great extent dependent on the shortness of its gap space.

Fig. 1 represents the standard arc-circuit arrester for station use. This single form is adapted to circuits carrying a pressure not over 3750 volts, and is so designed that

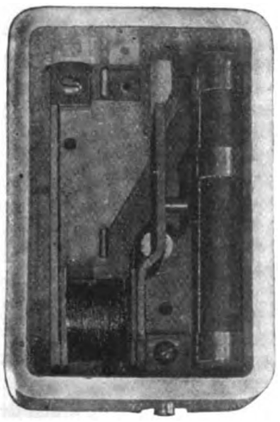

FIG. 8.—RAILWAY ARRESTER, SHOWING RESISTANCES AND MAGNETIC BLOW-OUT.

the current is all sent through the magnet coils, which are in series with the line. The small loss here is compensated by the permanence of the field during operation. The line is connected to the upper right hand terminal and the machine to the lower left hand. Any arc tending to hold across the discharge points its force in an upward direction by the field continually present. The divergence of these points and the upward curvature of the arc lengthens it to such a degree that the amount of current supplied by an arc machine cannot cause the generation of enough heat to hold it to the dischargers.

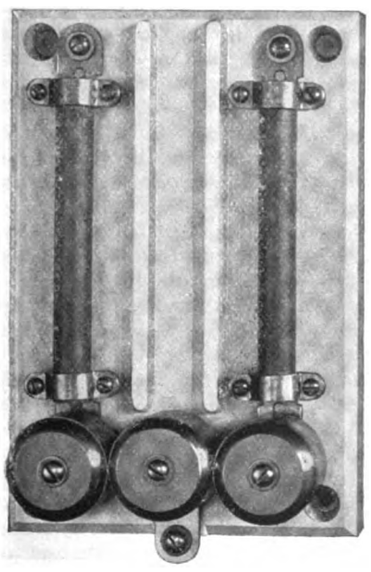

FIG. 12.—DOUBLE-POLE ALTERNATING ARRESTER FOR 1000 VOLTS.

For voltages higher than 3750 two arresters are arranged, so that their gaps and coils will be respectively in series, as in Fig. 2. The arc circuit arrester connections are shown in Fig. 4.

For incandescent service or direct-current up to 300 volts a series magnet would not be advisable, owing to the heavy currents, and in the arrester for such circuits. Fig. 5, the coils are in shunt with a small auxiliary gap in series with the main gap but so situated that it will not be affected by the field. The drop across this gap, should current arc cross it, forces enough current through the magnet coils to generate a strong field, which blows out the arc in the main gap. Connections for this type of lightning arrester are shown in Fig. 6.

For use of circuits of over 300 and up to 850 volts the type illustrated in Figs. 7, 8 and 9 was designed. The higher voltages, and possible heavy arcing, made it advisable in this arrester, as in the A. C. type, to use a low resistance to limit the possible flow of current. The principle

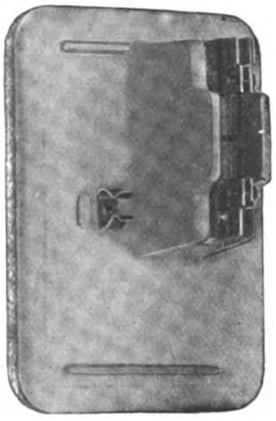

FIG. 9.—ARRESTER FOR RAILWAY CIRCUITS, SHOWING GAP.

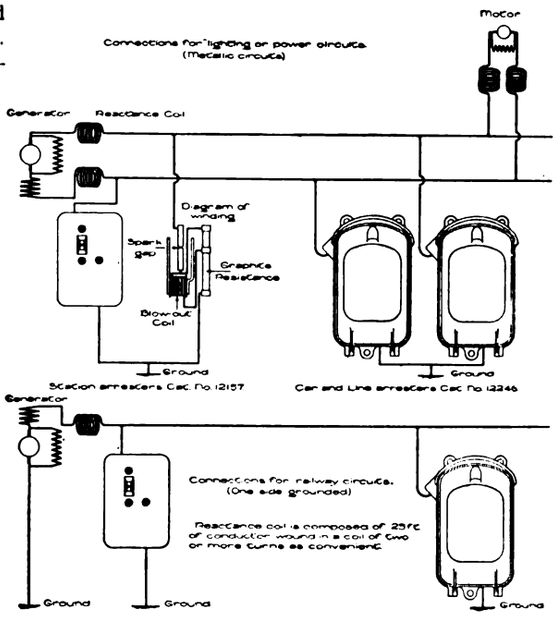

FIG. 11.—CONNECTIONS FOR MAGNETIC BLOW-OUT ARRESTERS FOR DIRECT CURRENT UP TO 850 VOLTS.

is the same, and the use of the resistance renders it possible to use a gap no larger in this form than in those for much lower voltages. For railway service this is especially important, owing to the dead grounding of one side.

As it would not be permissible to place the magnet coils in series with the gap, and not advisable to connect them in series with the line, it becomes necessary, in this type, as in the incandescent, to provide a drop across them without offering an inductive path to the discharge. This is obtained by placing them in parallel with part of the resistance. In Fig. 11 the connections are shown in general detail. It will be noted that choke coils are recommended. These should be placed in all circuits, *where but very little wire could otherwise be run between the arrester and the machinery protected.* The cut shows the uninclosed arrester for station use, and the type inclosed is an iron box for line and outdoor use.

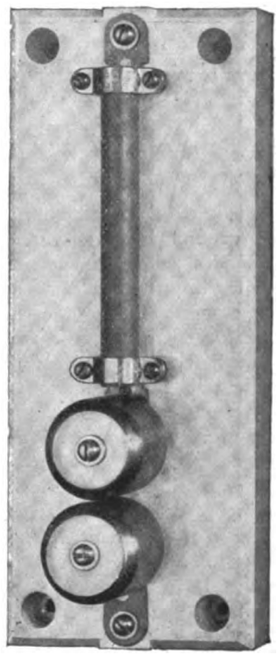

FIG. 10.—RAILWAY LINE ARRESTER FOR POLE USE.

FIG. 13.—SINGLE-POLE ALTERNATING ARRESTER FOR 1000 VOLTS.

Digitized by Google

The double pole arrester for alternating circuits is shown in Fig. 12. The discharging cylinders are 2 ins. in diameter and 2 ins. in height, and are screwed to studs fastened rigidly to the base. The resistance, which is of graphite, is clearly non-inductive. The various forms, which are simply convenient modifications of the same idea, are illustrated in Figs. 13 and 14.

For voltages over 2000, the 2000-volt double-pole form is used as a standard unit, and is connected as a single pole device, with such number in series as the voltage of the circuit demands. The voltage necessary to bridge one gap is 1500 volts, and their custom is to use one gap for each indicated thousand volts. On some very long lines with high voltage the capacity of the cylinders and line causes a small spark to jump one or two gaps, and in this case a few extra ones are added. The low or short gap space enables a very slight increase over the line voltage to discharge to ground, making them peculiarly effective as a means for dissipating the gradual charge to which long lines are subject. Connections for 1000, 2000 and 3000-volt systems are given in Fig. 15.

# Improvement of the Steam Engine.

## IMPROVEMENT IN THE ECONOMY OF THE STEAM ENGINE.

BY PROF. W. F. DURAND.

Having in a preceding article cleared the ground by a discussion of general principles, and of the less available methods for improving steam engine economy, we come now to the methods available for decreasing the amount of water formed on the cylinder wall, and thus of decreasing the readiness with which the heat exchanges take place. To this end, four means may be mentioned: First, compression; second, the splitting up of the entire expansion into a series of stages, each taking place in a separate cylinder; third, the use of superheated steam; fourth, the provision of an additional supply of heat to the steam while on its way through the engine.

Compression we may dispose of briefly. The steam shut in by the closure of the exhaust valve is compressed by the absorption of mechanical work from the engine, and its temperature is correspondingly raised. The cylinder walls absorb heat from this steam and become, in turn, raised to a somewhat higher temperature. The action is quite incomplete, however, and aids but slightly in preventing the loss we are now considering.

Splitting up the expansion into a series of stages produces the multiple expansion engine; compound, triple, etc. In such case all the heat used or wasted in the high-pressure or first cylinder is passed on to the next following, and so on. The use of the heat in a cylinder lower than the first may result in a partial loss, but small in comparison with its total loss as when rejected to the condenser without doing work. In this way the loss due to initial condensation becomes reduced nearly to that in the low pressure or last cylinder, and this, due to the small temperature range in the one cylinder, is small in comparison with the amount which might be expected if all the expansion were to take place in one cylinder only. In a general way, it may be expected that the loss due to initial condensation will be reduced nearly in the ratio in which the number of cylinders or number of stages to the expansion is increased. That is, with a compound the losses will be about one-half those in a simple engine working between the same limits; in a triple, one-third, etc.

Turning to the third method, we have already seen that superheating may conduce toward economy, in so far as it means an elevation of the initial temperature within the cylinder, and an increase in the temperature range. Still more effectively the use of superheated steam conduces toward economy by aiding in the improvement of the thermodynamic cycle, as above described. This favorable effect results from the fact that with a suitable degree of superheat the initial deposition of liquid on the walls may be much decreased, or even entirely prevented. This renders the heat exchanges between the steam and the walls less rapid and less extensive, and thus conduces toward economy, as above explained.

Turning to the fourth means, the additional supply of heat may be provided by means of jackets and by reheaters in the receivers of a multiple expansion engine.

By the use of jackets, heat is supplied through the metal of the liner while the steam is expanded within the cylinder. This is the only method, of course, in the case of the simple engine. By the use of reheaters heat is supplied while passing through the receivers. The action of the reheater is quite similar to that of the surface condenser, except that instead of the heat being withdrawn from the steam it is added to it. The exhaust steam passes either through or around a nest of small tubes, around or through which passes live steam from the boiler. In some cases the waste gases from the boiler have been used as the reheating agent. In either case the heat of the latter passes through the metal of the tubes—and as these are of brass or copper and quite thin, the transfer per square foot of surface is much more effective than in the case of the steam jacket.

We will now briefly compare the application of initial superheating and of reheating to the improvement of the economy of the modern steam engine.

Superheating the steam initially seems to be the more correct in principle, and, aside from its present practicability, the more efficient in action. A wide range of experimental data shows that in comparison with the same engine using saturated steam of the same pressure, gains may be made varying from 10 per cent to 40 per cent, or even higher in extreme cases. Many well-authenticated and carefully performed ex-

Digitized by Google

periments show that gains of 20 per cent to 25 per cent may be reasonably expected in simple engines using steam sufficiently superheated to keep it from falling sensibly below the saturated condition while in the cylinder, or, in other words, sufficiently superheated to prevent initial condensation, and its consequences on the transfer of heat to the condenser. This is attended, however, by mechanical difficulties. The necessary elevation of temperature is some 100 deg. to 150 deg. F., or more, above the temperature of saturated steam; and at these temperatures—450 deg. to 600 deg. F.—the superheating pipes, steam valves, piston, etc., are subjected to corrosion and chemical deterioration, while the difficulties of efficient lubrication within the cylinder become very great. With a lesser degree of superheat the gain will be correspondingly less, but even such a moderate elevation of temperature as 10 deg. to 20 deg. shows a well marked gain in economy. With multiple expansion engines the fundamental loss is less, and hence the percentage of gain is less, but even in such cases gains of 15 per cent to 20 per cent have been noted.

Superheating, where practicable, seems on the whole to be superior to any other means for reducing the internal heat loss. Compression offers a very incomplete and unsatisfactory means. Of all those mentioned it is of the least value. Jacketing suppresses only a fraction of the loss and the jackets add to the cost and weight of construction without in many cases yielding a corresponding return. Reheaters are only applicable to multiple expansion engines, and the degree of superheat is limited, though undoubtedly sufficient to materially affect the economy. The splitting up of the expansion into several stages, as in the multiple expansion engine, is efficient to a marked degree, but the method has its limitations and the cost and weight increase with the number of cylinders employed. Superheating distributes the additional heat uniformly through the mass of steam used, and thus it is provided just when and where it is needed. In spite of these advantages of superheated steam, it remains the fact that the mechanical disadvantages connected with its successful use have thus far prevented its general introduction.

While, therefore, high initial superheating may be the most efficient mode of increasing steam engine economy, it does not follow that it is necessarily the most available, especially for multiple expansion engines. For such the use of reheaters seems to offer certain advantages, as follows:

In an engine of this character the loss has already been reduced by the subdivision of the expansion into successive stages, and it then becomes a question of reducing as much as possible the individual loss in each cylinder, or more especially of that in the low-pressure cylinder. Now the number of expansions in each cylinder being small, and the temperature range in the cylinder being correspondingly small, the initial tendency toward cylinder condensation is small and requires a relatively low degree of superheat to successfully overcome or to materially reduce it. Also in the low-pressure cylinder, where it is more especially important to overcome these losses, a relatively higher degree of superheat is the more readily obtained, because the pressure and temperature in the preceding receiver are relatively low, and there will be thus a larger difference in temperature between the live steam and the steam in this receiver, and hence a more rapid flow of heat and greater elevation of temperature, as desired. The degree of superheat which is necessary to be effective in the cylinders of a multiple expansion engine is relatively small, probably not over 30 deg. or 40 deg. F. for each one, while even a smaller degree will produce markedly beneficial results. This amount of superheat is not sufficient to give rise to any mechanical or other difficulty, so that with reheaters, in which the highest degree of superheat will be less than these figures, rather than more, no departure from ordinary constructive practice or mode of operation is required.

The beneficial action of reheaters will therefore be marked in proportion as they are able to superheat the steam passing through them, especially that entering the low-pressure cylinder. As actually fitted in many cases, reheaters are probably able to do little more than to assist in drying the steam as it passes through them. Even then the results are probably beneficial, but in much less degree than when a sensible degree of superheat can be produced.

In all cases where supplementary sources of heat are used in order to decrease losses in the cylinders, it must not be forgotten that whatever saving is effected in the cylinder is at least partly offset by the expenditure in the jacket or reheater. It is the substitution of one loss for another. If the expenditure in the jacket equals the saving in the cylinder, as may be the case, then the apparent saving disappears entirely, or in extreme cases it might even be turned into a net loss. Usually, however, the expenditure of a certain amount of heat in a jacket or in a reheater will prevent a much larger loss within the cylinder and thus leave a balance of net gain. Thus an analysis of experiments shows that in the case of simple engines the expenditure of heat in the jackets resulted in a saving within the cylinders of from five to seven times as much, while in compound engines the ratio of gains to expenses was from three to four.* Equally good, if not better, results are to be expected from the use of reheaters or of initially superheated steam.

To sum up: The one thing needed above all others is to reduce cylinder condensation. The transfer of heat to the condenser by means of the walls with dry or superheated steam is comparatively small in amount. The great loss in the steam engine cycle comes from the exaggeration of this effect due to the presence of moist steam in the cylinder and a layer of condensed water on the inner surfaces.

To this end the use of highly superheated steam is the most effective, but is attended with serious mechanical difficulties. These may in time be overcome. At present they prevent the general use of this means. More moderately superheated steam may be successfully used with good effect especially in the successive cylinders of a multiple expansion engine. In such case it may be satisfactorily provided by means of reheaters between the cylinders, or more especially just before the low-pressure cylinder, where it is the most needed.

The most promising combination at present seems to be the multiple expansion engine (probably not beyond triple), with its naturally decreased loss by condensation, combined with suitable means for moderately superheating the steam between the various cylinders, or particularly before entering the low-pressure cylinder, where the most serious loss is likely to occur.

Edited by CHARLES T. CHILD

**Magnifying Telephone Sounds.**—Some very interesting experiments upon the amplification of the sounds of a telephone receiver were described by M. Dussaud, in "Comptes Rendus.' He produced a steady sound by means of an electrically driven tuning fork in front of a microphone transmitter. The receiving end of the circuit was divided into four branches, in each of which was placed a receiver. From various combinations of the four receivers, the author concluded that the more numerous these were the louder would be the sounds. He also found it very desirable to collect the vibrations from both sides of the diaphragm. By employing a set of collecting tubes from both sides of his four diaphragms leading to a resonator of the shape and size of a human mouth, he was enabled to reproduce the sound of wind instruments and the human voice in a large hall accommodating 1,000 persons, with such loudness that they could be heard perfectly well in all parts of it. In experiments conducted on the State telephone system of Geneva, communication was established between the two subscribers, so that the receiver sounds could be distinctly heard in all parts of the room. For this experiment the transmitter battery consisted simply of the two Leclanché cells ordinarily in use for the purpose.

**A Hysteresis Meter.**—In "Comptes Rendus," Prof. André Blondel describes a very simple and beautifully ingenious instrument designed by himself for the measurement of hysteresis of specimens of iron.

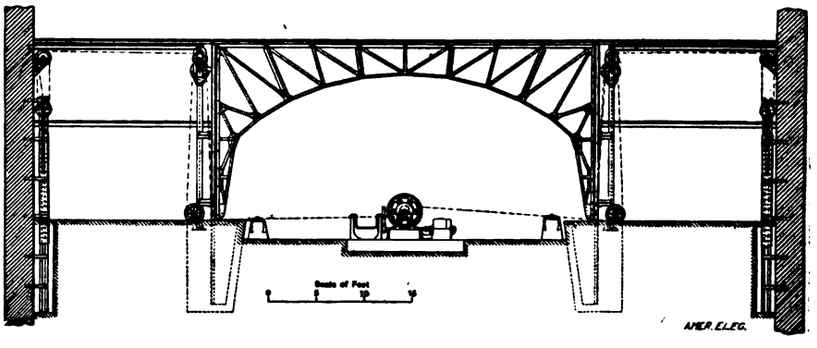
Digitized by Google

Referring to the illustration, *m* is a horseshoe magnet adapted to be turned about a vertical axis by the handle and gearing. A delicately pivoted axis, *a b* carries at its top a support for holding a cylinder of punched rings of the metal to be tested, *t* and the index *i*, which plays over a scale. On the lower part of the vertical pivot of the apparatus is a helical spring, *r*. It is evident that when the handle is turned and the magnet spun around there will be a corresponding tendency for the bundle of rings, *t*, to turn in the same direction. Readings are taken by swinging the magnet through one complete revolution slowly or rapidly, as the case may be.

BLONDEL'S HYSTERESIS METER.

**Electro Chemistry in Switzerland.**—According to the (London) "Electrical Review," the Swiss Society of Chemical Industry has just opened a competition for a treatise. This is to be of service in aiding the development of the electro-chemical industry in Switzerland, and is, of course, to be on some subject connected with that industry. A premium of $400 is offered to the author of the work winning the competition. The work must be sent to Dr. Henry Schaeppi, president Die Schweizerische Gesellschaft für Chemische Industrie, Mitlödi, Switzerland, by May 1st, 1900. Full particulars of the competition may be obtained from Dr. Schaeppi.

**Acetylene**—Prof. Vivian B. Lewes recently delivered before the Society of Arts (London) a lecture upon acetylene, which was reprinted in full in the "Mechanical Engineer." The history of the gas has been very interesting. Its first public appearance seems to have been at a meeting of the Royal Dublin Society in 1836, when Edmund Davy exhibited the gas. He made it from a black substance, formed when the metal potassium was made by heating calcined tartar and charcoal together. This substance was decomposed by water and yielded the gas, which was then called bicarburet of hydrogen. Over twenty years elapsed before any important addition was made to the knowledge of the subject, when Berthelot began his classical researches in 1859.



**The Resistance of the Human Body.**—Messrs. Siemens and Halske have been making a long series of measurements, says the "Electrician," upon the electrical resistance of their own workmen and of men employed at the sugar factory at Oschersleben, where recent fatal accidents occurred from low-pressure alternating shocks. It appears that there is absolutely nothing definite about the resistance of the body. Measurements from hand to hand of the men in the sugar factory varied from 900 to 2,000 ohms. Measuring from the hand to earth, the men in each case wearing the wooden shoes customarily worn by German workmen, the resistance varied from 14,000 to over 150,000 ohms. In the evaporating room the resistances lay between 1,700 and 900 ohms. In the boiler house from 1,200 to 3,000 ohms. One man in the repairing shop, who happened to have on new shoes, showed more than 150,000 ohms, the remainder varying from 1,500 to 7,000. All of these measurements go to show that the resistance of the human body is an absolutely meaningless expression, and one that electricians would do well to avoid in the future.

**Pulverization of Metals.**—At the recent meeting of the German Electro Chemical Society, at Leipsic, Herr Bredig read a paper on some applications of the electric arc, which is translated in abstract in "L'Eclairage Electrique." He discovered the curious fact that if an electric arc is established under water between metallic electrodes, such as zinc, lead, platinum, gold or silver, these metals are reduced to an extremely fine powder, which remains in suspension a long time, passing through most filters and giving distinctive tints to the liquid. The suspensions of platinum made in this way do not setttle, even after several weeks. It is probable that the metallic vapors of the arc, condensing instantly in the cold water in the form of a sort of metallic fog, give rise to this strange phenomenon. The author explains that by this extremely simple means, without the aid of any chemical reaction whatever, platinum wire may be converted into very finely divided platinum which has valuable catalytic properties.

**Lighting During Shut-Downs in Large Plants.**—It appears that this question has excited considerable controversy in Europe, as between the relative merits of accumulators or a small unit of engine and dynamo kept in reserve for the lighting of stations during the time when the large machines are shut down. "L'Industrie Electrique" has a short note upon a paper recently read by M. Pierron upon the subject. It describes a little unit found useful for this purpose, consisting of a steam turbine running at 2,000 r.p.m., and direct coupled to a 12-kw. dynamo. It appears that machines of this character have absorbed on power trial only 62 pounds of steam at 145 pounds pressure per kw. hour of output: Or taking account of the low efficiency of the dynamo, a consumption of 40 pounds of steam per h.p. hour upon the low speed arbor connected to the dynamo. This little machine, while not very economical in its steam consumption, serves admirably for the lighting of a large power installation, and costs very much less than the necessary equipment of storage batteries for the same purpose.

In connection with this question, it is worth while for plant managers to look closely into this matter of station lighting as an insurance. It may even be set down as a principle that a station should not be lighted from its own current; even gas, if no other source of current-supply is available, being preferable. This is because a general break-down, such as the explosion of a steam pipe or a boiler, or the breaking of a main shaft, will instantly leave the plant in darkness at just the time when light is needed for repair purposes and, in many cases, to avert a panic among the employees.

**Electrical Stage Appliances.**—At historic old Drury Lane Theatre, in London, a very complete installation of electrical stage appliances has just been put in, says the "Electrician," which also states that this is the first attempt to apply electricity for stage purposes on a really large scale.

ELECTRIC STAGE HOIST, DRURY LANE THEATER.

The plant consists of two big electric elevators, which operate sections of the stage floor, either section being capable of lifting a load of thirty to forty performers, with the ordinary scenery, etc. With the ever-increasing spectacular effects introduced upon the modern stage, where horses, carriages, sometimes even elephants, have to be taken into consideration, the construction has to be very solid; that adopted at Drury Lane being practically railway bridge trusses hung in cables, which are wound upon drums operated by motors. The illustration shows very clearly the method adopted. The sections are almost counterbalanced, each of them

Digitized by Google

weighing a little over 4¾ tons. The travel of each is from 6 ft. 6 in. below the stage floor level to 10 ft. 6 in. above it.

**Frequencies.**—An editorial note in "L'Industrie Electrique" gives some very curious facts about alternating current supply stations in England. It appears that that journal has compiled the statistics of the subject, especially examining the frequencies employed." The results of this examination are suggestive, because they show that arbitrary fancy is the only rule to which constructors and engineers deign to submit, if one can consider the absence of all rule to be a rule. In 75 alternating current stations we have found the following frequencies: 40 at Cardiff, Derby and Ealing; 50 at Blackburn, Edinburgh, Hammersmith, Harrowgate, Islington, Portsmouth, Preston, Southport, South Shields, Torquay, Wallasey, Westham, Woolwich; 55 at Sunderland; 60 at Ayr, Bedford, Bray, Croydon, Morby, St. Helens; 67 at Reading, Taunton, Wakefield; 68 at Tunbridge Wells; 70 at Brighton, Carlow; 75 at Burton-on-Trent, Keswick, Salford; 77 at Kingston-on-Thames; 80 at Altringham, Cambridge, Newcastle-on-Tyne, Scarborough; 85 at Blackpool, Bolton, Dublin, Eastbourne, Leeds, London Electric Supply; 85.5 at Lynton, Wokeby, Yarmouth; 85 at Newport; 86 at Halifax; 87 at Coventry; 90 at Hampstead; 95 at Bristol, Cheltenham; 100 at Bath, Bournemouth, Chatham, Chelmsford, City of London, Clerkenwell, Coalbridge, County of London, Brush Co., Dover, Exeter, Hanby, Hastings, Huddersfield, Killarney, Lame, Lynmouth, Metropolitan Electric Supply Co., Newcastle-on-Tyne, Prescott, Sheffield, Wandsworth, Worcester; 125 at Fareham.

At Leicester there are two (50 and 100), two also at Newcastle-on-Tyne, while at Scarborough the frequency varies between 75 and 80, which is delightful for the operation of constant speed motors."

**Platinum.**—The "Mechanical World" describes the platinum deposits of the Ural mountains as follows: "It is nearly all found on the eastern side of the range, the deposits of most value being confined to the districts of Nijni Tagilsk, Gora Blagodat, and Biseik. The first of these localities extends for about twenty-five miles to the south of the village, and, judging from the associated minerals, such as olivine and chromite, the deposits appear to be derived from the débris of a mass of serpentine known as Mount Solvaiska, or the White Mountain. The platinum is found in grains and nuggets—the largest of the latter known, weighing about 320 oz., is in the Imperial Museum at Vienna. The yield varies from 39 to 195 grains per ton. The richest deposits—those of the Martian River—are from 13 to 16 feet thick, and are covered by 60 to 70 feet of overlying material, chiefly clay. The conditions of occurrence in the other localities are similar, except at Gora Blagodat, where the bedrock of the alluvium is limestone, but outcrops of porphyry and serpentine are found in the vicinity."

**The Nernst Lamp.**—The (London) "Electrical Review" abstracts from the "Frankfurter Zeitung" a short description of the new arrangements adopted by Dr. Nernst for his glow lamp. In this lamp the source of light is a rod of magnesia, which is rendered incandescent by the passage of an electric current. If the magnesia is heated to a sufficient point it becomes an electrolytic conductor, but the principal difficulty with the lamp heretofore has been the initial heating of the magnesia, which, when it is cold, is a very perfect non-conductor.

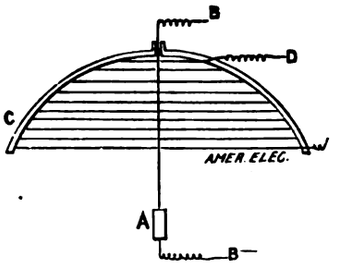


FIG. 1.—NERNST LAMP.

Referring to the diagram, Fig. 1, one of the new arrangements consists in putting the magnesia rod, A, at the focus of a concave reflector, on the inside of which is wound a spiral of platinum, D. This wire is first heated to incandescence by the current, and the heat so focussed upon the magnesia soon renders it hot enough to become conducting when the main current is switched through it.

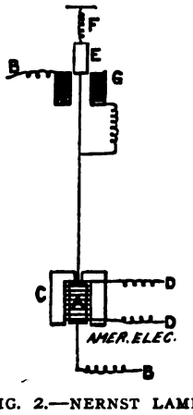

FIG. 2.—NERNST LAMP.

Another arrangement is shown in Fig. 2. Here the magnesia cylinder, A, is placed in a sort of electric oven, C, heated similarly by a coil of platinum wire, while a solenoid, G, is included in the main circuit. When the magnesia is hot and the current turned through it, this solenoid acts against the spring, F, and pulls down the cylinder, A, out of its enclosing oven.

**Becquerel Rays.**—The "Electrician" abstracts an article by Herrn. Elster and Geitel in "Wiedemann's Annalen," upon this most interesting subject. Perhaps the most puzzling question of physics is the origin of uranium rays. Uranium and thorium and some of their compounds have the property of continually sending out rays, called Becquerel rays after their discoverer, which exert photographic effects through opaque substances, and in many ways behave like the well-known Röntgen rays. While the origin of the latter is fairly well known and their nature in a fair way to be explained, the energy displayed by uranium is seemingly in open defiance of the law of the conservation of energy. To account for them, three very daring hypotheses have been put forth. Mme. Sklodowska-Curie supposes that the whole of space is pervaded by rays, somewhat more subtle than the familiar X-rays, which are only absorbed by bodies of high atomic weight, such as uranium. Sir William Crookes thinks that these substances have the strange power of absorbing some of the kinetic energy of molecules of gases impinging upon them,and radiating it in the form of Becquerel rays. A third hypothesis supposes that uranium combines with some unknown constituent of the atmosphere. The authors above referred to have been endeavoring to discriminate between these hypotheses, using a highly efficient uranium pitch ore for the purpose. They tried it in a vacuum and noted no difference. This is a serious blow to both the chemical hypothesis and Crookes' assumption. They then took their uranium to the bottom of a mine, nearly 3,000 feet deep, to see if this would free it from the hypothetical rays of Mme. Curie's hypothesis, but found that that expedient did not affect the uranium. Unless, therefore, these rays are capable of penetrating about 3,000 feet of rock, the last of the three hypotheses is clearly untenable and the question more of a puzzle than ever.

**Electricity and the Supply of Copper.**—The "Mechanical Engineer" gives some interesting figures on the supply and utilization of copper. In 1897 the United States produced 212,000 tons, against 184,000 produced by all other countries, and had a considerable surplus for exportation. The revival of electrical enterprise in the United States, however, may have the effect of reducing this. The Australian output is increasing, but the supply from Spain and Portugal seems to be decreasing; Canada produces a small but increasing quantity; Mexico is increasing her output, while that of South Africa is nearly stationary. One other important copper producing country, Chili, shows a fairly steady increase. No acceptable substitute has yet been found to take the place of copper for industrial purposes, especially for electrical conductors; so that an increase in electrical appliances creating an increased demand makes an increased supply a necessity. Where this is to come from is a question.

So far as electrical conductors in machines such as dynamos are concerned, this seems correct, but there is little need to apprehend any difficulty from failure to find a satisfactory substitute for copper for outside construction work. The price of aluminum has fallen, from one which ranked it with the precious metals a few years ago, to a point at which it already begins to compete with copper as a metal for line

Digitized by Google

construction. Possessing many advantages which copper has not and cannot have, such as lightness and freedom from corrosion, it will not require a very much greater cheapening to make it the only acceptable material for transmission lines of whatever character. Meanwhile electrical engineers have strangely neglected the possibilities of iron conductors, and it is only in such recent installations as the Chicago elevated railways that we have seen iron feeders employed with perfectly satisfactory results.

---

**The Exhaustion of Gutta Percha.**—The "Engineer" reviews two recent French articles on the danger of the exhaustion of gutta percha, and adds its own note of alarm to the somewhat pessimistic view taken by the two in question.

M. Lazare Weiller, writing in the "Revue des Deux Mondes," seems to have uttered the first warning. He was followed by M. Companaire, who, writing in "l'Electricien," says that the days of submarine cables are numbered. Gutta percha has been discovered nearly sixty years. Ever since the first cable was laid between Dover and Calais, in 1851, the use of this gum as an insulating substance has been an absolute necessity. Innumerable experiments, with a view to substituting other materials for it, have failed, and the attempts have been practically abandoned. A further difficulty has been found in the fact that of the various kinds of gutta percha, only two, produced exclusively in a district a few hundred miles in extent, in the Malay Peninsula, are useful for this purpose. Although several varities of trees produce gum, there is said to be but one method of gathering it, that of cutting down the tree. Contrary to the case of the india rubber tree, simple cuttings made in the bark are not sufficient.

When the report got abroad recently that an American cable was to be laid across the Pacific Ocean, the price of gutta percha rose 40 per cent to 50 per cent in a few days. It is stated that at this moment there are not ten tons of the gum to be found in France fit for use in a submarine cable. Until a new substance shall have been discovered capable of taking its place, there seems to be but one remedy for the gravity of the situation—the formation of nurseries for growing young trees. Unless the trees are to disappear from the face of the earth, they must be preserved, like game. While there is little doubt that Java, Borneo and Sumatra offer favorable ground for experimenting with the cultivation of the tree, nothing has been done to secure the supply of this product, which is absolutely essential to continued intercourse between the nations of the world.

---

**Some Swiss Electrical Appliances.**—In the "Bulletin de la Société Internationale des Electriciens" is published a long account of a journey among the various electrical works and installations in Switzerland by the pupils of the Ecole Supérieure D'Electricité, in Paris. It fully describes a number of installations with various methods in use, and among others, the novel and ingenious arrangements illustrated below.

Fig. 1 refers to a rheostat used by a company in Geneva, which is arranged to give a wide variation of resistance by very slow steps. Its arrangement is readily understood from the illustration. The two rheostats of which it is composed are geared together, so that while the tongue of the one on the left is making one complete revolution, that of the other moves forward one step. By making the total of the successive steps on the left-hand rheostat equal

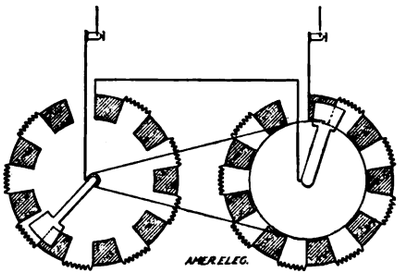

FIG. 1.—SLOW-STEP RHEOSTAT.

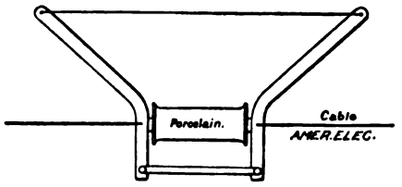

FIG. 2.—HIGH-TENSION MAIN-LINE FUSE.

to one step on the right-hand, it will be seen that by turning the left-hand tongue a sufficient number of times, the whole resistance may be inserted in small steps.

Fig. 2 shows an arrangement for a high-tension fuse in use at Wynau. The porcelain plug in the middle of the apparatus is

Fig. 3o.

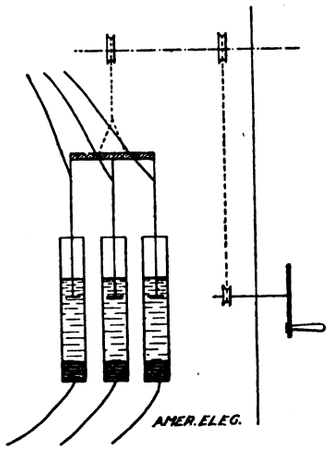

FIG. 3.—STARTING RHEOSTAT AND SWITCH FOR THREE-PHASE MOTOR.

simply a strain-insulator. Between the two copper horns at the ends of this are stretched a large lead fuse wire, of short length, and a very thin copper wire; the resistances of the two being so adjusted that the lead wire becomes hot and melts first. This, of course, shunts the whole current through the fine copper wire, which is instantly volatilized, but it is so long that no arc follows. This instrument is said to have given very satisfactory service.

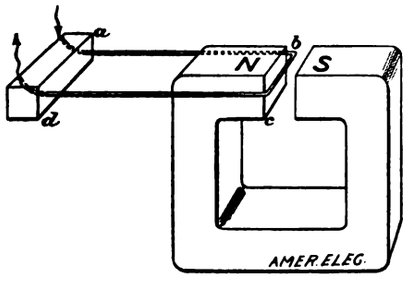
Fig. 3 shows a very simple starting switch and rheostat for a three-phase motor, which scarcely needs description. At the bottom of the three cups is mercury, upon which floats acidulated water. By the winch and handle arrangement shown on the right, the three contact-pieces can be lowered until full metallic connection is made with the mercury, the resistance, of course, being cut out as they descend through the water.

---

**Electrical Machinery in Prussia.**—Some very interesting statistics regarding the growth of the use of electrical machinery in Prussia are given in the "Practical Engineer." It appears that in 1891 there were 983 dynamos in use, of 49,489 total h.p. At the beginning of 1898 there were 3,305 in use, with a total horsepower well exceeding one quarter of a million. During 1897 alone the horsepower employed for driving dynamos increased by 66,800. The purposes to which dynamo-driving power is put show that the electric power industry is quite well developed in that country. In 1897 lighting absorbed 154,772 h.p.; lighting, combined with power transmission, 84,216 h.p.; and motor-driving, 10,785 h.p., the rest being devoted to various miscellaneous purposes.

It would be exceedingly interesting to see some statistics of this kind for American electrical industries. While the Prussian showing is very respectable, it is likely that New York city alone will soon be able to show as great a utilization of electric power.

---



**Space Telegraphy.**—Two very important papers have recently been read before the (English) Institution of Electrical Engineers by Dr. Oliver Lodge and Mr. S. Evershed. Both described researches upon a method of electro-magnetic space telegraphy differing from the familiar ether-wave system of Marconi and from any other that has been suggested as a possible practical method. In brief, it was demonstrated that if two circuits are arranged horizontally, each of considerable size and separated by a great distance, signals may be exchanged between them by the use of pulses of alternating current in the sending circuit and a telephone receiver, or other delicate detecting instrument in the receiving circuit, provided the latter be "tuned," so that its natural period of vibration corresponds to that of the alternator at the sending end. This tuning is easily accomplished by the use of condensers and reactance coils. It was demonstrated that with circular circuits about 65 miles in diameter, of one turn each, the wire being about 0 gauge, that signals could be exchanged at a distance equal to the diameter of the earth.

The demonstration, however, was based upon the assumption that the conducting mass of the earth would exert no appreciable absorption upon the long electro-magnetic waves issuing from a coil of this char-

Digitized by Google

acter under the action of an alternating current of ordinary frequency. This assumption is, of course, not warranted, but at present there are no experimental data upon which to base an estimate of the amount of this absorbtive action, while most considerations lead to the belief that it will be very small.

Dr. Lodge has devised a number of receiving instruments, as delicate as they are ingenious, to replace the less sensitive telephone. The fundamental principle upon

VIBRATING LOOP DETECTOR.

which they operate is the vibration in a strong magnetic field, of a very small and light coil. This receives the minute impulses of current and is supported upon a stretched wire, one end of which is attached to a large wooden sounding board. This arrangement may be tuned so as to become extremely sensitive for a note with which it is in unison and not sensitive to accidental disturbances.

The instrument employed by Mr. Evershed is shown in the illustration, which is almost self-explanatory. A loop of hard, non-magnetic wire is arranged, as shown, in the field of a powerful magnet, and is so adjusted that its period of free vibration is equal to that of the electric vibrations it is intended to detect. This very simple arrangement is said to be extremely sensitive and not liable to be disturbed by external influences. Its indications are noted either by the visible vibration of the wire loop, or else by causing this to work a relay contact.

It is probable that this work is the longest step in the direction of space telegraphy over great distances that has yet been taken. Despite the beauty of the ether-wave methods recently so much exploited, it has always been evident that these were strictly limited to short-distance work, and that it would be impossible to extend them to limits much beyond those at present attained. These new systems seem to contain germs of possibility. Whether or not it will be possible to signal across the Atlantic with large wire loops it is not necessary to discuss, but one is fully at liberty to imagine that, should it prove true, the lack of gutta percha, noted elsewhere in these columns, will not be so serious a matter after all.

# Northwestern Electrical Convention.

## SEVENTH ANNUAL CONVENTION OF THE NORTHWESTERN ELECTRICAL CONVENTION.

The seventh annual convention of the Northwestern Electrical Convention, held at Milwaukee, Wis., January 18, 19 and 20, scored another success for that vigorous young electrical body which, though founded but six years ago, has now the largest membership of any similar body in the United States. The attendance was not as large as at some previous meetings, but the character of the papers read and the interest shown in the objects of the association by those present made the meeting an extremely interesting one.

The absence of exhibits curtailed one feature that had added greatly to the liveliness of previous meetings. It was the sense of many present that while the meetings were somewhat better attended than would have been the case if the attention of members had been distracted by a commercial exhibition, it is doubtful if the loss of instruction that would have been received from such an exhibition was compensated for.

In the business discussions, several important points came up, affecting the interests of members from other States than Wisconsin, the final solution of which may result in the broadening of the scope of the association. Many of the Wisconsin members object to being assessed to assist in defeating adverse legislation in other States, the great majority of membership being from the State named. There was also objection to the meetings of the association being held outside of Milwaukee. A suggestion that appeared to meet with favor was that each State should have a separate protective organization, which would do away with the chance of a complication that might sometime affect injuriously the body now accepted as a representative of Northwestern central station men in general, and bring into greater relief its social and educational features.

Very commendably it was voted to hold hereafter but one meeting a year, omitting the midsummer convention. Officers in the future will be elected the last day of the annual meeting, the meeting to be presided over by the retiring president.

President Copeland, in his address, called attention to the fact that though but six years old, the Northwestern Electrical Association has now the largest membership of any similar body in the United States. This success he ascribes to the fact that the association aims to come in close contact with the practical man and to treat the practical questions involved in the every-day operation of central stations; that the large majority of its members are men of the Northwest, whose vitality, self-reliance and eagerness not only to learn but to teach, are great factors toward success; that the cost probably is the lowest of any similar association in the country, and that the combination of business and pleasure which characterizes the programme, and the atmosphere of good fellowship that prevails at the meetings, are strong attractions. President Copeland recommended that only one meeting a year be held, to be convened in January, and that some systematic plan be adopted to compile and issue to members published articles of interest to them, such as articles on municipal ownership, reports of cities operating their own plants, etc. Another suggestion was that the association have a representative at each State capitol in its territory, to examine all bills introduced into the Legislature and report promptly on those that in any way affect electrical interests. He also recommended that the dues of membership be raised to $10 a year and that officers be elected at the end of the convention.

The following officers were elected for the ensuing year: President, Henry L. Doherty, Madison, Wis.; first vice-president, John H. Harding, Laporte, Ind.; second vice-president, S. B. Livermore, Winona, Minn.; secretary, Thomas R. Mercein, Milwaukee, Wis. Board of directors, Col. W. W. Bean, St. Joseph, Mich.; J. H. Culver, Decatur, Ill.; George Innes, Eagle Grove, Iowa.

Below are given abstracts and discussions of the papers read except three, which will appear in the next issue, those reserved being as follows: "Inductive Loads on Alternating Current Transformers," by Prof. D. C. Jackson; "Design of Secondary Currents in Alternating Current Plants," by George L. Thayer; "Electricity Direct from Coal," by Prof. A. J. Rogers.

### THE QUESTION BOX.

At this meeting the new feature of the question box was first tried, but, owing to lack of time, but one question, "What is the best way to enlarge the arc, incandescent and motor capacity of a plant that is now filled up in all departments?" was considered. In answer Mr. Doherty suggested that an alternator with a reserve capacity for future needs be put in and the arc lights near the station be changed over to transformers, cutting them in and out with knife blade switches. Mr. Schott considered that the only way to answer the question, aside from the arc end, is that the true way is to take care of the incandescent and power load by putting it on a meter basis. He said that in one case the arc lights in a large district were changed from series arcs on a flat rate to incandescent arcs on a meter basis, and while during the first year the loss of income was large, the third year showed that the average rate was higher than when on a flat rate basis. Mr. Livermore suggested closer regulation of the plant and the use of 3-watt lamps, or the employment of 3-wire modern transformers; with the latter he made a saving of eight amperes at 1100 volts by replacing 49 old-type transformers with eleven 3-wire modern transformers Mr. Frund said that several years ago, when his plant was well loaded with 4-watt lamps, he substituted 3.1 watt lamps and this avoided putting in new machinery that time. The business was then changed over from a flat rate to meters with a consequence that one 60-k.w.

Digitized by Google

machine did the work which previously required two such machines, and the service was more satisfactory. Mr. Thayer spoke of an alternating plant using small transformers and having a 500-volt power circuit and a series arc circuit, which had reached its limit. It was then gradually changed over to two-phase alternators, new transformers and induction motors, the series arcs being retained, but with many extra arcs going on the alternators. Mr. Grover said that in changing from the flat rate to a meter rate he found that the revenue went down the first year about 20 per cent, but that the operating expenses decreased about 33 per cent; while the second year the income increased 50 per cent and the operating expenses still remained about 30 per cent less than previously. Mr. Thayer described a complicated system of charges which he employs. He stated that his company is gradually working over to a meter basis, at present about 40 per cent of the load being on meters.

### SYSTEMS OF METER RATES.

A paper by E. L. Debell discussed the question of flat meter rates and differential charges. Flat rates were pronounced neither logical nor satisfactory. Local considerations should be studied, he stated, in considering the adoption of differential rates, for if little or no demand can be found for current during the station slack hours, even at a very low rate, the success of the system would be doubtful, while if on the other hand, a large demand could be worked up, the system would be highly profitable to the station and prove satisfactory to the public. He stated that a device such as the Wright demand indicator should be useful to stations selling current on the flat rate plan, as monthly rates could be made for each customer, based on the greatest number of lamps they would use at any one time. In the case where a large number of lights were to be used on special occasions, the indicator could afterwards be reset.

Part in the discussion which followed was taken up by Messrs. Thayer, Copeland. Livermore, Grover, Innes, Schott, Norcross, McCullough, Lord and Frund. Mr. Thayer considers that one of the objections to the Wright demand indicator is that it cannot be applied in the case of halls, lodges, theatres, etc., and that there is an expense entailed in the case of residence, since the meter has to be reset after entertainments or when an unusual number of lights are used. These disadvantages, however, he did not think serious, and the system ought not to be condemned for them. Mr. Livermore said that some months ago his plant arbitrarily cut off flat rates and since that time he has secured his best customers. Mr. Grover stated that from the time, three years ago, when the station was changed over to the meter rate, the business has increased almost 100 per cent and is more profitable. After increasing the number of lights by 3200, it was only necessary to purchase 400-light capacity in transformers, owing to the rearrangement of circuits, whereby a number of residences are now on a single transformer. By this means the capacity of the plant was doubled, the revenue is almost double and the ampere output is less than that under the flat rate with about half the number of lamps. Mr. Innes said that owing to the small use of lamps by some of his customers, the bills of some ranged, at times, from 5 to 19 cents per month, the small amount being partly chargeable to the error of meters on a small current. Recently he has informed his customers that in the future the minimum charge would be $1.00 a month. Mr. Debell said that he charges a minimum of $1.00 per month for 16 c.p. incandescents, having first tried the mirimum of 25 and then 50 cents. Mr. Schott described a system of contracts based upon a minimum guarantee with a large discount for any excess. Mr. Debell stated that the rates charged by his company were 15 cents per kw. hour, with discounts varying from 10 per cent on bills amounting to $5.00 or less, up to one-third on bills amounting to $15.00 or more. Mr. Frund said that his company charged a minimum rate of $1.00, or a minimum of not less than 15 cents a lamp.

### UTILIZATION OF EXHAUST STEAM.

J. H. Harding, in a paper gave an account of a system installed in connection with the electric lighting plant at La Porte, Ind., for the utilization of the heat from exhaust steam for residence heating. The Yaryan system was installed at La Porte in 1897 and has since given great satisfaction. In the station house is a storage tank of about 55,000 gals. capacity, the water in which is heated by the exhaust steam to a temperature of 160 degs. The water at this temperature is pumped into the supply main and returns to the tank at a temperature of 130 degs.

The mains are so arranged that the return water can be run back through the tank or pumped direct through a bypath to the return main, a sufficient amount of hot water being taken from the tank to bring the outgoing water up to the desired temperature. The pipes are installed four feet below the surface in a box surrounded by an air chamber; that is, the sides, top and bottom of the box are each of two boards separated by a distance piece. Over the top of the pipes is placed a sheet of asbestos.

In reply to an inquiry, Mr. Harding said there was no sign of decay in the boards, which he ascribes to the fact that the heat from the mains is sufficient to keep dry the dirt in immediate contact with the boards. In the station part of the exhaust steam goes direct into the condenser forming part of the system, and part through a coil located in the bottom of the storage tank. Expansion is provided for every 600 or 800 feet along the mains by an expansion section.

The discussion was participated in by Messrs. Stahl, Thayer, Korst, Debell, Lord, Frund, Norcross, Innes, Doherty, Shott and Copeland. Mr. Stahl added many details relating to the La Porte plant. He said there was no corrosion of pipes, the reason being that the water passed through them was not distilled water, the storage system being supplied with ordinary water. As to distribution, radiators are connected in parallel on the mains and the water flows through all the piping of the building continuously. The drop at an end of a main does not exceed four or five degrees. The temperature of the houses is controlled by raising or lowering the temperature of the water according to the conditions of the atmosphere, both with respect to temperature and wind. The average temperature of the water is 160 degs. for freezing temperature, and the temperature is increased 1 deg. to each degree of drop in the outside temperature. For very low temperatures a back pressure is put on the engine, which increases the temperature of the exhaust and, therefore, of the storage water. During the hours of light load, live steam was formerly used to make up any deficiency, but at present water from a boiler is turned into the system.

Mr. Stahl advises the use of thermostats to keep the temperature of a house constant, and to operate the thermostatic apparatus an air compressor should be set up in the station and a third pipe laid in the boxes, with small taps to convey compressed air into the house. By this means the temperature of a house can be kept absolutely constant, and such a thermostatic arrangement would also simplify the heating system in several respects.

The cost for heating at La Porte is 12½ cents per sq. ft. of radiating surface. In an ordinary eight-room house there would be about 600 sq. ft. of radiating surface, which would bring the yearly cost up to $75. A charge of 30 cents per sq. ft. is made for installing the radiators, $20 for the thermostatic accessory, and $25 for steam connections, making a total cost of $225 for installation.

### CENTRAL STATION DESIGN.

Mr. B. J. Arnold presented a paper on the subject of the present trend of central station design. Mr. Arnold considers that the belted station is obsolete. The latest practice consists of water tube boilers capable of carrying high steam pressure. Mechanical stokers or improved furnaces or grates. Self-supporting brick or steel stacks, the latter costing less than the brick stack and for all practical purposes is equally as good and can be maintained a sufficient number of years to warrant its adoption in almost every case, if properly looked after. High pressure steam piping is not duplicated as was thought necessary by engineers eight or ten years ago. It has become the accepted practice to install as large engines as practicable, and these are almost invariably compound engines where it is possible to condense, and in most cases also when exhausting into the atmosphere. The tendency toward triple expansion engines is not as strong as it was five years ago, as the extra cost scarcely justifies the improved economy. Direct-connected generators of large capacity should be used. The use of economizers will result in an economy ranging from 5 to 7 or 8 and sometimes as high as 10 per cent. Mechanical draft is well spoken of,

Digitized by Google

principally where economizers are used, among its advantages being the absence of a smoke pipe and the control given over steaming.

Where water for condensing cannot be cheaply obtained, cooling towers and tables may be used, as they will effect an economy of about 15 per cent. Mr. Arnold believes that there is an economy in the use of electrical driven auxiliaries, such as air and boiler pumps, etc. As to converters, one type consists of synchronous motor driving series arc machines, which will give a combined efficiency of from 72 to 75 per cent, while the efficiency of the rotary converter ranges from 90 to 97 per cent. The rectifier for producing direct from alternating currents is referred to, and Mr. Arnold considers that it deserves consideration in this country, as it would cost much less than a rotary converter and has an efficiency of about 97 per cent. The rotary converter, run as a generator, is recommended, the efficiency of such a machine varying from 92 to 97 per cent. Mr. Arnold believes that the multi-circuit dynamo will be the arc machine of the future if the series arc is to survive. Such a machine will probably not have an efficiency greater than 80 to 82 per cent, and it is therefore open to the same objection as the present series arc machine.

Mr. Arnold referred to three principal types of central station which have lately been built and representing the latest practice. A composite station consists of two or more independent steam units carrying upon the engine shaft direct-connecting generators for light and power, and in addition a fly wheel driving shafting, from which direct-current arc machines or other old style machines derive their power. This type is pronounced admirable for utilizing out-of-date machinery. The second type consists of independent engines carrying direct-connecting generators, and is admirably adapted for plants where but one kind of current is delivered. The third type is known as the Arnold system, which consists of any type of generators mounted on independent bearings upon hollow shafts, and so arranged that either generator is available from two engines. This enables a generator to be released immediately from its engine and taken up from the second engine at once, and this is pronounced the chief advantage of the system.

Were it not for the motor, the alternating current central station would, Mr. Arnold considers, be the ideal one, but at present there is lacking a self-starting motor which will operate successfully on variable loads without seriously affecting the balance of the plant, and also a lamp producing a given amount of light with the same consumption of energy and the same cleanliness as the direct-current enclosed arc lamp. The chief difficulty at the present time is to get an alternating motor for printing press work, which is exacting in the extreme, and for electric elevator work; also a better arc lamp, as the present alternating current arc leaves a slight deposit of ashes, which requires the globe to be cleaned oftener than that of the direct-current enclosed arc lamp, and it absorbs more energy than the latter type.

In conclusion, Mr. Arnold stated that he believed the connecting link between the present direct-current station and the future alternating station lies in the use of rotary converters driven as generators. Mr. Arnold referred briefly to a magnetic clutch he has recently designed, which will transmit 3000 horse power with a consummation of energy of less than one-quarter of a horse power.

---

### ELECTRICAL VEHICLES AND THEIR RELATION TO CENTRAL STATIONS.

Mr. H. M. Maxim, in a paper, directed the attention of those interested in central station matters to the probable effect on central stations of the general use of electrical vehicles. After sketching the development of automobiles, Mr. Maxim said that at present the industry is on a firm practical commercial basis and that the immediate future contains the brightest promise. Recently the electric carriage has come into increased prominence, even abroad in the home of the gas and gasoline carriage, and so generally is the value of the former becoming recognized that he believes there are few who will deny but that it is pre-eminently the superior. As to the storage battery for use in electric vehicles both here and abroad, a combination of pasted and solid plates has been adopted. The present state of the art requires that a cell should show a capacity of 3.5 to 4 amp. hours per lb. of cell complete, at a discharge rate of not less than 1.3 amps. per lb. of complete cell, with a possibility of an increase of this rate to 4 or 5 amps. per lb. of cell for short periods without injury, and capable of being charged from empty to full in 3 hours or thereabouts. With a battery coming up to these specifications a mileage of 35 can be obtained under favorable road conditions with an electric phaeton seating two people.

The usual American practice is to equip vehicles with 44 cells in rubber jars, 4 groups of 11 cells each being boxed together. This makes a combination that can be charged from a 110-volt circuit, and 3 speeds can be obtained by merely changing the grouping of the boxes, giving 22, 44 or 88 volts at the motor terminals. While the combination of resistance and the alteration of the field connection of the motors can be used for further speed variation, it is found that the above simple changes in the cell groupings are ample for all purposes.

A description of a Columbia carriage is given as follows: Weight complete, 2000 lbs.; weight of battery, 900 lbs. The controlling apparatus consists of a foot lever connected to a band brake, a steering lever on the driver's right hand, a controlling lever on his left, a push button for a signal bell in the controller handle, and a foot reversing lever, used only preliminary to backing. The carriage can be turned in a 26-ft. circle and can be stopped on the level when going at the rate of 10 miles per hour within 25 ft. The batteries can be charged inside the vehicle when the service demands it, the charging currrent being 40 amps. for three hours. The battery is automatically cut out when filled by combining a recording watt meter with a cut-out magnet, the same meter also registering the discharge on a second scale. Delivery wagons at present are designed for a maximum mileage of 25. An investigation of the daily mileage of the busiest delivery wagons of some of the largest department stores shows that at present a wagon rarely accomplishes more than 18 miles on a single trip. As an example of this class of service it is stated that an electric mail van used in London made six trips per day and a total mileage of 40 with one set of batteries, carrying 1200 lbs. of mail matter each trip. Actual tests of the power consummation by the heavier class of electric vehicles show that 65 watt hours per 1000 lbs. per mile at a speed of 10.5 miles per hour is a conservative estimate, and the expenditure necessary to recuperate the batteries may be liberally estimated at one kilowatt-hour per 1000 lbs. per mile.

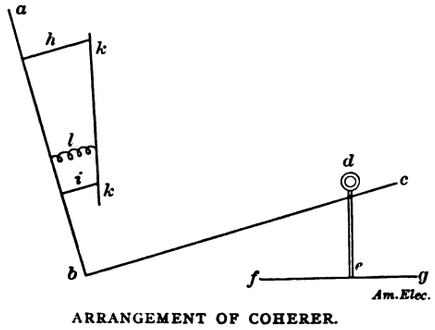
The following data are given of a Columbia wagon: Total weight, 4500 lbs, including weight of two drivers and 1000 lbs. of useful load; maximum mileage, 25; weight of batteries, 1500 lbs. The expense of running these wagons on a 15-mile trip would be the cost of 6.75 kw. hours.

From figures obtained from prominent retailers in large cities it appears that the cost of stabling two horses per year is $500, while, on a basis of two trips per day for the electrical wagon, the yearly expense of operation for 300 working days is 4050 kw. hours.

It was pointed out that by charging the batteries of electrical vehicles from central stations, a fairly constant load could be expected until about midday, when there would probably be more or less of peak, which would be followed by an afternoon load and another peak at the close of the day. With the use of electric wagons by a large number of small concerns, a day load approximating a fair degree of constancy could be carried. The operation of a cab or omnibus system would work to even greater advantage to the central station. An omnibus system planned for one of our central cities provides for 9 vehicles, each carrying 12 persons and running under a headway of 5 mins. The route to be traversed will necessitate the expenditure of about one-half the charge of the battery, so that each set can be brought to the full condition in two hours or less. This would, of course, necessitate a change of battery for each trip, and when running on a 5-min. schedule, a total of 24 sets of batteries constantly on the line. At the end of every five minutes a set would be cut out and a new one put on in its place. This would cause a load of approximately 930 amps., diminishing to 880 at the end of five minutes, when it would again rise to the maximum.

---

### ELECTROMAGNETIC STRESS.



The electromagnetic stress, set up at a given point in the air by a current flowing in a straight conductor of great length, is measured by the quotient of twice the current by the distance of the point from the axis of the conductor.

## A New Type of Coherer.

*To the Editor of American Electrician:*

Sir—The following may prove of some interest to those engaged in wireless telegraphy. Having for some time past been experimenting on Hertz rays and on the Marconi system of telegraphy, I found than an excellent powder for the Marconi coherer is a simple mixture of about equal parts by volume of silver and carbon filings, together with a very small proportion of iron filings. Very satisfactory results are obtained from the use of such a mixture, the telegraph relay and sounder working admirably with respect to delicacy, clearness and precision. I afterwards became aware that Lodge in England had

ARRANGEMENT OF COHERER.

used carbon in his coherers, but I have not heard that a mixture of carbon and metal had been tried.

Experimenting further I came to the conclusion that coherers could be dispensed with, and succeeded in doing so. This is, I believe entirely new. My method is as follows: Taking a microphone which I had made some years ago, I removed the carbon rod and substituted for it a narrow strip of tin foil which I allowed to hang loosely from the upper carbon support. By a screw in the foot of the microphone I inclined the apparatus until the foil rested lightly against the lower carbon, which I had filed down to a rather sharp edge.

Connecting this with the telegraph relay and sounder in the usual way and joining it in circuit with five "Samson" cells, it worked admirably with the oscillator. This method has an advantage, as one can regulate the pressure of the foil against the lower carbon with a delicate spring and thus receive clear, decisive signals.

The accompanying diagram will explain the apparatus; a, b, c is the microphone stand; d, e, adjusting screw; f, g, table or support; h, i, two-carbon supports; k, k, tin foil; l, spring for regulating pressure.

## Power and Pull of Electromagnets

*To the Editor of American Electrician:*

Sir—Under the title of "The Power and Pull of Electromagnets," in your January, 1899, number, I notice your invitation for experimental research and information contributary to a more intelligent procedure in the matter of the design of electromagnets, and feeling that I can give some suggestions that should prove useful to such ends I offer the following:

At the age of forty I began the study of electrodynamics and have since continued it vigorously for nine years, during which time I have lavishly supplied myself with the literature of the subject. I have had neither tutor, classmate or associate to curb the course of my studies, and I am now heartily glad for it, for I have thus escaped chronic orthodoxy.

My first work was to thoroughly acquaint myself with the most fundamental rudiments of the science, and, of course, believed it all—I believe none of it now-a-days until I have satisfied myself of its truth. At an early day I had my doubts stubbornly aroused concerning one of the most prominent rudiments, and as I could not reconcile its fundamental law I conducted its experiments in opposition thereto and to my ultimate satisfaction in the face of developed facts. Since this occurrence I have had similar experience with others of the elementary laws pertaining to this science. These statements are made in the hope that students may not swallow too much time-honored fundamental law, except, with an added grain of salt.

An electromagnet essentially comprises three functionary elements—a conductor-coil affording the seat for current, a magnetically permeable media enveloping transversely the seat of current, and, an air-gap (usually two) forming a breach in the magnetic enveloping girth and affording the seat for mechanical action due to magnetic tension.

There is no concept more foolishly wrong than the time-honored "ampere-turn," it having been universally offered and accepted as a measure of the current's energy—thus, "a convolution encircling in any manner a portion of the magnetic girth or circuit, said convolution carrying one ampere and contributing unit energy proportional to the circumscribed area irrespective of the length of said ampere-convolution." Instead of the value in "turns," each and every unit of length of conductor carrying an ampere has an exact energy-value capable of being given to a magnetic girth or circuit enveloping it, and exactly proportional to the geometric and the physical constituents of such circuit as a whole. The more permeable, the greater the cross-section everywhere and the shorter the mean length of the media or magnetic girth enveloping the current the more favorable is it for availing the energy of said current.

It should be carefully borne in mind that electromagnetism is never manifest or developed elsewhere than in a completed circuit surrounding the current to which it is due; furthermore, electromagnetic leakage never can exist elsewhere than in completing a magnetic circuit, leakage not performing useful work tending to impoverish said magnetic circuit. The term "core," as applied to any part of the magnetic circuit, is thus wrong and should be banished from use, said circuit invariably being an enveloping member; instead, the energizing copper coil would more truly be the core.

In none of the electrotechnical literature, so far as I can recollect, has there ever been explanatorily recognized a distinction against the "horse-shoe" type of magnet with respect to its windings surrounding the legs or yoke, as contrasted with the advantages of the "ironclad' type, wherein the total mass of the conductor-coil is enveloped by the working magnetic circuit. A study of this fact would show that in the design of a large share of electrical machinery of the present day there exists a shameful extravagance in the use of inert copper, entailing a heavy ohmic loss as well as unnecessary iron in the magnetic circuit, this again requiring additional energetic copper to overcome the added reluctance; and, while it is neither expected nor hoped that the designs should embrace the full advantages of ironclad construction—except in single magnets for traction purposes—it is important that one should understand the true function of each physical element in order to design intelligently.

The foregoing statements should afford a basis whereupon someone having time and opportunity may conduct an interesting and valuable line of experiments, both constructional and quantitive, and though much more could be said upon the subject it is to be hoped that what I have said will bring forth wholesome progeny.

H. C. HECKENDORN.

Philadelphia, Penn.

## NOTES.

**A Large Contract.**—The Third Avenue Railroad has awarded to Westinghouse, Church, Kerr & Company the contract for the boilers, engines and generators for its new power house. There will be sixteen Westinghouse generating units, each of 3000 kw., which will be operated in parallel in groups of four. Sixty Babcock & Wilcox boilers will be used, each having a rated h.p. of 520. Special engines for the plant will be manufactured by the Westinghouse Machine Company.

**Permanent Magnets.**—In some recent experiments on magnet steel, it was found that the intensity of residual magnetism of thirty-five specimens, tested in the form of bars, varied from 220 to 560 gausses (lines per square centimetre). In the case of thirteen specimens tested in the form of closed rings, the intensity varied from 625 to 860 gausses. Assuming an intensity of 700 for a circuit such as is that of magnetos, the section of steel, to produce the same flux, must be about thirteen times greater than if a cast-iron electromagnet were used, or more than twenty times greater than in the case of a wrought iron electromagnet.

**Expert Information.**—A correspondent having asked in a foreign contemporary, the size of wire for secondary distribution from a central point of current from a 40-amp., 1000-volt transformer, is informed that "the proper size of wire for secondaries depends upon the distance apart of transformers, but probably three No. 6 secondaries would be the best!" In the same journal it is denied that "a current of 2500 volts passed through a man's body," in an acci-

Digitized by Google

dent alluded to, "as the wire with which he came in contact was not capable of carrying that amount of current."

**Carbon Combination.**—A combination has recently been made which includes all but two of the large arc carbon manufacturing concerns of the United States—the Solar Carbon Manufacturing Company, of Pittsburgh, and the United States Carbon Company, of Cleveland, being the only well-known concerns that did not enter into the combination. The new company, which will be known as the National Carbon Company, is capitalized at $10,000,000, of which $4,500,000 is 7 per cent preferred stock and $5,500,000 of common stock. The companies included in the consolidation are the National Carbon Company, Brush Carbon Works, Standard Carbon Works, Crouse & Tremaine Carbon Company, Thomson-Houston Carbon Company, Faraday Carbon Company, Phœnix Carbon Company, American Carbon Company, Washington Carbon Company and the Partridge Carbon Company.

**Electric Automobiles.**—One of the features of the recent Cycle Show at the Madison Square Garden was a number of exhibits of electrical vehicles. In the exhibit of the Pope Manufacturing Company were shown a phaeton, a double-seated carriage, a dog cart and a delivery wagon. Data concerning the latter will be found in an abstract, printed elsewhere in this issue, of a paper read by Mr. H. M. Maxim at the recent Northwestern Electrical Convention. The Riker Electric Company had also an interesting exhibit, including a tricycle trap, seating two people and weighing with load but 1200 lbs. The same company exhibited an electric carriage and one of a number of delivery wagons built for a New York firm. Another exhibit consisted of a dog cart, shown in the space of the Waltham Manufacturing Company.

**Aluminum for Electrical Conductors.**—The large use of aluminum wire for electrical conductors at Niagara and Snoqualmie Falls, Wash., is directing greater attention to this material as a rival of copper for line wire. The latter plant employs no less than 80 miles of aluminum wire for the tranmission of power to Seattle and Tacoma. At Niagara, two 14-in. and four 10-in. mills are now being installed to further increase the output of this wire. In comparing the two materials we find that copper is 3.332 times heavier than aluminum, while the latter has but 63 per cent of the conductivity of copper. On a basis, therefore, of 14 cents per lb. for copper wire, for equal conductivity aluminum wire should cost 29 cents per lb. But aluminum wire has the advantage over copper for use as line wire in that on the basis of equal conductivity it will stand a greater tensile strain, thus materially reducing the number of line poles and insulators. Another advantage of moment in special cases is that aluminum is less readily attacked than copper by atmospheric influences and by corrosive gases, such as are produced by some coals. As to price, we understand that aluminum wire is now being sold cheaper than copper wire on the basis of equal conductivity.

**The Keely Motor.**—After an examination of the workshop in Philadelphia where Keely exhibited his various so-called inventions, a committee consisting of Mr. Carl Hering and several other Philadelphia engineers, discovered every evidence that the machines had been operated by compressed air. A reservoir was found concealed underneath the floor, and numerous concealed lines of piping were discovered. There was evidence that in the case of one of the most noted of the Keely motors, there was a belt drive from a water motor, the latter being controlled by means of a pneumatic connection similar to that used in manipulating the shutters of photographic cameras. Some years ago during an exhibition by Keely, Professor Spangler, of the University of Pennsylvania, challenged Keely to cut what purported to be a wire leading to one of the machines, Professor Spangler charging that it was a small tube conveying compressed air. This Keely refused to do, and pretending to become greatly enraged, ended the exhibition. A large number of such small tubes, having the outward appearance of wire as small as a No. 8 or 10, were found concealed in the walls and under the floors of the workshop.

**Standard Lamp Sockets.**—At the sixth annual meeting of the electrical committee of the Underwriters National Electric Association, a report was submitted on "Specifications for Standard Lamp Sockets." Among the requirements suggested is that the standard socket shall be for lamps not over 50 candle-power, nor 250 volts, and that the candle-power and voltage for which the socket is designed must be plainly marked upon it. The socket must contain an insulating material at least 1°1-32 in. in thickness, of such a form as will absolutely prevent the shell from becoming a part of the circuit, even though the wires inside the socket should stray from their position under the binding screws. The cap must contain sufficient room for a knot in the lamp cord. The terminals for the flexible cords must include a turned-up lug, so that the cord may be gripped between the screw and the lug in such a way that it cannot possibly come out. All screws in porcelain pieces must be sealed by a weatherproof compound, which will not melt below 200 degrees F. Bayonet joints, or the equivalent, are recommended for screwing on the case. Points of opposite polarity must be kept 3/64 of an inch apart unless separated by a reliable insulation. The socket shall not allow any portion of the lamp base to project beyond it.

**Electricity From Dirt.**—A Western man claims to manufacture an electrical generator which derives its power from "natural gravitation and dirt." The description, as given in a pamphlet, is as follows: "The electricity is generated by an electric concentrator. It has an armature 3 ins. in diameter and 15 ins. long, which revolves once per hour. The power of the concentrator consists of a holder made of galvanized iron, and resembles a half bushel; in this is placed 150 lbs. of earth or dirt. All that is necessary is to turn the switch, and the light is neat, clean and free from all odors, and it will not blow out when a window is raised. The electricity is produced by the natural gravitation of the earth, the cheapest known method of producing electrical energy. All that is necessary is to wind it up, like a large clock; time required is one minute. For ordinary use, one winding will last a week." The invention, it is stated, "is the product of the ingenuity of Mr. E. A. Maxwell, and is the result of years of application and research, by which he has succeeded in performing that to which has been given without result the energy of many great minds," and his invention "has been pronounced by scientists and experienced men as a superior article." A sketch illustrating the "concentrator" shows two concentric circles, from the outer of which two coiled wires lead to a lamp circuit.

**Reporting Extraordinary.**—A correspondent sends us a newspaper account of an accident which happened to a dynamo tender while attempting to file the slip rings of a rotary converter while in motion. Through carelessness, the file short-circuited two of the rings, between which there was an alternating E. M. F. of 370 volts. In the flash which resulted his hands were quite severely burned, but he was otherwise uninjured. Upon this simple foundation of fact a newspaper reporter produced an elaborate account under the scare heads: "Marvellous! Electric Current of Deadly Strength Fails to Kill! It is said that 11,000 volts of electric fluid passed through this man's bady." Omitting some of the wanderings of the newspaper writer, the report is as follows: "The accident is remarkable in that a current said to have a very high voltage of electric fluid passed through the man's body, and the man yet lives, and will probably recover. In some manner he short-circuited this powerful current of electrical energy. There was a flash, and he was hurled back as though a thunderbolt had struck him. He was found lying on the floor unconscious, and a curious circumstance noticed in connection with the case was that, while unconscious, he talked of electric matters with all the apparent knowledge of an expert in the science of electric power. A few weeks ago this man had the sight of one eye partially destroyed by the discharge of several thousand volts of energy, which hurled him back, but did not pass through his body. The passage of the current through his body yesterday is one of the unexplained marvels of electricity. How it is possible for a man to live after the passage through his body of a current at least six times more powerful than is necessary to cause death is one of those problems which electric experts cannot explain at this time." It would be interesting to know on what information the reporter bases his apparently exact knowledge as to the amount of current required to kill.

### Northwestern Electrical Convention.

The programme of papers read at the recent Northwestern Electrician Convention was by far the best of any yet presented before the association. The reproach which could have been urged against previous programmes—that many papers of an entirely perfunctory character were included—is one that does not apply in the present instance, for not a single one of the papers read can be thus characterized. In another column are printed abstracts of but three of the papers read and of the following discussions, those excepted being reserved for full abstract in a succeeding issue.

### The Electrical Exhibition.

The great success of the recent Madison Square bicycle show promises well for the Electrical Exhibition to be held in the same place the coming spring. The great revival of business now taking place renders the show particularly opportune at the present time. By holding its meetings in the Garden during the show and lending its support to the enterprise, the National Electric Light Association will benefit itself not only by the large attendance that will result, but from the opportunity thus afforded to its members of investigating through the operative and other exhibits, the very latest developments in the field of electric lighting and power. The time, in fact, has never been so ripe as the present for an electrical show, both with respect to the general public and on account of the large number of those engaged in the industry, aside from delegates to the convention, who will desire pointers as to contemplated summer extensions and improvements now rendered possible by the easy business situation.

### Electrically Driven Auxiliaries.

The superior economy from electrically-driven boiler and air pumps, blowers and other auxiliaries of the boiler and engine department of electrical generating stations, has for some time been recognized by central station and power house designing engineers. In a paper read before the recent Northwestern Electrical Convention, Mr. B. J. Arnold mentions the use of electrically-driven auxiliaries as one of the features of the latest central station design. In another column Mr. F. W. Roller gives an argument in favor of the use of electrical-driven auxiliaries aboard ship, which is supported by reliable data from tests made on board the U. S. S. Nashville, on the consumption of steam by the numerous auxiliary steam engines aboard that vessel. He found that the consumption of steam per indicated h.p.-hour varied from 96.6 lbs. in the case of an electric light engine, to 343 lbs. in the case of a water-service pump. While these figures appear startling, they are confirmed by a test made some time ago on another naval vessel, and there is no reason to believe that the data cannot be duplicated by tests of similar machinery ashore.

Upon these figures Mr. Roller makes an unanswerable argument in favor of driving auxiliary machinery aboard ship by means of electric motors. Unfortunately, owing to the present unsatisfactory condition with respect to naval electrical engineering, we cannot expect an extension of electric power aboard ship such as seems logical in view of the results of the tests made. It would indeed be poor economy to endeavor to effect a saving in steam consumption with the probability that the electrical equipments that would displace the present steam machinery "cannot," according to a recent report of a Naval Bureau, "long be self-sustaining without dockyard electrical work." The lesson that the figures teach, however, is one from which benefit may be derived in shore practice. It is not too much to say that one who at the present time designed a large central station or power house plant without specifying that the auxiliaries are to be electrical driven, would be rightly considered behind the times.

### Efficiency of the Steam Engine.

Of recent contributions to steam engineering literature, the article by Professor Durand, of which the conclusion appears elsewhere in this issue, is the most lucid. After an examination of the principles concerned, Professor Durand shows that the great evil to be combatted in improving the efficiency of the steam engine is cylinder condensation. As the loss from this effect is greatly aggravated by the presence of moisture in the steam and the deposition of moisture on the cylinder walls, the obvious remedy is the use of superheated steam. Unfortunately there are practical difficulties in the way, both with respect to superheating the steam and the effect of high temperatures on the working of the engine. The great use nowadays, however, of multiple expansion engines enables benefit from superheating to be derived through the employment of so-called reheaters in the receivers, and to this use the triple expansion engine lends itself more readily than the compound engine, as the superheating is performed in two stages, and in the most important stage, before admission to the low pressure cylinder, the steam is subjected to a maximum difference of temperature.

The economy of superheated steam is not a new discovery. More than a quarter of a century ago much was expected from it, but the practical difficulties met, to which Professor Durand refers, led to the utter abandonment of the idea, in some cases after an expensive experience. It is interesting to note that Corliss continued

Digitized by Google

to derive benefit after others had condemned superheating, by using vertical cylindrical boilers having a large tube surface above the water level. By some of the older engineers it is believed that no small part of the great economy obtained by Corliss in those early days was due to his recognition of the value of superheating, and to the care which he exercised, where guarantees were involved, to allow sufficient tube surface in the boiler steam space for that purpose.

---

**Magnetism.**

In a letter printed in another column ("The Power and Pull of Electromagnets"), a correspondent gives evidence of a queer state of mind concerning the basis upon which electrical science rests, and of the qualifications necessary for entering into the realm of scientific investigation and thought. As a preface to a criticism of present electromagnetic theory, the writer states—apparently as a qualification for the function of a critic—that he did not take up the study of electrical science until he had arrived at the age of forty, and is heartily glad of the fact that he has since pursued its study with the assistance of neither tutor, classmate nor associate. In view of this statement, we need not be surprised to find that our correspondent is evidently not aware that electrical science rests upon a solid foundation of experimental fact, instead of upon mere hypothesis and guesswork; and that he confounds speculation with true theory and disputes firmly-established law with dogmatic assertion unaccompanied by experimental proof.

---

Our correspondent first falls into the error that magnetism is a form of energy, or that it necessarily requires energy for its maintenance. Others, we fear, coincide in the last mentioned belief with respect to electromagnets, notwithstanding that they must be aware that a permanent magnet requires no application of energy to maintain its magnetism. Such need to be reminded that once magnetized, a medium no more necessarily requires energy to maintain its magnetic state than a spring requires an expenditure of energy to keep it in a state of compression or extension, or a weight when kept lifted from contact with the earth. In the act of magnetization a certain amount of energy is expended, which energy remains stored up in the medium influenced, and is partly or wholly returned in the form of electric current when demagnetization takes place. To illustrate, when a soft iron ring is magnetized, an expenditure of energy is required to introduce within the ring lines of force, and when the ring is demagnetized, this energy appears in the form of current in the magnetizing circuit, should that be closed.

In the case of a permanent magnet, the molecules once coerced into the state corresponding to magnetization, remain so. In the case of soft iron, however, the absence of molecular coercitive force requires that the magnetizing force be maintained as long as magnetization is to exist. But in maintaining this magnetism, no energy is impressed on the medium magnetized, whether air or iron, the entire energy of the current being expended in overcoming the resistance of the magnetizing coil—that is, in $C^2 R$ loss. In fact, the analogy between magnetism and forces like gravity or resilience is shown by its every application. The analogy with the latter is very exact, for energy is required to compress or extend a spring, none is necessary to keep it in a state of compression or extension, and when returning to its normal state, the energy originally imparted is returned in one manner or another. The constant-potential shunt dynamo furnishes a good illustration of the relation of electromagnetism and energy. As the number of shunt turns are increased the field current is decreased in the same ratio; since, however, the ampere-turns remain the same, the flux is unchanged, but the energy used to overcome the resistance of the coils is decreased directly with the current—this energy being the product of the current by the constant e.m.f. The energy may thus be decreased without limit and yet the same flux maintained.

---

Our correspondent evidently considers that the ampere-turn is a mere hypothetical conception as applied to the measurement of magnetic force, whereas it is a direct deduction from experiment, and in accordance with the fundamental laws of the science—the word law being here used, not in the sense of speculation, but as a generalization based upon experimental fact, and at no point in conflict with any fact. Thus, Biot and Savart proved experimentally that the magnetic stress exerted at a given point by a current flowing in a long, straight conductor, is, in absolute measurement, the quotient of twice the current by the distance of the point from the conductor. Laplace showed this to be also a proof that the effect of a current varies inversely as the square of the distance, thus corelating the force of electromagnetism with other central forces, such as gravity. From these facts it was demonstrated, both mathematically and experimentally, that the stress created within a coil is expressed by the product of a constant due to the geometry of the circuit, into the current and number of turns. The truth of this expression is proved every time a galvanometer, ammeter or voltmeter is used, and the ampere-turn is a direct mathematical and experimental deduction from it.

---

In disproof of the correctness of the use of the ampere-turn as a measure of magnetic flux, our correspondent refers to the undisputed fact that every unit of length of a conductor, whether straight or circular, will produce an equal magnetic stress. But Laplace showed that the proof of this was involved in Biot and Savart's experiment, and we are not aware that it has ever been denied. In fact, were this relation not true, the use of the ampere-turn in the manner challenged would be incorrect, for its proof rests upon the very stress equality of each unit length of a turn which is offered as a disproof. As to practical proof, this is furnished by the concordance of the results obtained with the ampere-turn basis of the design of actual machines.

---

As the remarks of our correspondent concerning the relative efficiency of horse-shoe and iron-clad electromagnets are unsupported by experimental proof, they can only be accepted as an expression of opinion or a speculation on his part. In any magnet the useful effect is the magnetic flux—the lines of force—set up. The amount of the useful flux will depend upon the magnetomotive force set up by the ampere-turns, the reluctance of the magnetic circuit and the leakage. With a given number of ampere-turns and a given section of iron and air-gap, the relative efficiency of the two forms will depend upon the length of the magnetic circuit and the leakage. The iron-clad form possesses no superiority in either of these respects, but as usually constructed there is greater leakage than in the ordinary horse-shoe type of field. The fact that no external magnetic effect is produced by no means implies that there is no leakage. The lines of force set up in the plane of any turn of the magnetizing coil tend to close on themselves, and if any circuit other than the main one offers less magnetic resistance, they will close through that circuit, this constituting magnetic leakage. Instead of the iron-clad form of field offering superior conditions for opposing such leakage, the reverse is the case.

## HOW TO MAKE A STORAGE BATTERY.

BY CECIL P. POOLE.

The accompanying engravings show the construction of a plate and a single cell of storage battery of the Faure type, which may be built with no tools beyond a pair of heavy tinners' shears, a small punch and a slitting saw of the sort used for cutting thin metals.

Each plate is made up of twelve strips of lead cut to the shape shown in Fig. 1; this strip is 0.075 in. thick, 8 ins. long, over all, and ⅞ in. wide. Midway on each edge is cut a square slot, s, 3-16 in. wide and deep; the ends of the strip are cut down to ½ in. in width for a distance of ⅞ in. from each extreme end, and two ⅛-in. holes are punched in the narrow part of the strip, as shown. The edges are folded along the dotted lines until the end view of the strip looks like B, Fig. 1.

Next three rubber forks, like D, Fig. 2, are provided for each plate (not each strip, but each group of twelve strips). Each fork is made from a strip of hard rubber, 3-16 in. thick, ⅝ in. wide and 7½ ins. long; the slit down the center must be just wide enough to admit the thickness of the lead strips forming the plate (A, Fig. 1) with no "lost motion," and must stop exactly 1 in. from the lower end of the rubber. When these rubber forks are ready, a plate is built up in three of them as follows: Cut one of the lead strips in two logitudinally, exactly down its center, and assemble the strips on edge in the rubber fingers so that the end view of the lead part of the structure looks like E, Fig. 2. Fig. 3 shows the face view of the complete plate. The halves of the strip that was cut logitudinally go at the top and bottom of the plate, and are indicated by a and b, Figs. 2 and 3.

After the strips are assembled in the retaining forks, D, D, D, tie the upper ends of the fingers tightly with lead wire so that they clamp the plate; this tie-wire should go just above the top strip, at z, and it is imperative that no material other than lead be used, unless very strong, short rubber bands are obtainable, in which case they may be used. Then cut two strips of lead, C, c, each ⅝ in. wide, and of the same thickness as the lead strips composing the plate; the longer one, C, is 8½ ins. long, and the other one, c, 6½ ins. long. Rivet one of these to all the ends of the plate strips at one extremity of the plate and the other one to the ends at the opposite extremity, using lead rivets. The engraving

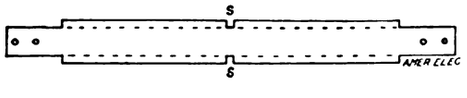

FIG 1.—SHAPE OF STRIP.

shows holes punched in the connecting strips, C, c, to correspond with those in the ends of the plate strips, A. Bend the upper ends of the long connectors, C, about half an inch from the end, at right angle to the main body of the strip; the bending point is indicated by x, Fig. 3. The edges of the plate strips which were bent at an acute angle to the body strips (B, Fig. 1) are designed to serve as shelves to hold the paste or active material which is to be applied to each plate. The process of pasting will be described later on.

After the paste has been put on the plates and has hardened, nine plates (four positive and five negative) are assembled in a glass jar, as shown by the plan view, Fig. 4, where A is the lead portion of the

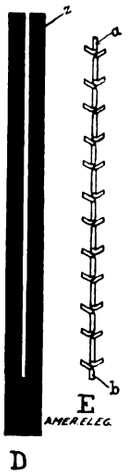

FIG 2.—RUBBER FORK AND PLATE EDGE.

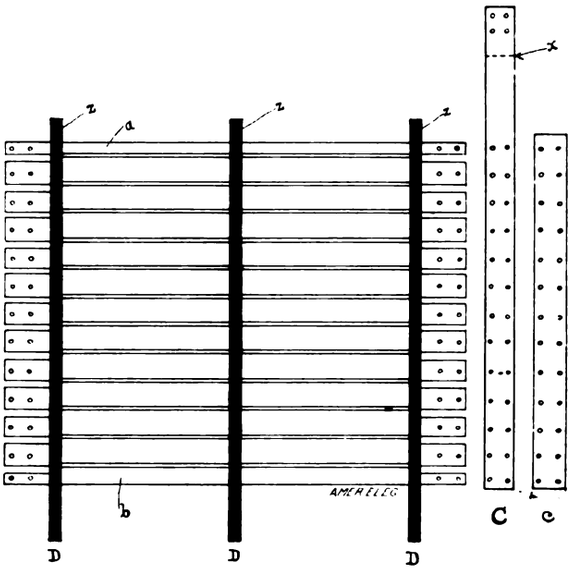

FIG 3.—COMPLETED PLATE.

outside plates; P the paste, or active material; D, the rubber retaining fingers; J the glass jar, and C, c, the vertical connecting strips. The strips, C, are shown coming straight upward instead of bent over, to avoid obscuring the view of the plate ends. The rubber fingers, D, in addition to holding the twelve strips composing each plate in their proper positions, serve to prevent the plates themselves from buckling and shifting in the jar. The edges of these rubber fingers are shown slightly separated, but, as a matter of fact, they must abut each other so as to keep the plates firmly in position. The jar, J, is rectangular, and should be 8¼ ins. long, 5¾ ins. wide and 7½ ins. deep, inside measurement. None of its dimensions can be smaller than specified; if the width or length be greater, a rubber strip of wood may be used to bring it down to the figure desired. A sheet of soft rubber must be laid against each end and side wall of the jar, and the plates must fit snugly against the rubber sheets so that they will not shift in the jar; soft rubber must be used for the wall sheets in order that the plates may expand without tending to buckle.

As above stated, each cell contains four positive plates and five negatives; the two outside plates are negative, and have paste on only *one* side each, as the sides next to the wall of the jar are not active. The terminal strips, C —, on the right hand end of the cell are all negative; those marked C + on the left hand end are the positives, as their signs indicate. The short strips, c, serve simply to connect the parts of the plates to each other, and should not project above the upper edges of the plates.

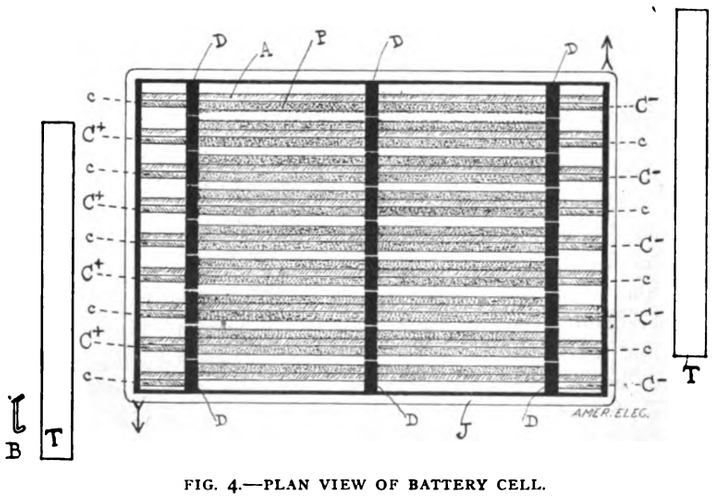

FIG. 4.—PLAN VIEW OF BATTERY CELL.

All the positive ends, C +, at the left are riveted to a lead strip, T, which is laid along the top of the bent-over ends of the strips, C +. The negative connectors are similarly riveted to the other strip, T 2, and these two strips form the terminals of the complete cell. The arrows at the corners of the jar indicate the direction in

Digitized by Google

which the ends of the terminals are led from the cells to connect to an adjoining cell or to leading wires, as the case may be.

Each cell of battery of the above dimensions, when properly pasted and "formed" will give an electro-motive force of about 2 volts during the greater part of its discharge, and it may be discharged at the rate of 18 to 20 amperes. To operate any of the small motors described by the writer in the issues of February, April and September, 1897, and February, 1898, four of these cells will be required. (The battery winding given in each article, must, of course, be used on the motor.) After the cells have been "formed" as described below, they may be kept charged sufficiently for light, intermittent service by connecting up 10 cells of gravity battery in series with the four storage cells, the copper terminal of the blue-stone battery being connected to the positive terminal of the storage battery. This connection may be left permanently on, during the use of the storage cells as well as when they are idle, the only attention necessary being the replenishment of the gravity cells at comparatively long intervals.

The plates of the storage cells are pasted, the positives with a thick paste made of red lead and dilute sulphuric acid, and the negatives with a similar paste made of litharge and dilute acid. The acid should be one-tenth concentrated sulphuric acid and nine-tenths water, and the water should be distilled; the proportions of one and nine parts are by weight, not volume. In mixing, always pour the acid into the water, never the reverse. The pastes must be mixed with wooden spatulas in glass or earthenware vessels, and should be so thick (containing so little dilute acid) as to appear almost powdery. The pastes are applied to the sides of the plates and pressed firmly in with the spatulas until the surface of the paste is flush with the edges of the little shelves; the entire surfaces of the lead strips, except the edges of the shelves, must be covered evenly. The best procedure will be to take all the positive plates first; lay them flat on a board, and apply red lead paste to one side. Set them aside and mix the litharge paste (in a separate vessel and with a separate spatula), and then treat one side of all the negative plates. When the plates are all dry, turn them over and treat the other sides, being careful not to jar out the paste already on the under sides. It should be remembered, too, that two of the negative plates in each cell are to be treated on one side only—the side which comes next to the neighboring positive plate.

When the plates are all pasted, assemble them in their cells, as described above, and then rivet the ends of the connectors, C+, and C—, to the horizontal terminal strips, T and T2. Connect the positive terminal of one cell to the negative terminal of its neighbor, and fill all the cells with a solution consisting of one part concentrated sulphuric acid and four parts distilled water, measuring by weight. Connect the series of cells in an arc light circuit, just as though they were arc lamps, and let the current pass through them from the positive to the negative terminal of the series until the paste on the negative plates has all turned color. The cells will then be "formed" and ready for service. They should not be allowed to remain charged long before being put into service, and it will be advisable, therefore, to have the apparatus for which they are to furnish current all ready to start up before putting the cells in circuit for formation. The arc light circuit on which the cells are "formed" may have any current value from 4 to 20, but as most of the circuits in this country carry either 6.8 amperes or 9.6 amperes, one of these values will doubtless be found in the charging circuit.

If the circuit is an intermittent one (does not run constantly, 24 hours a day), care must be observed to take the battery out of circuit as soon as the current is off at each shut-down, so that it cannot discharge in case the line is closed before current is restored.

## TELEPHONE PARTY LINES.

BY H. S. WEBB.

So far there is nothing in the system as explained and illustrated in the preceding section of this article, to prevent any subscriber from taking down his receiver and overhearing a conversation going on between two others, although his local bell has not been rung at all. To accomplish this very desirable feature two current combinations are reserved, one for locking the apparatus at all the stations except at the one called, and the other for unlocking all instruments when the central station operator clears out the line. Six combinations are thus left for selective signaling, so that in the present arrangement there are only six stations on one pair of lines. This is generally a sufficient number, because if more are put on it is apt to result in bad service and dissatisfaction, owing to the fact that one of these subscribers must wait, if the line is busy, till it is clear before he can be served, and similarly some one else on a separate line calling up a subscriber on a party line which is already in use must wait his turn.

Figures 1 and 2 give the diagrams of the system for six subscribers' stations on a pair of lines when locking and unlocking devices have been added. A positive current over the A and B lines in parallel, returning through the earth, is used for locking, and a negative current in place of the positive for unlocking. This leaves a positive current over A to call subscriber No. 1, negative over A to call No. 2, positive over B for No. 3, negative over B for No. 4, positive over A returning through B for No. 5, positive over B returning through A for No. 6. In the last two combinations the lines A and B are in series and the earth circuit is not used at all.

If it is remembered that currents of proper direction only will close the polarized relays, but a current in either direction will open the neutral relays, it will be clear that positive or negative currents over both lines A and B will not call up subscribers Nos. 1, 2, 3 or 4, because a current in either direction will open the neutral relays. Nor will subscribers Nos. 5 or 6 be called up by locking or unlocking currents because they each have two polarized relays requiring a positive current over A and a negative over B, or vice versa, to close both their relays. A current in the wrong direction will leave them open.

In Fig. 2 is shown the arrangement used in each subscriber's instrument for locking and unlocking. R and $R_3$ are the same relays as shown in Figs. 3 and 1. The upper half of Fig. 2 shows the instrument for a subscriber which requires only a positive current over A to ring its bell. $R_3$ is an electro-magnetic apparatus with a closed iron circuit. Over the limb 41 is wound the wire from R, and over 40 is wound the wire from $R_3$, both being wound in such a direction that the flux set up in the iron, by any combinations of currents through 40 and 41 used to call up any

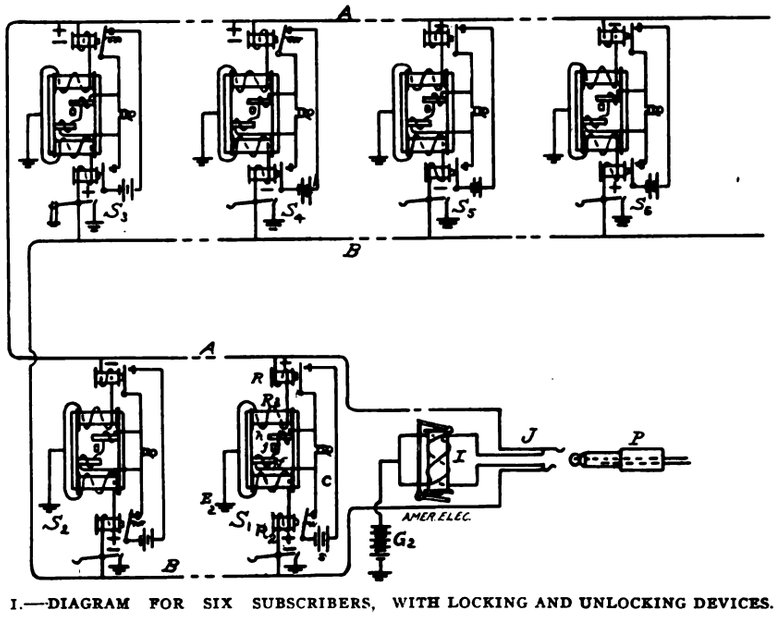

FIG. 1.—DIAGRAM FOR SIX SUBSCRIBERS, WITH LOCKING AND UNLOCKING DEVICES.

Digitized by Google

of the six stations, will be in the same direction through the iron yokes connecting cores 40 and 41. That is, the magnetomotive forces producing the magnetic flux are in series, and the cores and yokes form a continuous magnetic circuit of low reluctance for this flux. f and h are soft iron projections, as shown, with a polarized steel armature (j) between them. Coils which are connected in a shunt circuit around the bell D are wound over the soft iron projections f and h. Before any current can flow through these coils both contacts 10 and 11 at relays R and $R_2$, respectively, must be closed; that is, when this subscriber is called up by the ringing of his bell a current will, at the same time, flow through the coils on f and h.

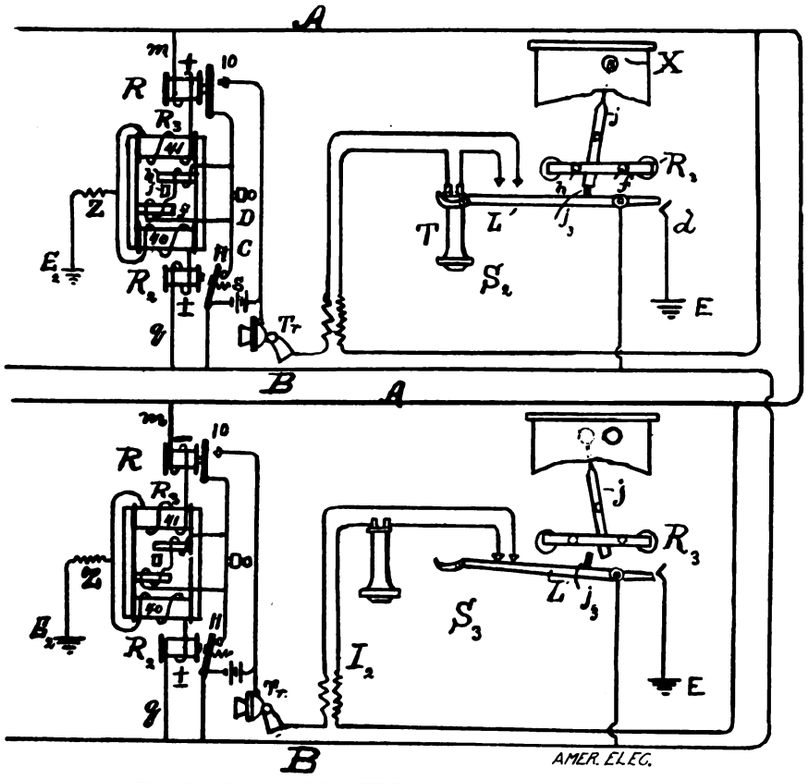

FIG. 2.—DETAILS OF LOCKING AND UNLOCKING DEVICE.

Now in the normal state practically no flux will flow through the high reluctance circuit 40 h j f 40, or through 41 f j h 41, when it can pass through the closed iron circuits formed by the cores and yokes, whose reluctance is much less, since it contains no air gap comparable to the gap between h and j and between j and f, even if the joints between the cores and yokes are bad. Therefore the polarized armature, j, will be unaffected, because the magnetic poles at f and h are too weak. This is the normal condition at all stations.

Suppose the operator desires to call $S_3$. A positive current is first sent over both lines A and B in parallel by pressing the proper key at the central station. This current, passing through 40 and 41 in parallel and returning through the ground, sets up an opposing flux in the yokes, thus causing the lines of force to complete their circuit through h j f, moving the polarized armatures j in such a direction as to lock all the instruments, i. e., by means of the lug $j_3$ it prevents the hook switch from moving up, even though the receiver be removed, and at the same time displays through a hole in the telephone box a busy signal, showing the subscriber that the line is in use and that he will have to wait until a clear signal is shown before he can use his telephone. The lever will remain in its locked position until either the unlocking current (negative over both lines A and B in parallel) or the proper calling current for $S_3$ causes it to be unlocked.

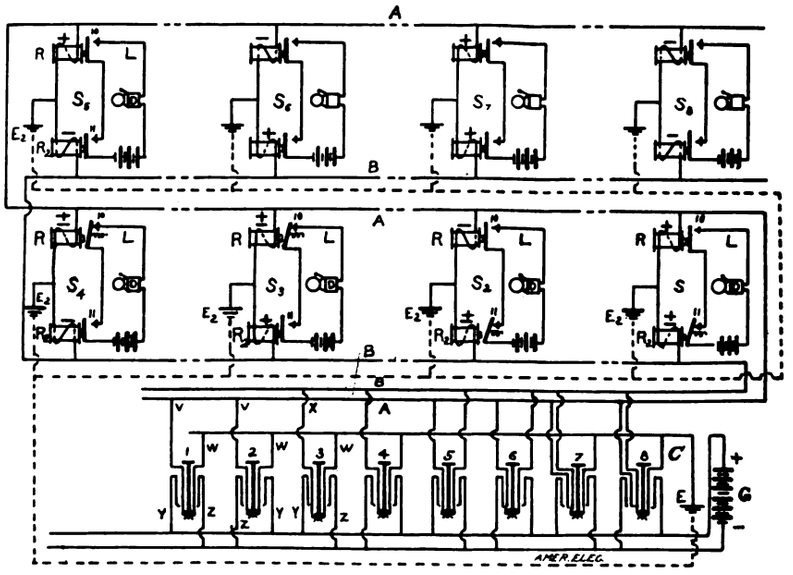

FIG. 3.—DIAGRAM OF CONNECTIONS FOR EIGHT SUBSCRIBERS WITHOUT LOCKING AND UNLOCKING DEVICES.

The operator now presses the proper key to call up $S_3$, that is, a negative current only is sent over line A. Both relay contacts at $S_3$ being closed, the bell rings and at the same time a current flows through the coils on h and f in such a direction as to move the armature j to its unlocked position. All stations except $S_3$ will evidently remain locked, since their coils on h and f have no current passing through them. Thus only the subscriber called can connect his telephone to the line by removing the receiver. When the conversation is ended, the operator unlocks all stations by sending a negative current over both A and B in parallel. This causes the polarized armature j to be moved to its unlocked position and the busy signal to its clear position at all six stations. The locked and unlocked positions of j are shown at $S_2$ and $S_3$, respectively.

The central station annunciator, I, Fig. 1, has two equal coils wound upon the same core. A small, steady current is normally flowing in opposite directions through these two equal coils so that the annunciator is not affected. This same current also flows through the coils 40 and 41 on $R_3$ at all stations, tending to keep all the switches unlocked.

When the line is not in use, all that a subscriber has to do in order to call up the central office is to remove the receiver from the hook. As the rear end of the hook switch moves down, it momentarily touches the spring d, connects line B direct to earth, thereby reducing the resistance of the B line circuit below that of the line A circuit, because the path from B to earth through the rear end of the switch and spring d has less resistance than the path from A to earth through R 41 Z E. Thus more current will momentarily flow through one half of the winding on the annunciator than through the other half, and consequently it will cause the annunciator shutter to drop.

At the central station there are eight separate keys, one for calling each of the six subscribers, one for locking and one for unlocking the receiver hooks. These eight keys are connected to a plug P, as the six keys in Fig. 4 are connected. By the addition of one or a pair of push-button keys to

Digitized by Google

each set of cord plug circuits now in use it could be arranged so that in place of using the ordinary alternating current generator for calling this system of eight keys and battery could be connected to the plug line circuit, thus obviating the necessity of having entirely separate plug sets for use on the party lines alone. Thus only one set of eight keys will be required at each section for a multiple switchboard having party line jacks.

S. W. Whittemore later took out another patent by means of which he does away with the polarized magnetic device $R_2$, replacing it with an electromagnet; and furthermore no separate key is needed for locking or unlocking the hook switch.

In this system for selective party lines, Fig. 4, the combinations of relays at the subscribers' stations to close the local battery and call bell circuits and the current combinations required to work these relays are the same, but the locking and unlocking device is entirely different from that described in the previous patent.

This device consists of a double electromagnet and, except the winding, it resembles the self-restoring annunciator used on the bridging multiple switchboard system. As can be readily seen in Fig. 4 the wires from the lines A and B are wound around M, which may be called the locking electromagnet, in opposite directions, then they join at point 7 into one wire, which is wound around N, the so-called unlocking electromagnet, and finally connected to earth. Opposite the end of the unlocking electromagnet is hung a shutter armature held upright by a hook on the end of an arm controlled by another armature at the end of the locking or double-wound electromagnet. The shutter armature has attached to it a light aluminum vane which serves as a visible busy signal. There is also a pin or lug extending outward from the shutter armature which, when the shutter armature is released, prevents the receiver hook from rising and closing the telephone circuit even if the receiver is removed.

In parallel with the calling bell is an electromagnet, F, which when energized holds the armature K with sufficient force to prevent it being moved by the pull of the electromagnet M. In Fig. 9 the locking and unlocking device is only drawn complete at one station, since it is exactly the same at all other stations.

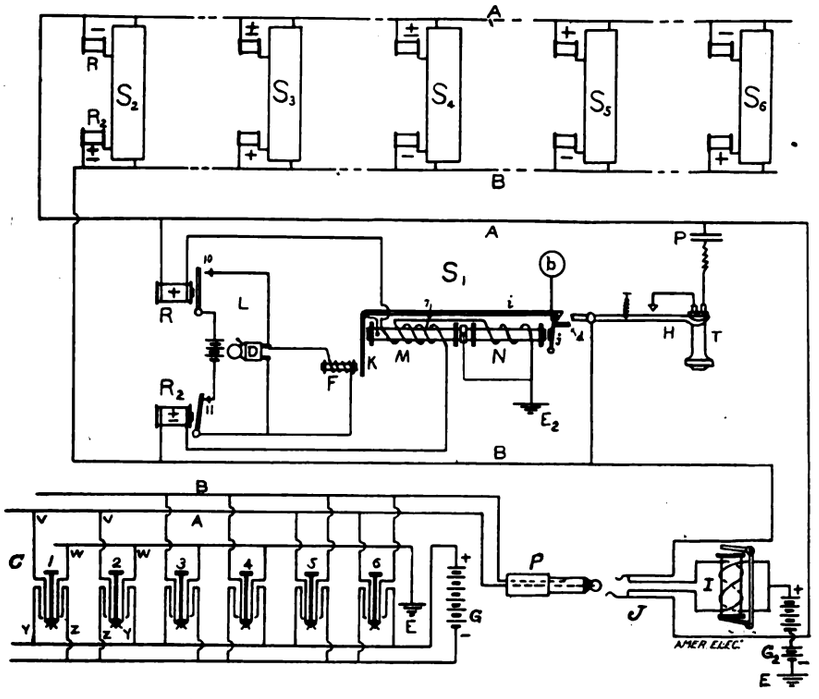

FIG. 4.—DIAGRAM OF SELECTIVE PARTY LINE SYSTEM.

The working of this system is as follows: The lines A and B pass in opposite directions through a differentially wound annunciator at the central station switchboard and through a battery to earth, practically the same as shown in Fig. 2 for the preceding patent. When the line is not in use equal currents from the central station battery flow through the two windings on the annunciator in opposite directions, so that it is not magnetized, through lines A and B in parallel, through all the station relays to earth at $E_2$, energizing N but not M, since the current flows through its two windings in opposite directions. Thus the hook switches are normally held unlocked at all stations by a positive current through the two lines.

When a receiver is removed, while the line is not engaged, the rear end of the hook switch as it moves down (Fig. 4) momentarily touches the rear contact d, thus completing the connection from ground at the subscriber's station, through line B, one half of the annunciator, the generator $G_2$, and to ground E at the central station, thus dropping the annunciator shutter for exactly the same reason as in the system previously described. When the operator inserts the plug into the spring jack the annunciator and battery are cut off.

Suppose the operator desires to call up subscriber S. The plug is inserted into the spring jack and key 1 at C is closed. For the same reason as in the preceding patented system the only local bell circuit which will be closed will be that of subscriber S, and hence this bell only will ring. Furthermore, this operation of ringing up subscriber S will lock the receiver hooks of all the subscribers except that of subscriber S for the following reason. Whenever a key is pressed a positive or negative current circulates in one of the lines A or B or a positive current circulates in one and a negative current in the other line, and the coil M at all the stations will be energized. Under these conditions its core will attract the armature K, the shutter j will fall, and the hook switch H will be locked, except at the station S, whose relays R and $R_2$ respond to the current sent to close the local circuit L, thereby ringing the bell D and magnetizing the core of F, which attracts the armature K and thus keeps it from moving toward the core of M. Consequently the shutter j at station S does not fall, and the hook switch H at that station is not locked.

If the shutters j at the several stations should be attracted by the core of N while a ringing current is traversing the circuit and causing the attraction of the armature K, the shutter will fall after the current has ceased, as it will have passed beyond the reach of the arm i as the latter returns to its depressed position.

When the conversation is over the operator removes the plug from the spring jack, thereby sending positive currents from the battery $G_2$ over both lines A and B in parallel, which currents neutralize each other in the oppositely wound coils M, but magnetize the core N, causing the shutters j to be attracted and to become locked to the arms i.

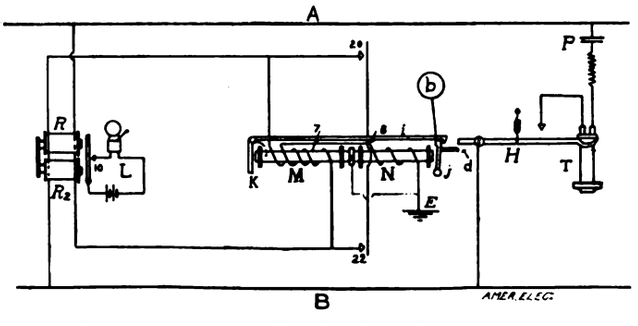

FIG. 5.—MODIFIED SELECTIVE PARTY LINE SYSTEM.

In the modification shown in Fig. 5 the relays R and $R_2$ are combined into one piece of apparatus, and to close the local call bell circuit requires the closing of only

Digitized by Google

one contact, and it is thereby easier to keep the signaled station unlocked. In this case the coil M can be prevented from being energized by short circuiting its coils by means of the armature 10 at the station called, as the said armature in falling back to complete the local circuit L can be made to close 20 and 22, which points are connected direct to point 8 between the coils M and N. When 20 and 22 are closed the two coils M are short circuited and no appreciable current passes through them.

The advantages claimed for this system are: First, that of a locking device that cannot be unlocked by jarring the box containing it; and second, an apparatus so constructed and arranged that the act of calling up a subscriber from the central station will automatically lock the other stations on that line, and the mere pulling out of the connecting plug unlocks all the stations, thus doing away with the locking and unlocking keys and at the same time saving the operator the two motions necessary to lock and unlock the telephones. Third, replacing the device for locking and unlocking which required permanent magnets, which are objectionable for various reasons, by apparatus requiring no permanent magnets.

Although this latter system seems to be superior to the former one, where eight keys are used, I do not know that it is in use at all, but I do know that the former is used quite extensively, one local company alone having two thousand instruments installed.

Although no magneto generator is required and a polarized bell is replaced by a simpler vibrating bell, nevertheless the apparatus at a subscriber's station, when either of the two patented systems are employed, is rather complex, and further, their use also complicates matters somewhat at the switchboard. However, this is all much more than offset in having practically six independent subscribers on one pair of lines.

## AN ENGLISH CENTRAL STATION ACCIDENT.

Some time ago the entire supply of the Brighton, England, central station was shut off during the evening, owing to a peculiar accident. The armature of a 220-kw. machine developed a sudden short circuit in its windings, and all dynamos running at the time immediately dropped their circuit breakers, shutting off the whole supply—9000 amps.

The accident having caused considerable discussion in our English contemporaries, the engineer of the station gave the following account (in the London "Electrical Review") of the conditions under which the station was running at the time of the breakdown.

"For the sake of clearness two only of the larger generators are shown in the accompanying sketch, in which F, F are fuses; B, B, bus bar; M, C, O, minimum circuit breaker. It will be noticed that all the dynamos were practically self-exciting and that no battery was in use. All the machines, with the exception of two half-voltage balancing dynamos, were provided with minimum magnetic circuit breakers on one pole and switches on the other, and were without fuses. The other machines were provided with fuses, which were not affected. The shunt circuits derived their current directly from the bus bars, as shown, and were provided with two-way switches and spark-absorbing coils (not shown). By this arrangement any rise of voltage in the shunt circuit at breaking is entirely prevented. Eight generators were running, having a total capacity of 1400 kw. with a load of 1170 kw. The dynamo which gave out is rated at 220 kw. At the time it was fully loaded, and had been running for six hours. A fact of importance is that everything was running quite smoothly, no change of generators being in progress. The possibility of a blunder being the cause is therefore precluded.

"The sequence of events was as follows: The first indication that anything was wrong was a series of loud reports, accompanied by a shower of sparks and molten copper, with a drop of about 50 per cent in the pressure. The light then remained steady for a period of perhaps five or six seconds, and then gradually died out, this taking probably from forty to

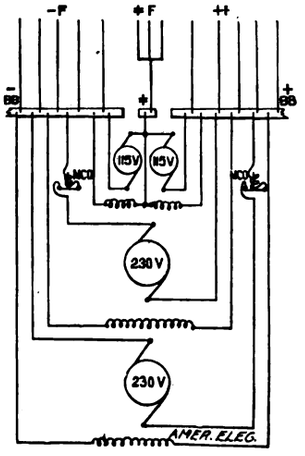

DIAGRAM OF STATION CIRCUITS.

sixty seconds. The circuit breaker of the faulty machine was seen to fall and was badly burned; the falling of the remaining circuit breakers was heard in the dark but not seen. On inspection afterwards, none of these showed any signs of burning on the contacts.

"The switchboard attendant immediately replaced all the circuit breakers, pinning them up, and within four minutes every available generator was running and connected, but doing no work. The feeder fuses were then disconnected, thus throwing off the load, and enabling the dynamos to re-excite, which took a period of seven or eight minutes; when this was accomplished the network was gradually reconnected, fuse by fuse, and everything went on again as usual. The whole shut-down lasted from twenty to twenty-five minutes. A band was found loose on the armature of the damaged machine, and a large hole was burned in the copper bars immediately under it."

In another journal the engineer of the plant expresses the opinion that the cause of the other machines dropping their loads was the combined effect of decreased speed and armature reaction, due to the short circuit, which reduced the fields to zero. The circuit breakers used were all for "minimum current." The engineer states that the use of "non-return" instead of "minimum current" circuit breakers, and the separate excitation of machines, are absolutely essential in this and similar installations to afford complete security from the class of breakdowns that occurred.

## GENERAL METER PRACTICE.

BY LYMAN C. REED.

The testing of meters on the consumers' premises has frequently to be done, and, in fact, is, for various reasons, the best practice if properly carried out. That branch of meter testing will form the subject of the greater part of the present article.

The difficulties encountered in making a reliable test of a light or power meter in circuit have in the past been found somewhat greater than was anticipated. Years ago a lamp bank was employed, but owing to the large size necessary for testing large meters, and also the fact that the consumer was entirely deprived of current while test was going on, it has been abandoned. The volt-ampere meter method is very much used, but where the current is variable, either in potential or amount, this method becomes very inaccurate, and a correct test cannot be made. The indicating wattmeter connected in series with the load is only a modification of the above, and admits of the same serious objections.

Especially are these methods absolutely unreliable when used on direct-connected elevators or other installations where the load is constantly varying. To meet all the varying conditions and at the same time overcome the objections cited above, the following method has been found by the writer to answer the purpose:

A regular stock meter of such type as the ones in use is converted into a portable meter in very short time and at a minimum expense. As we are dealing with the Thomson wattmeter, the method of converting it into the form desired will be given.

We first remove casting which ordinarily fastens the meter to the wall, and place a handle of leather on top of the regular cover. The cover is fastened to the base by the usual bolt and wing nut, with an additional one placed at the back. Four turnbuckles with hooks are provided and fastened to the meter, one on either side of the dial plate, and one in each wooden strip that holds binding poles for inleading wires. The turnbuckles are preferably 1½ ins. long and connected by brass chains.

The portable meter is now suspended under the meter to be tested by means of the hooks, and readily levelled while in this position by the turnbuckles. The two meters are placed in series, and then the

Digitized by Google

desired load turned on. The discs are started at the same point, and in a few revolutions it can be seen whether the meter being tested is fast or slow. Any degree of accuracy can be obtained by letting the meters run for, say, fifty revolutions, when it will be seen that a small portion of one revolution will be a fraction of 1 per cent. The meter is readily adjusted if fast or slow. The portable meter is kept standardized by testing after each day's work.

The many advantages of this method can be readily seen, as the consumer is not interfered with in his burning, and can be given a practical illustration of the correctness of his meter. The test can be carried on under the widest variation of load and with equal accuracy, and, in fact, is the only practical way of testing meters on motors where the load is constantly varying. A practical accuracy is obtained free from theoretical errors, errors in figuring, or errors from stop-watch. The mechanical features are equally desirable, as meters, in whatever position they are placed, can be tested with the same ease and quickness. If too near the floor to admit of suspension, the meter is placed on the floor, and the test conducted as before.

Where the current is alternating, this method is about the only correct one if the load is inductive, as the difference between the apparent watts as indicated by volt ammeters, and the true watts, may be such as to give a very inaccurate test by that method. In practice it has been found that from four to five sizes of portable meters are all that are required to test a whole system of either alternating or direct current meters, and the expense incident to inaugurating the system very small.

The question of how often to test meters on circuit can not be decided by a sweeping rule, but must be also a matter of judgment and determined by the locality in which the meter is placed. It is best to err on the right side, and tests of at least twice a year should be made; in some cases much oftener. It has been found in practice that one man can keep a whole system of 2500 meters in perfect condition by testing each meter once in four months, and certainly no evil results can ensue from this practice.

The relation of the consumer and company should always be of a harmonious character, and anything which tends to educate the consumer out of the belief that the meter is more or less a part of the paraphernalia of a "confidence" game, is a direct gain. By all means, let the consumer understand his meter, if possible very thoroughly, and he will then see that he is getting the proper returns for his money, and any number of "kicks" will be avoided. In this connection we have found it good practice to send around to each consumer a printed card or circular, giving exact directions for reading the meter and figuring out the bill. In this way the consumer is enabled to make rough tests of his own by the dial hand, and finds out how much he is burning and when he burns it. That a great many complaints are made which would be avoided if the consumer was in a position to know what he was using has been proven over and over again.

In the discussion of making retests on complaints, the method of charging a nominal amount for the test is a good one. However, the conditions are changed if there is active opposition unless the opposition companies act in unison on this point; otherwise the company that did not charge for tests of their meters would secure the business. Where the meter is found in error and the complaint a justifiable one, no charge should be made, or even where for some cause unknown to the consumer the bill increases suddenly, no charge for the test should be made. The object of charging for a test of the meter is to stop all complaints made with an idea of gaining time or in hope of some rebate on the bill, and it is this class of "kicks" that form the larger part of the complaints.

Our opinion with regard to reading meters coincides so fully with the methods as set forth by Mr. E. A. Leslie in his recent paper before the Electric Light Convention, that I take pleasure in referring all those interested to that paper for a much fuller and better explanation than I can give. I take great pleasure in heartily indorsing this method, because, after several years' trial, we have found it to be an excellent one.

The question of special rates is one which is occupying the attention of nearly all general managers at present, and as yet no definite system has been established on which to operate. This subject lies just outside of the scope of this article, as it only affects meters in the different methods employed to obtain the rates. The consumer's load curve is obtained as nearly as possible, and a rate given from the conditions presented. Two-rate meters are employed in some instances with two dials, and the movement connecting the registering train switched over at fixed hours. Others guess at the consumer's load curve and allow him a rate accordingly. Another method is the one already referred to, of placing two meters in parallel and having the load on each regulated by an automatic switch. Another well-known system is the "Wright Demand." All of these methods are simply modifications of general meter practice, and in some cases call for special devices and special practice outside of any general plan of operating.

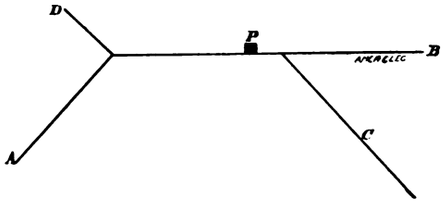
Generally speaking, the province of the meter department is to see that all current is accurately measured, and when this is obtained, the minor considerations are relegated to their proper place. If the central station is earning a 10 per cent dividend on $500,000 gross receipts, the amount of dividend is $50,000. If, owing to poor management in the meter department or inaccuracy of instruments used in testing, etc., errors of only 3 per cent are introduced, these affect the dividend directly by this amount, as all operating expenses and fixed charges remain the same as though these errors had not occurred. This instance is cited merely to show how absolutely essential it is to have all parts of the work connected with the testing done as correctly as possible.

We take it for granted that to those interested in the selling of current from central stations, the meter question is probably the leading one of to-day, and when one stops to consider the large gains and losses incident to good or bad meter practice, it proves itself to be a subject well worthy of our best attention.

## SNOW-BOUND STREET-CAR SYSTEMS.

BY WM. HERBERT DONNER.

There are many standards by which it is possible to gage and compare the workings of a street railroad system, but there is no more severe test of what we may call the effective running power than the ability to keep within reasonable touch of the regular schedule during the prevalence of a heavy snowstorm. Doubtless, many people have noticed that, under what may be approximately the same conditions, one road will keep its cars running, by some means or other, while another road will have its power house idle and its cars stalled at different points all along the line.



There will be a reason, of course, for each case. The more fortunate system will have more power at disposal with which to clear away the snow, and force its cars along; or its grade will be easy; or its tracks will be less exposed to drifts. But there must be still another and more important reason, and it will generally be found to be true; it is, that the system that can keep its service going has a better hand guiding it, and a head which is clear-sighted and equal to all emergencies. It is not sufficient to provide only the machinery to guard against breakdowns; there must be some well-considered method of operation calculated to successfully meet all conditions and deal with them promptly.

In the matter of sweeping the track there is plenty of room for discretion. The superintendent should understand his road so thoroughly that he will know at once where he may expect the most trouble, and where the snow is likely to form drifts. This may depend somewhat upon the direction of the wind, which should, accordingly, be taken into account. These drifts must be attacked as soon as possible, using a heavy snow plow to cut a way through. The sweepers should be kept running as soon as the snow begins to lie thickly on the ground, and may even be sent over the line earlier, as a precaution. There should be no delay on the score of want of repair, unless there has been some recent accident, for the motor circuits should all be ready tested and everything in running order on the approach of a storm.

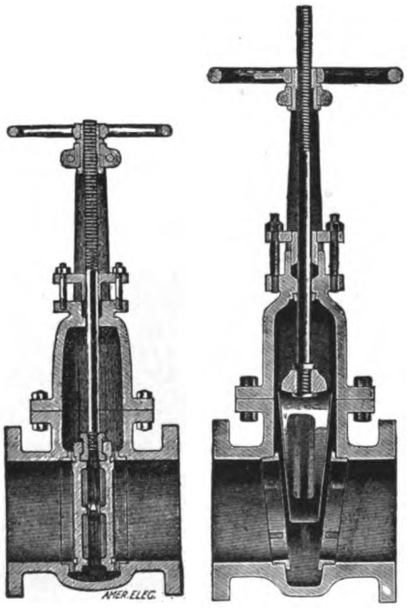
It is a very good plan to have sheds for the snow-sweepers at different points on the line; as, for instance, at the junction of branch lines or midway along them, and at each end of the main line, so that the sweepers may be kept there during stormy

Digitized by Google

weather, instead of being all bunched together at the central car house, from which several of them may pass over the same track in going out. Suppose, for example, in the accompanying figure, that the power

house is at P; then, if there are sweepers available, they may be located at A and B on the main line, at C on the branch line, and possibly another on lineD, and at the power house.

In the adjustment of the sweeper to the work it is required to do, there is opportunity for a little applied intelligence. During a storm there will inevitably be a heavy strain on the power house machinery to keep the cars running, and any additional power taken to operate sweepers should, therefore, be well used. The writer has seen the brooms set down so far that they bore hard upon the frozen ground, tearing up and scattering small stones and particles of earth along with the covering of snow, and consuming an appreciable amount of power to no useful purpose whatever, as well as subjecting the brooms to a very unnecessary wear and tear. So long as the snow is removed there is no necessity to do more, and the brooms should be set at such a height as to clear off the snow without touching the ground continually. Some men set the brooms to clear the track where the ground is low between, as in the case of T-rails on ties, and neglect to readiust them for higher ground, as, for instance, when entering on paved streets.



Excuses are frequently made for electric traction systems that get snowed-up, even on roads operating hundreds of cars. We are told that the adhesive force between the wheels and rails is so low that the cars cannot force their way through the snow. There is a remedy even for this. If the road has been neglected during the early hours of the storm, or some accident has prevented the tracks being quickly cleared, there is still no reason to give up while power is available. If the city ordinances will permit, a certain proportion of the cars should be coupled into trains consisting of three or four cars, or more. Stops should be made at correspondingly longer intervals, determined beforehand, even if people get left behind by waiting at the wrong place. Single cars may be run between the trains, making stops as signaled, the number of trains used being determined by the conditions to be met in each case. All the starting bells of one train may be connected to one cord, and one conductor given general charge; or the ordinary method may be employed, as when a motor car and trailer are coupled, of ringing the starting bells in succession. If it is necessary to use a snow-sweeper, and sufficient tractive force is not available from the driving wheels, the same expedient may be used of coupling on one or more heavy motor cars and running them straight through, in the same way as a sweeper alone would ordinarily go.

There are other details concerning the management of street car systems which depend primarily upon the intelligence and vigilance of the person in control, but the perfection of thorough efficiency can be secured only by careful and conscientious study of existing conditions.

## STEAM AND WATER STOP VALVES.

### GATE VALVES.

There are certain cases where plain wedge gate valves are more to be desired than any improved form that raises the disc from the seat before imparting movement to the former. For such cases the valve shown by Fig. 1 was designed by the Kennedy Valve Manufacturing Company. The wedge gate fits between hard bronze seats, and is made for 125 to 250 lbs. steam pressure and superheated steam. The seats in the body can be unscrewed and removed at will, thereby being easily replaced when worn or damaged. This valve has a collar —shown in the engraving—which fits the spindle and closes the bottom of the stuffing box, thereby enabling the valve to be packed without the necessity of closing it. The metal is distributed to withstand not only the strains of the liquid or gas, but the tremendous strains of expansion and con-

FIGS. 1 AND 2.—WEDGE AND PARALLEL SEAT GATE VALVES.

traction are also provided for so that the valve will not be internally distorted thereby.

The same company also manufactures the parallel seat valve, shown by Fig. 2. This form of construction follows the scheme of relieving the disc and seat of pressure through contact with the moving parts, and this is effected in a decidedly novel manner by connecting the two gates to each other by means of heavy right and left hand thread screws, which so connect the discs and are so attached to them that the first turn of the valve spindle removes all traces of pressure between the seats and discs. Fig. 3 shows the discs used, and also the manner in which the screws are arranged. These are so connected with the stem mechanism that they are operated only when the discs are in their seats, either being tightened by the last turn or part turn of the valve stem, or loosened by the first partial revolution of the stem as the valve is being opened. All wedge surfaces or seats are dispensed with by this arrangement of the discs, and, as stated, none but parallel surfaces must be prepared or maintained in the making of the valve. Pressure can be applied at will to either side

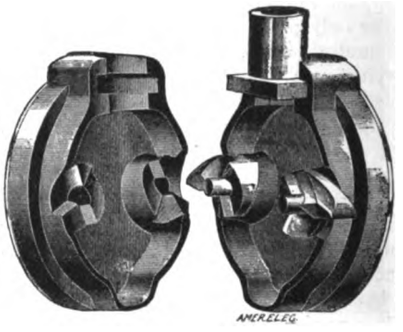


FIG. 3.—RIGHT AND LEFT HAND SCREW DISCS FOR DOUBLE GATE VALVE,

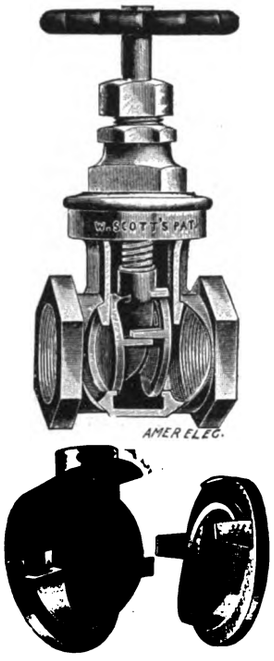
of these valves, and they are made both with and without the by-pass.



Figs. 4 and 5 show the working parts of what is known to the trade as "Scott Valves," made by the Roe-Stephens Manufacturing Company, and include both the rigid, solid disc and the "collapsible" disc as made by other companies. Fig. 4 shows the general internal arrangement of the Scott valve, and Fig. 5 shows the manner in which the discs are constructed. The maker of this valve states that by the peculiar construction of the cylindrical wedge and the full circular bearing upon the back of the disc or gate, the wear is taken from the face and seat, thus ensuring a perfect seating and the impossibility of the discs springing, bending or getting out of shape. The discs are raised by their lugs coming in contact with corresponding shoulders on the wedge. By the peculiar arrangement of the lugs, the bearing of one disc slightly rotates upon the other, so that the least movement on the stem releases one disc slightly in advance of the other, thereby causing the valve to open easily under the heaviest pressure.

It has always been claimed by some mechanical engineers that a solid disc valve does not allow for unequal expansion; consequently the disc expands more in one place than in another, causing the valve to leak when the closest examination of the valve after it has been removed from service shows not the least thing to cause leakage or failure of the valve. The form given to the above described valve—a full circular bearing—is intended to ensure a perfect seating, and impossibility of the disc either springing, bending or getting out of shape. These valves have no special

Digitized by Google

inlet side. On the contrary, they may be connected in any manner, either horizontally, vertically, or, on either side to the pressure.

The Scott valve (Roe-Stephens Manufacturing Company) are made as stated, either solid or double cylindrical, and they

FIGS. 4 AND 5.—SCOTT STRAIGHT WAY GATE VALVE AND WEDGE.

are all made wedge-shaped. None of these valves is made with parallel seats. They are made to stand pressures of from 150 to 300 lbs., the latter being known as "Extreme high pressure gate valves," and tested up to 1000 lbs. hydrostatic pressure. The seats in all these valves are screwed in, and are interchangeable. There is a ground joint under the internal end of

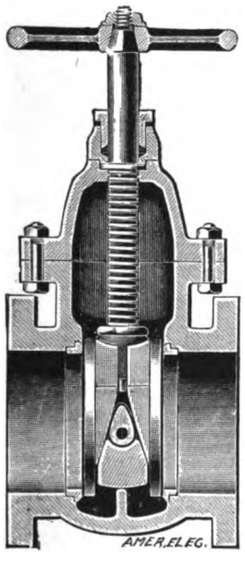


FIG. 11.—PARALLEL SEAT, DOUBLE-DISC VALVE.

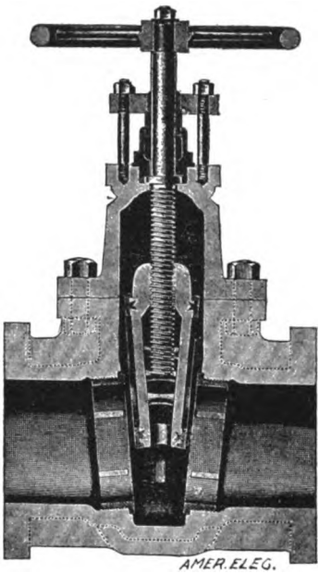
stuffing box so these valves can be packed either when closed or fully open.

While some concerns have striven to the utmost to perfect the "collapsible" disc for gate valves, other concerns have confined themselves severely to the solid-wedge form of discs, and contend that this form is the best for any and all purposes. The Crane Company takes this stand, and its valves, one of which—its "extra heavy straightway valve"—is shown by Fig. 6, herewith in section, has a disc cast in one piece with a facing of some other metal dovetailed to the disc. The guides



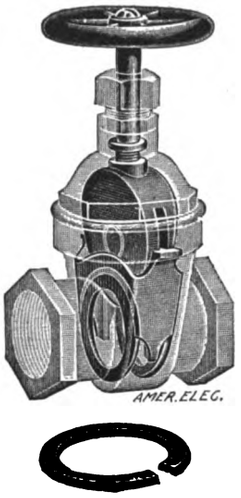


FIG. 6.—CRANE WEDGE VALVE.

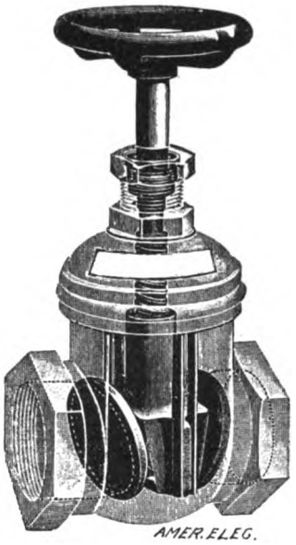
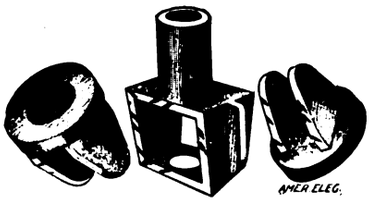
on discs and ribs in the body of the valve are fitted and finished very accurately so as to ensure a true and easy movement of the disc, to prevent a wear of the faces, and also to prevent the disc from touching the seats except at the point of closing. The seats and faces of discs are made of brass.

It is only fair to the manufacturers of this valve to state that they make their valves in three groups or qualities—the "Standard," for steam pressures up to 100 lbs.; medium pressure valves for pressures up to 150 lbs., and extra heavy valves for pressures up to 250 lbs. The strength of the valve body is modified in each kind to suit the conditions of pressure. In the "Standard" valves the discs are faced with brass as stated. In the medium pressure valves the facing is of a metal slightly harder, while in the extra heavy valves for high pressures the discs and seats are faced with hard metal throughout, thus reducing steam cutting to a minimum.



A peculiar form of gate valve is manufactured by the Fairbanks Company, which is known as the "renewable vulcanized asbestos seat gate valve." It is claimed by the manufacturers that the seats, of specially treated asbestos fiber, will not crack, flake or chip off, nor adhere to the gate (or wedge). That they are sufficiently elastic to compensate for the usual expansion and contraction of the valve body, and thus prevent binding or pinching of the gate or wedge while closed. And that being of softer material, they prevent the injury ordinarily resulting from pipe chips, grit, scale, etc., intercepted between them and the wedge. Furthermore, that they



FIGS. 7 AND 8.—RENEWABLE ASBESTOS SEAT GATE VALVE, AND SEAT RING.

are instantly renewable without special tools or skill. The gate is a single casting, wedge-shaped and double-faced, and the

FIGS. 9 AND 10.—THE "S. & B." GATE VALVE, DISCS AND WEDGE.

grooves in its sides slide on the guides in the valve body, holding it in the center and relieving the stem of strain from pressure on either side.

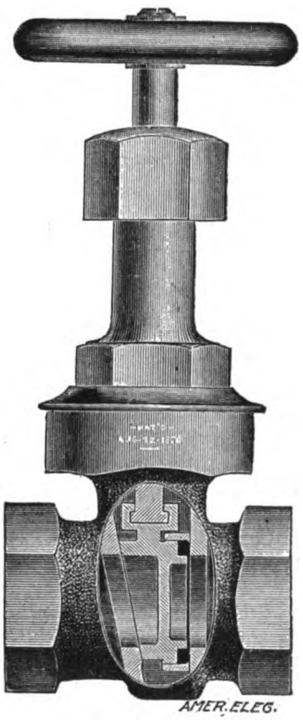


FIG. 12.—JENKINS GATE VALVE.

These valves are made in a considerable variety for all pressures, also for water and acids, and especially for ammonia used in ice-making and refrigerating. One of the

Digitized by Google

seat rings is shown by Fig. 8. These rings are provided, when so ordered, with special retaining rings for holding the seat rings in place. This device, however, does not seem to be needed except under very heavy pressures, when it is particularly desirable. Either gate or cock by-pass is furnished with the larger sizes of these valves as desired.

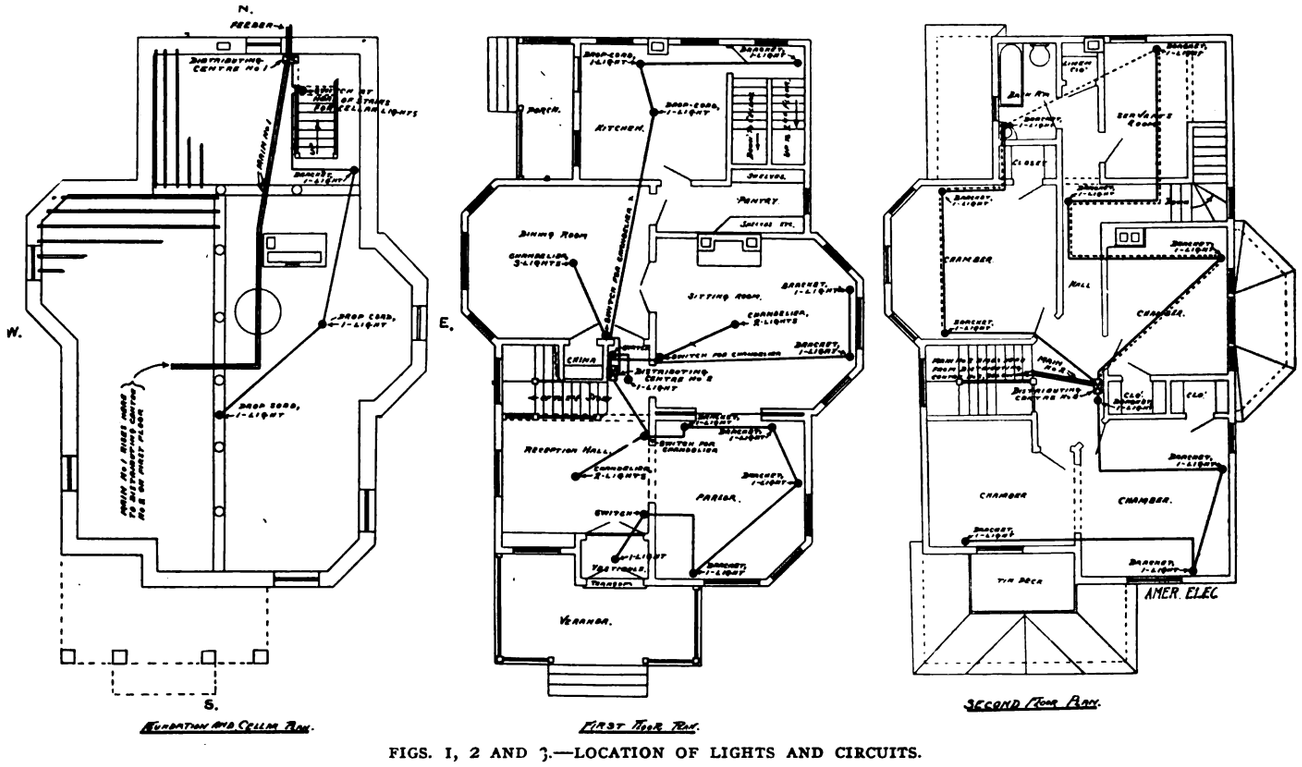
A valve in which the bearings of the wedges come one against the other is shown by Fig. 9. This valve is called the "S. & B." gate valve, and is made by the Nelson Valve Company. This valve is of the double-disc wedge variety, and the bearings of the discs approximate the ball-bearing principle to a certain extent. In operation the rounded ends of the lugs of each disc—shown in detail by Fig. 10—engage the back of the other disc, thereby virtually forming a solid yet elastic and adjustable disc, which is pushed down by the cage on the end of the stem, and the discs slide over the seats at the end of the travel until the valve has been closed sufficiently tight. The movement of opening frees the valves from the valve seats, thus preventing them from dragging across the valve faces.

The advantage is claimed for this valve that if dirt or scale gets under one of the discs it can rock from its position enough to lie upon the obstruction thus encountered. At the same time the other disc is not affected in the least, and the rounded ends of the lugs permit the discs to assume the necessary positions independently of each other.

A valve placed on the market by the Eaton, Cole & Burnham Company has the advantage of parallel seats and a wedging action to throw the discs against the seats. without the least inclination of the discs to be dragged across the seats during the act of tightening or loosening in the last and first movements of the valve stem. The manner in which the wedging action is effected is plainly shown in the cut, Fig. 11. The discs moving down quite near together until nearly across the valve opening. Then the bottom portion of the valve stem strikes a lug on the body of the valve, which prevents the wedge from going farther. The continuing action of the valve stem is thus turned into a lateral motion, which forces the discs apart and against their respective seats. Here the full advantage of rocking discs is obtained at once, and in a very simple manner.

One more valve completes the list of gates, and we will then proceed to examine the globe valve. This valve, the Jenkins (Fig. 12), is different from all the others. It is a "one-sided" valve, for only one side—the vertical one—is expected to make a tight joint upon the seat. This side is vertical and does the stopping act, while the other side is beveled, and does the wedge act to force the disc to a seat. The disc is practically solid, the only separable piece being a ring which is slipped on over the Jenkins packing with which the vertical face of the disc is fitted. This valve can, of course, be used with the pressure in either direction, but the construction of the valve is such that the observing fitter would invariably connect up the valve with pressure against the disc on the vertical side only.

## Electric Cooking.



A recent catalogue of electric heating apparatus gives the following data of energy required for the cooking utensils named: Chafing dish, 440 watts; broiler, 1500 watts; griddle (large), 1500 watts; farina boiler, 440 watts; stew pan, 200 watts; coffee heater, 400 watts. The current is found by dividing the watts by the voltage.

## INTERIOR WIRING.

BY CHARLES E. KNOX.

In the preceding articles we have outlined the principal points to be considered in "laying out" the interior wiring in various kinds of buildings. At different times we have selected various types of buildings, by way of example to illustrate some particular feature of interior wiring. Let us now, however, in this number select some particular building, and proceed to lay out the electric light circuit work, from start to finish. This will be by way of resumé of all the preceding articles.

For this purpose, in order to avoid undue complication, we will select a building in which the electric wiring will be extremely simple. The building adopted is one shown in the supplement of the "National Builder" (Chicago, Ill.), of November 15th, 1898, and designed by George O. Garnsey, architect. It is apparently a country residence, consisting of a cellar, two stories and attic. The general arrangement of the rooms, etc., is shown in figures 1, 2 and 3.

FIGS. 1, 2 AND 3.—LOCATION OF LIGHTS AND CIRCUITS.

The building is about thirty-two feet wide, forty-eight feet deep and thirty feet high.

Before starting to locate the lights, it would be well to have three points settled in regard to the installation. These points are: First, what kind of current will be supplied to the building; second, what will be the voltage at the point of supply; third, what rules and regulations will govern the installation.

The necessary information on all three of these points can be obtained from the local company supplying electric current in the town in which the building is located. Let us assume that the building is to be located in a small town, of say 3000 inhabitants. In a town of this size there is very

Digitized by Google

little question but that the alternating current system of distribution would be used. The current would probably leave the station at a pressure of either 1100 or 2200 (approximate) and be reduced by means of the transformer at the point to be supplied, to 104 volts. We will therefore assume first that the house is to be supplied with single phase alternating current at a pressure of 104 volts; second, that the transformer will be located on one of the electric light poles near the rear of the house; third, that the installation will be governed by the rules and regulations of the National Board of Fire Underwriters. As alternating current is to be used, it must be borne in mind that owing to induction, any two wires constituting one circuit must be placed in one tube. We may also safely decide that all wires must be inserted in some form of iron tube, having an insulating lining. As the rules are constituted at present it is difficult (and it is well that this is the case) to use anything but iron conduits. Owing to the reduction in the price of iron conduit and to the fact that only one conduit is needed for a circuit instead of two (which is the case, if any other kind is used), it is probably about as cheap as any other kind of conduit.

These points having been settled, we may proceed to locate the lights. Starting with the cellar, we find that three lights will probably be sufficient; one of these should be placed at the foot of the cellar stairs (see Fig. 1), one near the furnace and one in the front portion of the cellar. All three of these lights would better be controlled by a switch located at the head of the cellar stairs as shown.

In the kitchen on the first floor (see Fig. 2), provision should be made for two single lights (cord pendants) one to be located in the center of the room and the other near the range. If the range is to have a hood, this latter should be changed to a receptacle placed under the hood. No switch is needed for these lights, as they may be turned on or off by the key on the socket. Provide a light at the foot of the rear stairs leading to the second story. In the dining room the light will be placed to the best advantage in the ceiling and, unless the ceiling room of the room is such as to invite more elaborate lighting, they should be located at one point as a chandelier in the center of the room. The cubical contents of this dining room is about 2000 ft. (being 13′ 0″ x 16′ 0″ x 10′ 0″) and unless the finish is to be rather dark, a three-light fixture will be ample. If the appropriation for the electrical equipment is sufficient (this, by the way, should be borne in mind constantly in the arrangement of the lights, etc.), it will be well to provide a switch for this chandelier. If, however, it is absolutely necessary to cut down the first cost to the lowest possible figure, the switch will have to be omitted here, as well as in other places. In the sitting room a chandelier in the center of the ceiling with two side brackets would give a good distribution of the light. The brackets are shown between the windows for the reason that they would be useful for reading if a couch or window seat were placed in front of the windows. They could of course, be placed on the south partition wall or else one on each side of the mantel; as the cubical contents of this room is about 2800 ft., the chandelier should have two or three lights and the side brackets, one light each. While a switch is not quite as requisite here as in the dining room, (the chandelier being more easily reached), nevertheless a switch should be provided if the cost will permit. The two side brackets need not be controlled by the switch. In locating the lights in the parlor and reception hall, we must bear in mind the two side brackets need not be controlled by the switch.

In locating the lights in the parlor and reception hall, we should bear in mind, that in these rooms the fixtures themselves should give a decorative effect and their location should be such as to conform with this idea. If side brackets are used here, care should be taken to avoid placing them

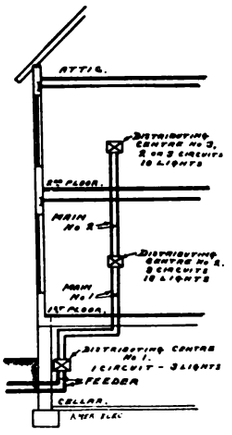


FIG 4.—SECTION OF BUILDING.

where it would be desirable to hang pictures, etc. In the parlor the conventional and less expensive mode of lighting would be by means of a chandelier, but a better effect would probably be obtained by the use of side brackets, as shown. Of course, four lights are more than is absolutely necessary in this room, but they need not be all turned on at once. A switch is not essential for these lights, as they may be turned on by the key on the lamp-socket, unless the fixtures are placed more than 6′ 6″ from the floor. A two-light ceiling fixture would light the reception hall properly unless the color of walls and ceiling was dark. This fixture should be controlled by a switch. A single light (either a receptacle or short-stemmed fixture) should be placed in the vestibule, controlled by a switch from inside. A single ceiling light controlled by a switch should also be placed at the foot of the main stairs.

On the second floor, the two larger chambers (see Fig. 3), should have two lights each, (their cubical contents being about 1700 ft.), while for the smaller rooms one light for each would probably be ample. These lights would be placed to better advantage on the walls than in the ceiling. There should be two side lights in the hall, a single side light in the bath room and one in the servants' room. No switches are needed for these lights. In the next article, the branch circuit will be laid out, and the conductor calculated.

## ECONOMY OF STEAM PRODUCTION.

BY A. L. HARRISON.

Buying coal and paying for the labor to handle and burn it, and then throwing it away in useless waste of heat up the chimney, is so common that if any one man could have an income equal to the waste of this kind in any Western manufacturing district he would hardly exchange income with a Rockefeller.

The district in and about Pittsburgh, Pa., is probably the most prodigal in this respect, because, in the early days of its iron industry coal was almost "as cheap as dirt," and manufacturers bought boilers with principal reference to their possible "crowding" capacity, and thus established a custom of waste which, like all "custom," is slow to yield to more intelligent methods.

As an example of the best practicable economy in a plant of ordinary equipment, there is a flour mill in the Central West which, in the beginning of its history, was a country custom mill; the owner, an energetic, enterprising, progressive business man, developed his business until now, with the aid of three grown sons, this mill has become an 800-bbl. mill, and the largest of several which furnish flour in large quantities, not an inconsiderable part of which is for the export trade. In the evolution of the power plant, a slide valve engine gave place to a Corliss, and it, in turn, was made into a compound condensing engine. The boiler plant grew from one horizontal tubular to three of same type, the amount of steam now required being not more than about double that in the beginning, because of the improved economy in its application or use.

The present engineer, who is unpretentious, but competent and conscientious and devoted to his profession, has been in charge of the plant for several years, and, after the engine had been compounded and all apparent practicable economy secured in application of the steam, turned his attention more earnestly to the possible practicable economy in the production of the steam. The result is that when the mill is running full it requires an average of only about 200 h.p. of steam, including engine, to operate dynamo to furnish lights, the heating of the mill, of the separate office building, and of the proprietor's residence, across the way. As an example of the attention given to details, in the boiler room, the engineer found his gases going off at a high rate, and, as there seemed to be no other better way to save excessive loss from this source, he built a brick flue across the front of the boiler setting of sufficient size to admit inserting a section of coiled pipe, and so arranged as to be accessible for cleaning, through which the feed water passed after leaving heater, and thus reduced the temperature of the escaping gases about 100° F thus

Digitized by Google

increasing both the economy and capacity of his boilers, two of which, 14 ft. x 60 ins., supply the steam. Later, when he found there was a large amount of radiation from the sheet-iron flue leading to the chimney, he jacketed the flue, and, by use of a suction blower, drew air through this and discharged it into the mill, thus effecting another economy and relieving the danger of fire, due to the wooden roof of boiler room being unsafely near.

Finally, within the past two years, the Murphy automatic smokeless furnace displaced the hand-fired flat grates, effecting a decided saving in fuel, and insuring a chimney practically as clean as if anthracite were used, instead of the "steam" grade of soft coal, which is used. If an iron truss roof, set at proper height, were to displace the present wooden roof, the boilers reset so as to utilize more advantageously the boiler room space, height of stack increased to 100 ft. or more, and some minor additional conveniences provided for use of the fireman, that little old boiler room and boiler plant would compare favorably in every economic respect with the best in the land.

In this case it will be noticed the furnace or method of burning the fuel or producing and applying the heat, received attention only after every other known practicable source of economy had been provided. In this particular, that engineer is a faithful representative of a large majority, not only of engineers in charge, but also of a very large majority of those interested in the purchase or use of boiler plants. Even of the prominent consulting engineers, few give proper attention to possible practicable economies in producing heat. I venture the assertion that not one in ten knows, even fairly thoroughly, the construction and operation of the furnace referred to, although it has been in prominent use a dozen years or more, or the best arrangement of an ordinary hand-fired furnace, much less the relative merit of the various forms of furnaces in use.

Every person contemplating the purchase of a power equipment, is anxious to secure the most economical outfit practicable, and more or less care is taken in selecting the engine and the boiler, but, in most cases a little or no attention is given to the selection of the form of furnace or setting for the boilers. This is usually left to the boiler company, and I am sorry to say the results show that even the boiler manufacturers fail to give this feature the thought its importance should demand.

Coal is now burned under most of the latest improved boilers, substantially the same as it was 50 years ago, and with about the same waste, due to incomplete combustion and to admission of excess of air. Why this should be so, I leave the reader to answer.

Scientific knowledge surely indicates that decided improvement is possible, and the mechanical furnace for boilers has attained practical success, through application of such knowledge, increasing the volume of $CO_2$, and decreasing the volume of free oxygen, thereby causing the complete combustion of bituminous coal, with consequent higher temperature and prevention of smoke.

Three different recent tests, under varied conditions on one type of this furnace (the Murphy), by Professor R. C. Carpenter, of Cornell University, show superiority in reference to the above essential points in securing improved economy in the burning of western "steam" coal. In view of the evidence accumulated as to the efficiency of the mechanical furnace, it should receive greater attention than it has from consulting engineers who desire to keep abreast of the times.

If clients would insist on the consulting engineer knowing what is best, and why it is best, there would be fewer cases of money wasted on appliances and forms without special merit, and the coal bills would be perceptibly reduced.

In these times of close margins and keen competition, every owner and manager should realize all the economies practicable in producing his steam, whether for power, light or heat.

In the case of electric light or power plants, the cost of coal or fuel is a large and important part of the cost of the product. If a merchant were to negligently disregard a possible ten per cent reduction in the cost of his goods, he would soon find his more enterprising competitors getting profit where he could find none.

There are scores, yes, hundreds of steam plants where ten per cent or more can be saved by enterprising improvement in the method of burning the coal, and in the practice of the boiler room.

Those who take the lead by intelligent improvement in this particular, other things being equal, will soon find they are at the head of the procession.

## Lessons in Practical Electricity

ALTERNATING CURRENTS.

Before again taking up the subject of alternating currents, a brief review of the general principles of the subject will be given, in order that the reader may be more fully prepared to understand the subsequent articles.

There is no doubt but that the subject of alternating currents is in the minds of many surrounded with much mystery. This is partly due to the nature of the subject, and partly to the manner in which it has been expounded, both by so-called practical writers and by those who would conceal the principles concerned, however simple, in complicated mathematical analysis.

In starting out the student should take it for granted that he will meet with more difficulty in understanding alternating than direct currents. The latter branch is in general so extremely simple that the slightest mental labor is sufficient to enable one to obtain a fair knowledge of its principles, and to solve the practical problems which ordinarily occur.

On the other hand, alternating currents introduce the idea of variations, which is one foreign to everyday mental processes, being evaded wherever possible by the use of averages. Nevertheless, there is no real difficulty in understanding alternating currents if the student makes up his mind that some thought is required, and that this he is willing to give to the subject. In fact, what difficulty there is over direct currents is an advantage in the sense that one versed in alternating currents will have fewer competitors.

One caution is necessary for the beginner, which is that he should view with suspicion any explanations of alternating phenomena based upon analogies. An analogy, while it may assist in apparently making clear to his mind one phenomenon, will often render the understanding of other phenomena more difficult if the same analogy does not also apply to them. For example, the phenomenon of inductance is often explained by ascribing the property of inertia to the alternating current. How unsafe this analogy is will be realized when it is considered that it does not apply to circuits carrying alternating currents but containing no inductance; that the value of this so-called inertia is dependent, not only upon the factor of current, but also on the geometry of the circuit and the permeability of the medium; that is, where there is a coil in circuit, upon the number of turns and whether or not any iron is enclosed. Nor does the analogy apply to condensers unless we endeavor to think of such an absurdity as negative inertia.

The great use of mathematics in alternating currents is doubtless a legacy from the time of Joubert, who in 1881 established that the variation of current and e.m.f. in a certain alternator which he tested following the sine law. Up to this time no theory had been attempted of alternating currents such as are generated by commercial machines. In Joubert's celebrated experiments, the machine used was one which happened to give a very close approximation to a sine curve, and this result was eagerly seized upon by mathematical physicists owing to the ideal basis which it gave for building up a complete mathematical theory of alternating currents, the sine curve hypothesis lending itself most admirably to mathematical processes. In consequence of this the treatment of alternating currents became a branch of mathematics rather than that of physics, and only recently has there been a tendency toward a return to a physical basis, or the explanation of the phenomena themselves previous to the application to them of mathematics.

The generation of a true sine-curve of e.m.f. by an actual generator can only be approximated to. If we have a perfectly uniform bi-polar magnetic field, and a wire is revolved in such a field at a uniform rate, then the e.m.f. produced in the wire will vary accordingly to the law of the sine curve. For example, when the wire is at the pole gap, there will be no lines of force cut, since the lines there are parallel to its motion, and, consequently, there will be no e.m.f. induced in the wire; when it is opposite one of the pole pieces, the e.m.f. will

Digitized by Google

be a maximum; and between these positions the value of the e.m.f. generated at any point is proportional to the line of the angle between the wire at that point and its position at the gap. Similarly, as the revolution of the wire is continued, the e.m.f. decreases according to the same law until the wire reaches the other gap; then, since the lines of force begin to be cut in an opposite direction, an e.m.f. will be induced as in the first half of the revolution of the wire, but in an opposite direction—that is, the e.m.f. will be negative if it was positive in the first case.

It is always desirable that an alternating current machine shall generate a sine curve e.m.f. for several practical reasons, which reasons, however, were not appreciated by those who built up the sine curve mathematics of the alternating current. First, the line inductive counter e.m.f., or inductive drop, is a minimum when the variation of current follows the sine law. Second, the form of the curve of the e.m.f. of a motor should be identical with that of the generator from which it receives current; there is thus a necessity for a standard form of curve, which standard is best supplied by a sine curve. Third, all of the formulas relating to alternating currents are based upon the supposition that the variation follows the sine law, and would not apply exactly if this were not true; moreover, a mathematical treatment of any other form of variation than that following the sine law would become so complicated as to be almost entirely useless, both theoretically and practically. It may here be remarked that the constant $\pi$ found in alternating current formulas is introduced in most cases by the sine curve hypothesis.

Owing to the distribution of the bi-polar field when a current is flowing in the armature, and to its non-uniformity otherwise in practice, only an approximation to a sine curve would in practice be generated by such a machine. In the case of the ordinary multi-polar alternating current machine, the shape of the pole ends and of the armature slots, as well as the depth of air gap, must all be carefully proportioned in order to obtain the sine curve variation. In fact, in such a machine a smooth core armature with a small air gap and with pole ends concentric with the armature would produce an e.m.f. very far from the sine curve form.

It will thus be seen that in commercial work the sine curve form of alternating current and e.m.f. is attained only through proper proportioning of the parts by the designers of machines, and that it is desirable to approximate to the same curve as near as possible for entirely practical reasons—that the inductive line drop may be a minimum, and on account of the necessity for a standard form of variation, the fact that this form of variation admits of the simplest possible mathematical processes being secondary to the above considerations.

In considering alternating current, mathematicians, as stated before, have treated the subject as if it were a branch of mathematics, and it is for this reason that we read so often of angles, cosines, etc. The beginner has every reason to be perplexed when he reads of electrical currents differing in phase by 90 or 120 degs., or of a current lagging behind an e.m.f. by a certain number of degrees, or of sine waves of current and e.m.f. The idea of angles connected with electrical currents and e.m.f. is an absolutely impossible one to conceive of, if one is dealing with their phenomena instead of their mathematics. In the succeeding article this point will be taken up, and it will be shown that angles, cosines, etc., are introduced, not as properties of the phenomena, but as conveniences in submitting them to numerical calculation; and that naturally alternating current and e.m.f. values add and subtract the same as in the case of continuous currents, vector addition and subtraction being used merely because problems can thereby be solved in a fraction of the time necessary if the natural process were followed.

## Letters on Practical Subjects

### Transforming Direct And Alternating Current Motors.

A letter appearing under the above head in the December issue was contributed by Mr. J. C. Brocksmith, Ithaca, N. Y. The signature attached—J. C. Brown, New York,—belonged to another letter, the printer having inadvertently changed the linotype final slugs.

### A Mild Puzzle.

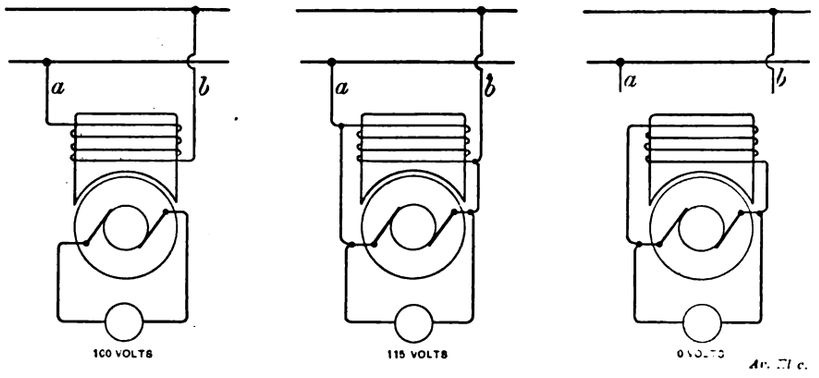
*To the Editor of American Electrician:*

The writer recently had an experience with a small dynamo that will probably puzzle a good many of your readers and be of interest to those whose knowledge of such machines will enable them to account for the peculiar action of the dynamo in question.

The machine had a six-pole field magnet, built up of ⅛-in. wrought iron laminations, with a 3-16-in. air-gap The armature was cross-connected so as to allow collection with two brushes, which were at diametrically opposite points on the commutator. It was about 1 kw. in capacity, and was belt driven by a 5 h.p. C & C motor during the test. When the field magnet was excited from 110-volt mains, as in Fig. 1, the e.m.f. at the brushes was 100 volts, and a 50 c.p. lamp was maintained, of course, without difficulty. When the brushes were also connected to the mains, as in Fig. 2, the machine ran as a motor at a considerably higher rate of speed, the voltmeter showing 115 volts at the lamp, and the C & C motor being dragged ahead of its normal speed. When the connections, a, b, from the mains of the machine were cut, leaving its field and armature connected as a self-exciting shunt dynamo, as in Fig. 3, the voltmeter at the lamp terminals showed not a particle of e.m.f., and, of course, there was no current. The field simply died out almost instantaneously when the connections, a, b, were cut. What is the solution?

J. C. BROWN.

New York, N. Y.

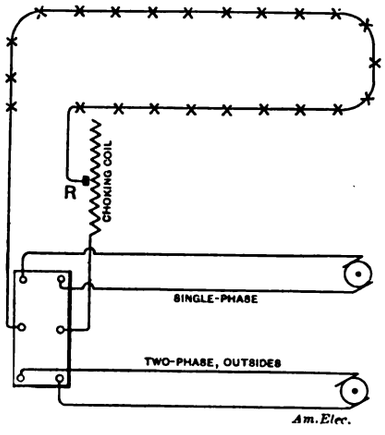


### Series Circuit Lighting.

*To the Editor of American Electrician:*

Sir—Referring to Mr. V. E. Hunter's arrangement for changing over a circuit of series lamps from a two-phased alternator of a given voltage to a single-phased machine of higher voltage, the writer would suggest that the arrangement shown by the accompanying sketch would be much more economical as to both first cost and cost of operation. It consists of using a simple choking coil having means for regulating its counter e.m.f., such as a movable contact, as indicated in the diagram, or a core which may be moved inwardly or outwardly ni the coil, according to the demands of the conditions.

The choking coil will have to be "set" every time the double-throw switch is changed over, just as Mr. Hunter's transformer switch has to be set each time, but a simple choking coil, the maximum counter, e.m.f., of which is equal to the maximum difference between the e.m.f. required at the terminals of the work circuit and that of the alternator, is obviously a much less expensive device than a transformer having a capacity equal to the full load of the circuit, and with an adjustable primary.



The arrangement of the voltmeter connection, shown by Mr. Hunter's sketch, is very bad, and would be advantageously

FIGS. 1, 2 AND 3.—SHOWING DYNAMO FIELD CONNECTIONS.

Digitized by Google

displaced by an ammeter in the work circuit, as he himself suggests. Even if series incandescent lamps are used there is no reason for using a voltmeter to indicate

SERIES STREET LIGHTING CIRCUIT.

the condition of the circuit, but if it were desirable, the simplest means would be to connect one in shunt relation to a lamp in the work circuit, located on the switchboard.

CECIL P. POOLE.

New York, N. Y.

## Two More Electrical Paradoxes.

*To the Editor of American Electrician:*

Judging from the number of solutions, both correct and incorrect, which were offered in your last issue to the problem of the electrical paradox of Mr. Blake, perhaps some of your readers will be interested in showing (or trying to show) how currents would flow under the following conditions:

In Fig. 1 there are two independent circuits connected together at one point, as shown, by a thick copper block a. In this block there will then be two parallel cur-

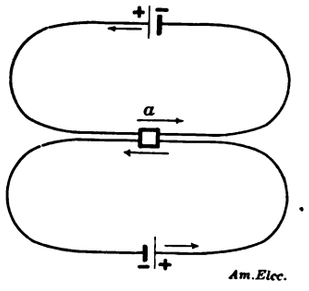


FIG. 1.—SMALL RESISTANCE IN CIRCUIT.

rents flowing in opposite directions, and they will therefore not be obeying the laws which govern them and which forbid this.

Now suppose this copper block to be replaced by a long, thin wire R of considerable resistance, as in Fig. 2; what will the currents do then? It will be noticed that the drop in volts in the portions of the circuits which they have in common will be in two opposite directions—that is, of opposite algebraic sign—and that is what causes the difficulties.

I would advise those who think they have solved it to test their solution by applying it to the case in which one current is small and the other is large; also when one voltage is low and the other high; also when one is an alternating and the other a direct current.

Here is another paradox. If a hollow non-conducting ring be filled with an elec-

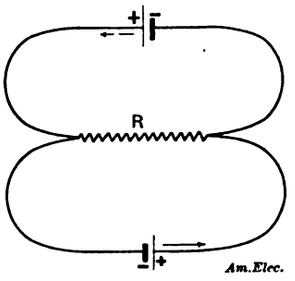

FIG. 2.—LARGE RESISTANCE IN CIRCUIT.

trolyte and placed around a magnet in which a current is being started, an induced current will then flow in the electrolyte, but there will be no decomposition. This is contrary to the laws of electrolytes, but nevertheless it will happen.

Here is another. If an alternator be excited by an alternating current it is well known that the frequency of the current which is generated will be doubled. It then must follow that if an alternator is made to excite itself an infinite frequency will be produced.

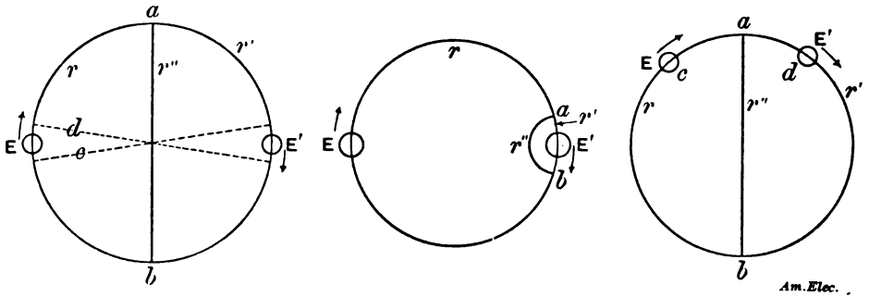
S. T. LAIRD.

Chicago, Ill.

## An Electrical Paradox.

*To the Editor of American Electrician:*

Sir—The electrical paradox propounded by Mr. Blake, in the November number, when fully investigated develops some relations that probably are not very generally understood.



Mr. Gibson's answer in the January number shows the relation between the currents in the different parts of the system of circuits, but the investigation is not carried far enough, and, moreover, the statement in the last sentence is liable to mislead, as it implies that an e.m.f. cannot be applied between the points A, B in a direction opposite to that of the current flowing under the influence of the e.m.f. E, and such an assumption is not correct since the e.m.f between these points can act in either direction.

By changing the diagram to the form shown in Fig. 1, the action of the e.m.fs. can be more readily understood.

In this diagram, let E be the principal, e.m.f. acting in the direction of the arrow. Let E′ be the secondary e.m.f.; that is, the one that is to oppose the flow of current from *b* to *a*. Let r be the total resistance from *a* to *b*, through left portion of the diagram, and let r′ be the total resistance of the right hand portions from a to b, while r″ represents the direct resistance between *a* and *b*. The difference of potential between a and b is e, and the several currents are I, i and i′.

If E′ acts in the direction indicated by the arrow, the two e.m.fs. E and E′ will act in the same direction through r″, and if E′ is reversed, they will be in opposition in r″, hence an equation can be developed that will give the current through r″, in magnitude and direction by simply introducing E′ with the proper sign.

If E′ acts in the direction shown, and can impress upon the points a b, the same difference of potential as the e.m.f. E, then all the current induced by both e.m.fs. will flow through r″ from a to b. If E′ is sufficiently weak, E will force a current through r′ from *a* to *b*, but if E′ is sufficiently strong it can force a current through r from a to b.

FIGS. 1, 2 AND 3.—DIAGRAMS SHOWING FLOW OF CURRENTS.

If E′ acts in a direction opposite to that indicated by the arrow, the current in r′ will be in the same direction as in r, but it is not perfectly clear what the direction will be through r″, for if E is great enough, the current will flow downward from a to b, but if E′ is sufficiently strong, the flow can be upward, from *b* to *a*.

The direction of the current in r″ will depend upon the potential of a and b, and to determine this much we must know the strength of the currents I, i and i′.

From the diagram we can see that

$$I = (\pm i) + i' \ldots . \quad (1)$$

i being negative when flowing toward a.

The current i′ is:

$$i' = \frac{E - r}{r''} \ldots\ldots\ldots (2)$$

and since rI = difference of potential between a and b, through E.

$$e = E - rI \ldots . \quad (3)$$

For the current in r′ we have

$$= \frac{E - rI \pm E'}{r'} \ldots\ldots\ldots (4)$$

By substituting in (1) the values of i and i′, in (2) and (3) we get

$$I = \frac{E - rI \pm E'}{r'} + \frac{E - rI}{r} \ldots\ldots\ldots (5)$$

which by reduction becomes

$$I = \frac{(r'' + r')E \pm r''E'}{r''r' + r''r + r'r} \ldots\ldots\ldots (6)$$

By substituting this value of I in (2) we can get the current i′ flowing through r″.

Digitized by Google

From an examination of equation (5) we can discover some important relations:

If $E = E'$, and $E'$ is negative, the equation reduces to

$$I = \frac{rI}{r'} + \frac{E - rI}{r''}$$

from which we get by reduction

$$I = \frac{E}{r' + r + \frac{r'r}{r}} = \frac{r'E}{r''r' + r''r + r'r}$$

and if $r = r'$, then

$$I = \frac{E}{2r'' + r}$$

In this case the currents I and i will be $i = i' - I$.

If $E = E'$ and $E'$ is positive; that is, directs a current toward b, then equation (5) becomes

$$I = \frac{2E - rI}{r'} + \frac{E - rI}{r''}$$

which reduced is

$$\frac{(2r'' + r')E}{r''r' + r''r + r'r}$$

and if $r = r'$ we can multiply both sides of the last equation by r and obtain

$$rI = \frac{(2r'' + r')E}{2r'' + r'} E$$

hence, since $rI = r'$, then the e.m.f *e* acting have: $e = o$.

From this we see that if E and E' are equal and in the same direction in the circuit r r' and $r = r'$, then the e.m.f. *e* acting between a and b will be zero, hence no current will flow through r''.

This condition is illustrated diagramatically in Fig. 2, in which E and E' act in the same direction in the circuit r r' — and $E = E' - r = r'$. Under these conditions the current impelled by E, tends to enter r'' through a with the same force as the current impelled by E' tends to enter through b, hence the two actions balance and the current in r'' is zero. So long as $r = r''$ and $E = E'$, the current r'' will be zero regardless of the position of a b, or of the magnitude of the resistance r''. If a b is moved anywhere from position c to d the current through it will remain zero even if the resistance of r'' is infinitesimal.

If the two e.m.fs. are not equal, points *a b*, between which no current will flow can be found, and these will be where

$$\frac{E}{r} = \frac{E'}{r'}$$

for then we will have $I = i$; hence

$$i' = I - i = o.$$

In Fig. 3, if E' and r' are very small, and E and r are very large, their relation can still be such that

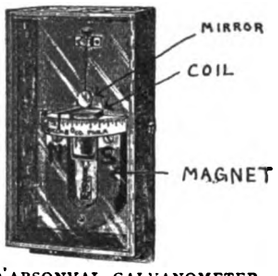
$$\frac{E}{r} = \frac{E'}{r'}$$

and if so, there will be no current through r''.

If $\frac{E'}{r'}$ is greater than $\frac{E}{r}$, then i will be greater than I, and i' will have a value, and since this value is equal to the excess of i over I, the direction of i' will be from b to a. If $\frac{E'}{r'}$ is smaller than $\frac{E}{r}$, I will be greater than i, and i' will flow from a to b,

If the two e.m.fs. do not divide the circuit resistance equally; that is, if in Fig. 4 the resistance c a d is less than c b d, the points a b, between which no current will flow, must divide the sum of the two resistances equally, if $E = E'$, and proportionately if E is greater than E' or E smaller than E'.

To summarize, if two e.m.fs. act in the same direction in the circuit, either e.m.f. can be shunted and no current will flow in the shunt if the shunted e.m.f. divided by the shunted resistance is equal to the other e.m.f. divided by the remaining resistance. If the two quotients are not equal, then a current will flow through the shunt, and its direction will be opposite to that due to the e.m.f. giving the smallest quotient, and this is true regardless of the resistance of the shunt.



WM. BAXTER, JR.

Jersey City, N. J.

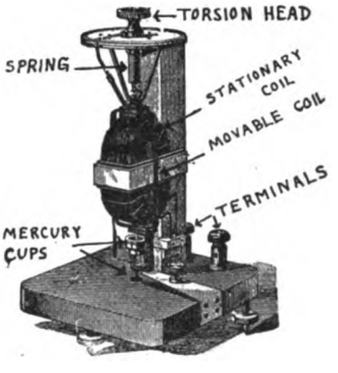
## Electrical Catechism

*270. How are instruments affected by outside magnetic influences?*

All instruments depending upon the magnetic effect of the current are more or less sensitive to outside magnetic fields, for these either weaken or strengthen the magnetic field inside the instrument. Generally speaking, the weaker the regular magnetic field the more easily it is affected by outside disturbances. Delicate galvanometers, which depend upon the earth's magnetic field, are sometimes sensitive to the running of a dynamo hundreds of feet distant or to the return currents from a trolley car some thousand feet distant. Almost every instrument is affected if close to a dynamo or a motor. Instruments having permanent magnets are liable to affect one another unless kept at least 2 ft. apart. The magnetic field around conductors carrying heavy currents is strong enough to affect instruments of the electro-dynamometer type, and sometimes even those of the d'Arsonval (see No. 233, "American Electrician," August, 1898, page 391) type. In no case should instruments be placed within two or three feet of a dynamo or a motor.

D'ARSONVAL GALVANOMETER.

*271 How can one tell whether an instrument is being affected by a stray magnetic field?*



By turning the instrument around, the effect of the outside disturbing field will be reversed, so that if the reading was too high before, it will then be too low. The average of the two readings taken with the instrument in two positions will be close to the correct reading. If the instrument does not depend upon the field of a permanent magnet, its readings may be corrected by simply reversing the current through the instrument, instead of reversing the instrument itself.

*273. Are instruments measuring alternating currents affected by stray fields?*

That depends upon the nature of the disturbance. If the outside field is uniform in strength and direction, it will not ordinarily affect the readings of an instrument measuring alternating currents. But if the outside field is due to or is affected by the alternating current, it may affect the instrument. An instrument for measuring alternating currents is liable to be affected by the field due to the current in the wires leading to and from the instrument. Such instruments are liable to be affected by eddy currents induced in any solid masses of metal that may be near the coils. Any pieces of iron near the instruments are liable to become more or less magnetized by the current, which will result in strengthening the magnetic field in the instrument itself.

*274. Do instruments calibrated for use with alternating currents give correct readings when used with direct currents?*

Instruments of the electro-dynamometer type give equally correct readings with direct or alternating currents, except that they are more liable to be affected by outside magnetic disturbances when used with direct currents. Instruments having iron cores or needles give higher readings with direct than with alternating currents; with alternating currents, the higher the number of alternations the lower the reading. Electro-dynamometers are independent of the frequency. The type shown in the illustration has been improved upon in modern instruments.

SIEMENS ELECTRO-DYNAMOMETER.

# Queries and Answers

**What horse-power is required for a 9.6-amp. arc lamp? W. J. L.**

One lamp of the given rating to the horse power.

**Is it necessary to have a starting rheostat for a 50-h.p., 2080-volt induction motor, or is the sliding resistance on the shaft sufficient? H. T.**

The resistance mentioned is designed to be sufficient.

**What size of storage battery would be required to run two 8-c.p. 10-volt lamps for twelve hours? J. S.**

Five 70-ampere hour cells, since each lamp will take about 2.8 amperes, and each cell will give 2 volts.

**How is polarity testing paper made? H. T.**

Saturate filter paper with a solution of ten parts of distilled water and one part of iodide of potassium. The positive pole is indicated by a brown mark on the paper.

**As a telephone current does not pass through zero, can it be called an alternating current? R. W. W.**

Broadly speaking, yes, since it is continually alternating in value and direction. Usually, however, the term is applied to a current having uniform cycles of variation.

**Should the exciting current necessarily flow through the coils of an alternator, as indicated by arrows on the same? H. T.**

Not so far as the action of the machine is concerned, but as the machine is tested and connected to conform to the direction indicated, it should not be changed.

**What will be the effect of running a motor whose power factor is .50 on a line, the cosine of whose angle of lag is .60? W. N. C.**

The amount of the increase of the angle of lag will depend entirely upon the relative magnitude of the motor inductance and the previous inductance of the line and its load.

**What is a potassium amalgam cell, and the value of its e.m.f.? J. L. T.**

Potassium amalgam (mercury alloy of potassium) contained in a porous cup immersed in dilute sulphuric acid in which is a peroxide of lead element. The e.m.f. is 3.525 volts, but the cell has never gone beyond the laboratory stage.

**What would be the result if one or two wires of a 10,000-volt three-phase circuit were to come into contact with the trolley wire of a 500-volt street railway circuit? J. R. B.**

If the three-phase circuit were properly insulated, there would be no effect if one wire came into contact with the trolley wire; if two of the three-phase wires came into contact, the trolley wire between would be promptly melted in any case.

**What is the best excitant for a silver chloride cell? J. L. T.**

Warren de la Rue, who first made this cell, used a solution of 2-3 of an ounce of sal ammonia to a quart of distilled water; if made stronger, it will dissolve the silver. Caustic potash may also be used, in the proportion of three parts of potash to four of water.

**If a lighting generator and its circuits are insulated from the ground, is there any tendency of the current to reach the earth? C. J.**

No, but if the system becomes grounded at a single point, there is a strain everywhere between the earth and the system. It is for this reason, and not from any natural tendency of current to seek the earth, that "grounds" have to be carefully guarded against.

**Is it safe to connect in parallel a transformer of 15-kw. with one of 5-kw., both being of the same make? G. W.**

All transformers having the same regulation may be successfully connected in parallel, but if two transformers having different regulations are so connected, the one having the better regulation will take an undue share of the load. Should this one be the smaller, there will be trouble.

**Does an alternating current possess any static properties? C. J.**

Any body will have a static charge with respect to another body insulated from it if they are at different potentials. If this potential is variable, the charge will also be variable, the value at any instant depending upon the difference in potential, capacity of insulated body, its distance and nature of the intervening medium.

**What is a rule for determining the width of a belt? O. A.**

It is best to obtain the size of a belt from a manufacturer's list. One formula is as follows:

$$\text{width} = \frac{K \times HP}{D \times V}$$

Where H P = horse power; D = diameter of pulley in inches; V = speed of belt in feet per minute; K = 38,000 for single belting and 24,000 for double belting.

**What amount of electricity may be produced by a given consumption of coal? R. N. P.**

The quantity of electrical energy that may be obtained from a given amount of fuel depends upon the quality of the coal, the efficiency of the boiler, engine, dynamo and distributing system, and the character of the load curve. In an ideal case, a kilowatt-hour may be delivered on three pounds of coal. In some cases a consumption of twelve pounds and over has been reported.

**I have an electric heater in series with four lamps on an electric railway circuit, the coil consisting of 40 ft. of car-heating wire, but it will not heat appreciably. What is the matter? F. B.**

Since it displaces one lamp, if the other lamps burn normally, it merely gives out the same amount of heat as the lamp displaced. Of the energy supplied to an incandescent lamp, 97 per cent is directly transformed into heat and the other 3 per cent into light, and finally also into heat. An electric lamp is therefore as much of an electric heater as one made of resistance wire and using the same watts.

**What are the data of a 6-in. induction coil? J. V. L.**

If made after the instructions in the January, 1897, issue, the core may be 18 ins. long by 1¼ ins. diameter. Use 6 lbs. of No. 36 wire on the secondary, and a single turn of No. 16 wire on the primary. The current will be fixed by the heating of core and length of spark, and must be experimentally determined. If connected to a direct-current lighting circuit, place incandescent lamps in parallel until the required current is obtained.

**How should electromagnets be connected for quick working—in series or in parallel? N. T. S.**

That depends upon the resistance of the external circuit. When the resistance of one of the spools is greater than that of the external circuit, the spools should be connected in series; or in parallel if such resistance is less than that of the external circuit. The law applying to the connection of magnets in circuit is, when inductance is considered, precisely similar to the law for connecting batteries in parallel or series.

**Are any devices in use to prevent inductive cross talk on telephone lines? R. S. H.**

No device can restore to or subtract from the receiving voltage, the voltages that inductive action has added to or subtracted from the transmitting voltage. By properly arranged line transpositions, however, inductive action in one section may be neutralized by the oppositely acting inductive action in an adjacent section. The transposition causes cross-talk voltage in one section to be opposite to that in another section, therefore neutralizing each other.

**Knowing the power factor of a motor, as given by the manufacturer, how is the effect on the lag angle of the line determined? W. N. C.**

Knowing the resistance and the power factor of the motor, its inductance may be determined. Knowing the resistance and lag angle of the line, its inductance may similarly be determined. Lay down a right-angled triangle whose base is the sum of the two inductances, and whose perpendicular is the ohmic resistance of the line, neglecting the resistance of the motor. Then the angle between the perpendicular and hypotenuse is the resultant line lag angle.

**In speaking of line loss, is it meant that there is a loss in both voltage and current? R. M. K.**

In voltage alone, the loss in volts being the e.m.f. required to force the given current through the circuit resistance. In the case of alternating currents and inductive circuits, there is an additional drop, being the e.m.f. required to overcome the counter e.m.f. of inductance. The first-mentioned drop involves a direct loss of energy due to the whole current passing, while inductive drop only involves an energy loss due to the so-called idle current, which is additional to the energy current.

**I have made a solenoid, using 2000 ft. of No. 22 wire and a core 2 ins. in diameter, which draws a weight of 25 lbs. when connected to a 110-volt circuit. What change should be made to bring the capacity up to 60 lbs.? O. F.**

A larger core, balanced, might improve the working, but as the ampere-turns are arleady more than sufficient for a 150-light dynamo, this is doubtful if the pull is exerted over a considerable distance. A solenoid is a very poor appliance for the transformation of electrical energy into mechanical work. A shuttle-core, with small clearance, in a bi-polar field is better, using a pulley on the shuttle shaft to multiply the motion. Best of all, is a motor suitably geared or belted.

## BIOGRAPHY OF AN ARC LAMP CARBON.

The most essential factors in arc lamps are the carbon pencils, from the consumption of which the light is produced—not, as is sometimes thought, from the arc itself, but almost entirely from the glowing ends—but very few people who use them, or who note the unburned stubs that are thrown in the street by the lamp trimmers, have any definite idea of what material or how they are made. To supply this information is the object of this story.

At the outset it must be noted that there are various grades of carbon pencils produced for lighting purposes, and until recently the high-grade carbons employed in enclosed arc lamps have been mostly imported, and have for a long time been regarded as superior to any product in this country.

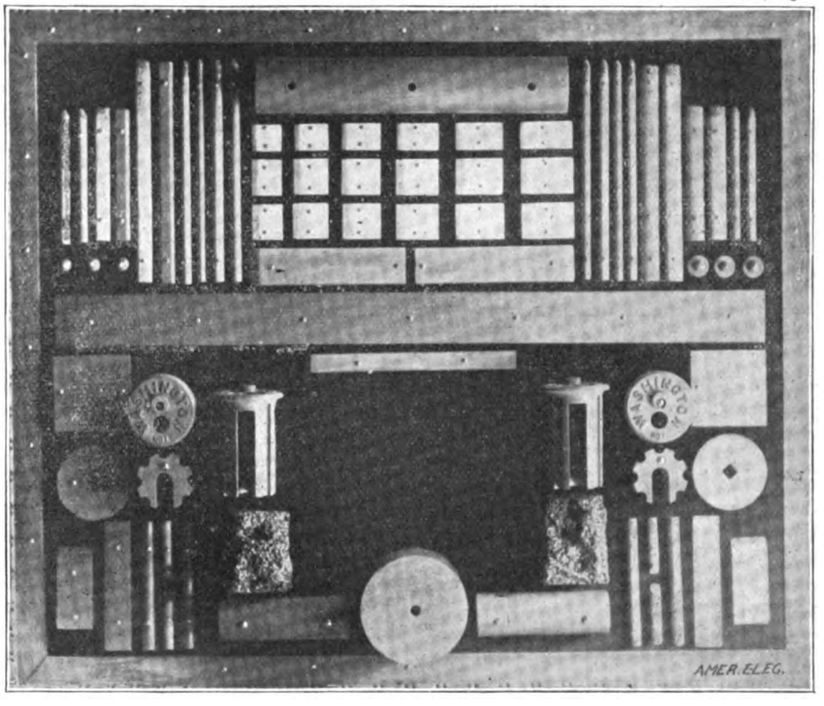
This is a doubtful claim, however, for the works which turn out the carbons which we are to describe are now competing successfully with the reputed high-grade products of the old country. These works are located at Washington, Pa., thirty miles from Pittsburgh, and are owned and operated by the Washington Carbon Company. They really embrace two factories, in one of which carbons are made by the moulding process, and in the other by the forcing process.

The material from which the ordinary carbons are made is a kind of coke, the residuum of petroleum oil stills, and is purchased directly from oil refineries. It is a porous black material, a little darker than ordinary coke, and has about half the specific gravity of the latter. The high-grade carbons, however, such as compete with the imported article, are made from lampblack, or what is known as lamp-black carbon, and is produced by the burning of coal tar in suitable chambers.

In preparing the coke in the Washington factory it is first ground in a bark mill to pea size, and is then elevated by belt conveyers to large storage bins on the second floor. It is next calcined by being placed in fire-brick furnaces or retorts which, on being filled with the material, are fired by the consumption of natural gas, the fuel being first introduced through suitable burners, entering the front wall. Air is excluded, so that the material burns in its own gas, and by this process all the volatile matter is driven off, leaving a mass of ninety-nine per cent pure carbon. When removed, it is allowed to cool, and is then again elevated and ground in an ordinary burr stone mill to a fine flour, and is bolted through a silk cloth into four grades.

The next process consists in incorporating with the carbon a binding material, which is a product of coal tar distillation. This binding material is first ground to a fine powder, when it is combined with the carbon powder in certain proportions, and then the mass placed in a revolving heater or mixer, in which the materials are thoroughly combined under a temperature of about 200 degs. When cool it is again ground in what is known as a centrifugal mill, consisting of two discs set edgeways, and which are revolved in opposite directions. It is thus reduced to a fine powder, and again bolted in revolving sieves, when it is ready for the moulding process.

The moulds are of metal, made in two parts, and contain from twelve to eighteen grooves, depending upon the diameter of the pencils to be formed. These are kept hot by means of natural gas jets kept burning under the grated surface of the moulding tables. Each moulder carefully weighs out sufficient material to fill all the grooves, and when filled the mass is smoothed off with a straight-edge, and the upper half of the mould is placed on top of the powder, being slightly pressed down by hand. It is now carried by means of endless conveyors in the direction of two hydraulic presses, located at the end of the conveyor. There are three of these endless conveyors, which are about 18 ins. wide, 70 ft. in length, and are placed not far apart in parallel lines. The middle conveyor travels in an opposite direction from the others, and twice as fast.



The moulders occupy booths or pockets in each side of the conveyors, and when the moulds are filled they place them on the one running in the direction of the presses, while the other two serve to bring back the moulds after the press has done its work.

As the moulds reach the presses, attendants slide them to the right or left upon the plungers of the presses, which are about 13 ins. in diameter. By means of a foot lever the plunger is lifted and the two parts of the moulds are subjected to a pressure of about 350 tons as indicated by a gage, and is automatically cut off as soon as the requisite pressure is obtained. The attendants then place the moulds with their contents upon the returning conveyor, and the moulders take them off in turn and remove the pencils, which are held together by a thin web of material. The moulds, still hot, are then greased and again filled.

The pencils on being removed are placed on racks and taken to a dressing table, where they are broken apart by a wedge-shaped tool that is hit with a light hammer. The pencils are then fed by hand into a stripping machine, in which they are drawn by power between the edges of two steel discs about 6 ins. in diameter set at an angle to each other, which process serves to shave off the remaining portions of the web, so that the entire surface of the pencil is made true and perfect. The pencils are then packed in trays and are made ready for the baking or firing process.

For baking there are twenty-one furnaces employed in the first factory, each having a capacity for receiving from 60,000 to 100,000 carbons. These furnaces are made of fire-brick, and have a sectional arched covering, which is removed for filling or cleaning. In charging the furnaces, the carbons are carefully piled in layers to the depth of 4 ft., with a thin course of black sand between each layer. When filled, the furnaces are closed by replacing the arch section and are fired by means of natural gas, the walls being so constructed that the heat passes entirely around the mass of carbon. It requires about three weeks for suitable baking of a batch of carbons, which includes the time consumed in charging the furnaces and allowing for the cooling of the contents.

By means of forms the carbons are removed from the furnaces and taken to the sorting room, where the "crooks" are separated from the straight pencils. The "crooks" are detected by allowing the carbons to roll, one at a time, down on the face of an inclined metal plate, set at such an angle to the eye of the operator that he readily detects any unevenness by the light

A VARIETY OF CARBON PRODUCTS.

Digitized by Google

rays which appear underneath. The "crooks" are not all scrapped, however, but are cut up for making short carbons, the ordinary lengths being from 12 ins. to 14 ins.

The copper plating process follows, in which the carbons are suspended from copper bars by being attached with plating snaps, and immersed in the copper-plating solution, about 400 pencils being placed in each vat. The process requires about twenty minutes, and the plating current is produced by two generators, one having a capacity of 800 and the other of 500 amps. The carbons are then placed on drying racks, after which they are packed in boxes, containing from 500 to 1000, and are ready for shipment.

There are two processes employed in forming the carbons, one the moulding process described above, and the other known as the forcing process. In this later process the material is prepared and mixed as above described, when it is pressed by hydraulic power into cylindrical forms about 6 ins. in diameter and 6 ins. in length. A number of these billets are then placed end to end in the chamber of large horizontal hydraulic presses, of which there are four. Power is then applied to the charge with a pressure of about 250 tons, which

ARC CARBON MOLD.

serves to force the material in a continuous rod through discs at the outer end of the cylinder, the size depending on the diameter of the dies employed. The rods are then cut up into suitable lengths, and are fired as described for the moulded carbons, when they are pointed on an emery wheel. The cored carbons are also made on these machines, a small round rod being placed in the middle of the die, which delivers the carbon in the form of a tube. These are then filled with a material softer than the body of the tube, and are designed for use with alternating and direct current lamps on incandescent circuits. In this department carbons for enclosed arc lamps are also made, but by a process which is kept a trade secret.

The output of the works, however, is not confined exclusively to arc light pencils, but includes brushes for generator and motor service, carbons for primary batteries, and large carbons up to four or more inches in diameter, for use in electric ore reduction works and electrolytic processes.

The success obtained in producing durable high-grade carbons is largely due to the careful tests to which the crude material and samples from the finished products are subjected. It is the practice to chemically test samples from every lot of the crude material when received, and in addition samples from the contents of each furnace are thoroughly tested, both for light, efficiency and for resistance. For these purposes a testing department is established, which occupies the second floor of the office building adjoining the works. Here are provided arc lamps of various types, some of which are located in cupboards lined with asbestos, having in the doors plates of colored glass, for determining the durability and character of the light ray, and screens or graduated sheets, for measuring the length of the arc, which is reflected through suitable lens provided for the purpose.

## HOW TELEPHONES ARE MADE.

While commercial telephones have about the same number of parts and general characteristics, still they may differ widely in the method of manufacture, and adjustment of various parts, so that when one is informed as to the methods followed in a certain telephone manufacturing establishment, he is not sure that he knows all that there is to be known in the science of telephone construction.

To add to the fund of knowledge regarding telephone making, this article details some of the shop practices, as found in the works of the Hipwell Manufacturing Company, of Allegheny, Pa. The name of the company is comparatively new in the telephone field, and although the firm has been engaged for a long time in the manufacture of telephones for various jobbing companies, it has only recently put its own instruments directly on the market, which it now does, with a guarantee warranted by experience.

The works occupy a four-story brick building, 100 ft x 40 ft. at 100 North Avenue, but all this space is not by any means devoted to telephone manufacture, the principal output of the works being oil lamps of almost every description, including lamps of several of the well-known trade mark specialties, which the company manufacture in great quantities for firms who put them out under their own name. The equipment of the works is very complete, including stamping presses and metal working tools for shaping sheet metals and the wick adjusting mechanisms of many of the high-grade lamps. The lamps are made in every possible variety, from plain table lamps to the highly ornamental and artistic designs found in parlor and pier lamps.

It is, however, with the making of telephones that we have chiefly to deal, and in this department there is also a complete line of special machinery. For bending and tempering the generator magnets, there are two magazine feed furnaces, in which natural gas is employed for fuel, and which is considered superior to coal for such purposes, because it does not leave a scale on the surface of the metal heated. The bars, which are ⅜ x 1 in., are first cut into suitable lengths and are then fed endways into the opening of the firebrick furnace, each one pushing those ahead of it along as it is inserted.

After the bars have traveled a certain distance and they become suitably heated, they fall out to one side and are immediately placed by tongs in a hand bending machine and formed in horse shoe shape. Being formed, they are next passed to a second furnace and hang over a slanting rod on which they slide one against the other through the fire, when they are taken out at the end at a proper temperature, and tempered by being immersed in water, the very best steel that can be had being employed for magnet purposes. The furnaces have a capacity, should it be necessary, to bend and temper several thousand a day, while the capacity of the works is equal to about two hundred completed generators a day.

The work of forming the magnets is carried on in the basement of the building, while that of forming the more delicate parts, the winding of the armatures and assembling, is carried on on the upper floor. The machines include punches, lathes, screw machines, many of which are the company's own design and make, as well as are the dies and templates employed.

Following the magnets, we go to the grinding room, where by means of emery wheels the outer surfaces of the horseshoe forms are carefully ground and polished. From here they go to the nickel-plating department, and are thoroughly plated, for which purpose a number of large vats are employed, with a generator for supplying the plating current. They next go to the buffing room, from which they come out as bright as a looking glass, and are ready for magnetizing. This is done by placing them one at a time on the poles of a powerful electromagnet, drawing them back and forth, and turning them over endwise, until they are thoroughly magnetized. Three are usually placed side by side in each machine.

In the process of cutting the gears which revolve the armature, from fifteen to sixteen blanks are placed on an arbor and thoroughly clamped together, when the cutting tool is run across the face of the whole lot, and the teeth cut very rapidly. Hardened templates, dies and micrometer gages are provided for each of the workmen, so that like parts are made interchangeable and all to an accurate fit.

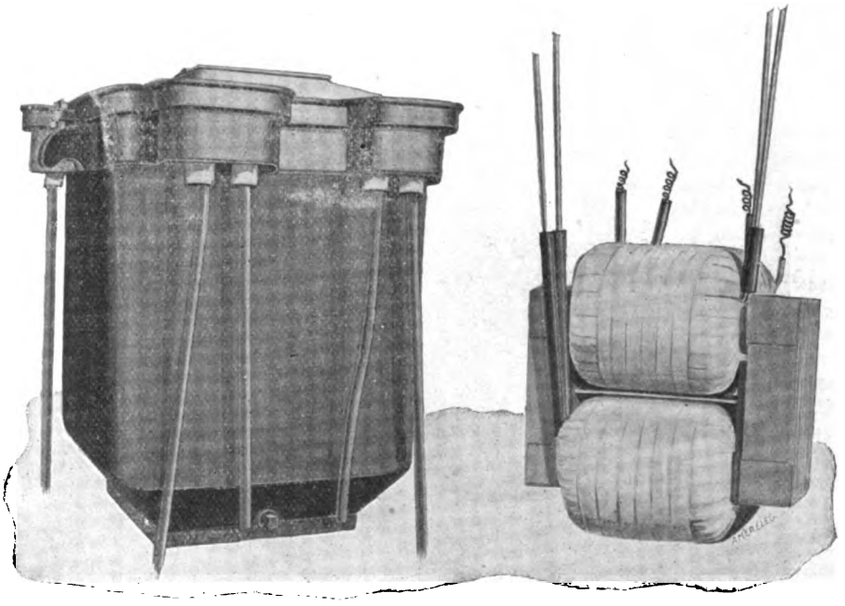
The armatures are cast with two poles, and for finishing up, they are inserted endwise in an arbor die, when the outer faces of the poles are turned to fit the contour of the die. They are then placed in a hollow mandrel, in which they fit accurately, and the journal bearings of the shaft are turned, being self-centered in the operation, the workmen not being required to make any measurements or adjustments.

For winding the fields a special power lathe is provided with an automatic register, which records the number of turns, and rings a signal when a coil is complete. For winding the coils of the receiver magnets, the register records the length of the wire employed, and the spindle of this machine is driven by means of a friction disc, which runs in contact with the face of the driving disc, the former being so mounted that it can be moved back and forth across the center of the driving disc, by which means the speed of the spool may be increased or diminished, or it can be reversed at the will of the operator, should it

Digitized by Google

be necessary to unwind a lap that goes wrong. The armature cores before winding are covered with an insulating varnish.

A special feature of the telephone manufactured is a moisture-proof transmitter, in which the carbon granules are so housed that they are not exposed to moisture, and these transmitters are put up so that they can be carried about and new ones put in place of old ones at any time. The induction coil of the transmitter is made with heavier wire than is employed by most manufacturers, and the cores of the induction coil are made of a special grade of soft wire. The parts of the 'phones are assembled and mounted in cases of various patterns, including plain and ornamental designs, and of the leading varieties of wood usually employed for telephone cases.



## THE MANUFACTURE OF STATIONARY TRANSFORMERS.

There is no class of electric apparatus that seems so simple in the arrangement and number of its parts as that designed for changing the voltage in circuits either for lighting, high tension transmission or other purposes and yet to produce an efficient transformer it is necessary to carefully proportion the relation of the windings of the primary and secondary coils, and it is of the highest importance that a grade of electrical sheet steel be employed which is uniform in quality and which will remain free from deterioration under any period of service, while, at the same time, the core must be carefully proportioned in its relation to the copper, so that the losses may be reduced to the minimum.

All these conditions, the manufacturers claim, have been met in the construction of what is known as the Type "K" transformer, which is now being manufactured by the Pittsburgh Transformer Company, of Pittsburgh, Pa. While this company is comparatively new, the principals, Mr. A. F. Harrold and Mr. F. C. Sutter, have been long engaged in the design and manufacture of transformers for one of the leading electrical manufacturing companies, and, furthermore, being in close touch with one of the large manufacturers of electrical sheet steel, they are able to obtain picked lots from which to make the cores, so they can guarantee all their output as being of the highest possible grade.

This type of transformer is manufactured in capacities ranging from .6 to 30 kw. In the design, as will be noted from the accompanying illustration, the core is of rectangular form, with the winding placed about the long sides. The core is built up of thin strips, known as No. 29 gage, and the quality is such that all spring tendency is eliminated from the metal, so that when bent it yields as limp as a piece of lead. The quality of this steel has heretofore been regarded, though highly desirable, as commercially impracticable. In the process of construction these plates are set up side by side; after the coils are placed over the long sides, the short sides are constructed by placing one end of every alternate strip between the plates on one side and letting it butt against the edge of the plates on the other side, so that the end plates are virtually dovetailed into each other.

In the construction of the coils, each of which contains a primary and a secondary winding, the secondary, generally of multiple strap, is wound upon a mould having the size and shape of the core. Over this is wrapped heavy mica plate reinforced by pressboards, and on this is then wound the primary. The primary is set in somewhat from the edge of the secondary, and is further protected by a collar of mica which completely incases the ends of the high tension winding. The mica plates alone used in this construction have a minimum breakdown strength of 20,000 volts, so that it will be seen that the company has taken the most rigid precautions regarding their insulation. The cores are heavily wrapped with pressed board and tape and the coils

TRANSFORMER CASE AND COILS.

then slipped over them, with b fibre plates, which wedge them closely to the core.

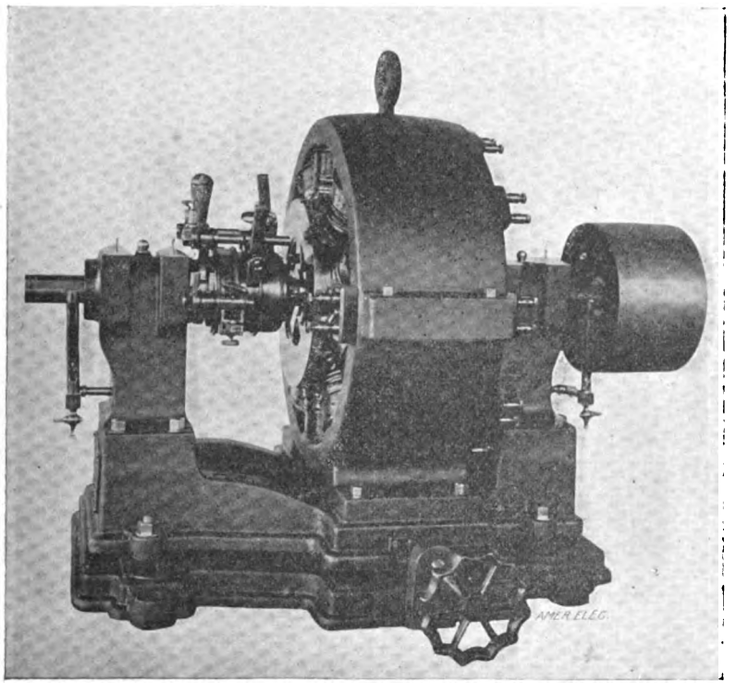
By bringing out to the line wires, the ends of the primary winding from the outside layers, repairs can be readily and easily made should the coil be damaged by lighting discharges, or static sparks, which very seldom penetrate more than a single layer of the windings.

The terminals of the primary and secondary coil are respectively brought out on opposite sides, the primary leads going to a terminal plate. They are then soldered to the leads, which pass out vertically downward through porcelain bushings. The coils being in place, the end sections of the core are then built up and both ends are capped with a spider, which fits the core and has arms which hold the transformer in place within the case.

In the large sizes the core with its coils is placed in horizontal position, but in the smaller sizes the coils are vertical. Being finished, the transformer is mounted in a cast-iron case, handsomely japanned, and is designed to be operated either dry or immersed in oil. The use of a high-grade of mineral oil is recommended, as by its use the insulation resistance is increased to a marked degree, while it tends to keep the parts at a lower and more equable temperature.

On being finished each transformer undergoes a thorough test, both for insulation, operation and for measurements of the iron and copper losses; for the former a 10,000-volt alternating current is employed, and it is estimated that a piece of apparatus that can stand these tests is assured of a long life. The containing case, as will be noted, is cast with lugs on the back with chambers designed for receiving the heads of bolts or lag screws, by means of which it is suspended in position. The transformers are all designed to safely carry overloads of 25 per cent for periods up to five hours, with a temperature rise of not over 45 degs. C. above the air.

For the protection of the transformer the company provide a porcelain single-pole primary fuse terminal. They also provide a tube terminal insulation, which prevents the oil from following up the leads by capillary attraction, thus protecting the rubber coating of the cables from softening.



The works of the company are located in the Arrott Power Building, on Penn Avenue, and are well equipped for the manufacture and shipment of the product. The principal features of the shop are the winding lathes and shearing machines, all winding being as nearly automatic as possible. The company has adopted the method of preparing all transformer plates on these shearing machines, as much better work is possible than by the use of dies and punches. A testing outfit, consisting of a generator, designed to give a true sine wave, switchboards and instruments, makes the work of testing convenient and expeditious. Although on the market but a comparatively short time, the company has secured a liberal patronage, and has installed its apparatus in all parts of the country.

# New Apparatus and Appliances

"IDEAL" ALTERNATOR.

The accompanying cut shows a type of "Ideal" alternator, of which a number have been built for experimental purposes for use in the laboratories of colleges and manufacturing works. Machines of this type are now in use in the laboratories of Stevens Institute, Georgia School of Technology, University of Wisconsin, Pennsylvania State College, Gale University, Drexel Institute, Alabama Polytechnic Institute and in the works of Queen & Co., Bristol Company, Ward Leonard Electric Company, Keystone Electrical Instrument Company, Hunter Fan & Motor Company, Lakon Company, Fleming-Spence Electric Company, Diamond Electric Company, Ironclad Resistance Company, Empire Elec. Instrument Company, Dupont Laboratory, and elsewhere.

IDEAL ALTERNATOR.

This alternator is designed to generate three-phase currents at 220 volts, and is therefore supplied with three collector rings, between any two of which it is possible to obtain a current of 13.3 amperes and 220 volts, when the armature is revolved at a speed of 720 revolutions per minute. Two additional pulleys are provided by means of which it is possible to drive the alternator at 600 revolutions per minute and 420 revolutions per minute, at which speeds the voltages are 180 and 100 respectively, the field excitation being maintained constant.

The field frame is a massive steel casting with ten poles. The ten field spools are connected in series, each consisting of 410 turns of No. 14 B. & S. wire, requiring a field current of 3 amperes at 100 volts to excite the field at full load. The armature is 10⅞ ins. in diameter, is of the tooth type and provided with 60 slots, each 11-32 in. wide and ⅞ in. deep.

The core is built up of discs of the best grade of soft sheet iron, and the winding, which is embedded in the slots, is well insulated from the core. The portion of the winding at the ends of the armature is protected from injury by two ornamental brass end shields, provided with openings of sufficient size to allow free circulation of air and ventilation.

The 60 slots above mentioned provide space for 30 coils, each of which consist of 21 turns of No. 12 B. & S. wire. These 30 coils on the armature are divided into three groups of 10 coils each, and the three groups are joined together in star fashion. The coils are connected around the armature in regular order to the first, second and third groups. The two halves of a coil are separated by two slots. When all the coils are connected to the three groups the three starting ends are soldered together and well insulated. The three finishing ends are brought to the three collector rings.

The bearings are of the self-oiling type, and the armature is so well balanced that there is no vibration, even when the machine is driven at the speed of 2500 revolutions per minute. For varying the degree of tension on the belt, a hand wheel and belt tightener are provided on a special sub-base furnished with the machine.

This company also builds larger alternators for single, two or three phase currents, and winds the armatures for any voltage up to 2000 volts. The fields are either separately excited or provided with a composite winding; the latter is excited by a portion of the total armature current, which is rectified by passing through a special commutator. By this means the field excitation is increased as the load increases, and by making the proper adjustments, any degree of compounding can be obtained. Machines are also built according to engineer's specifications.

F. A. LaRoche & Co., Thirteenth and Hudson Streets, New York, are the manufacturers.

---

VOLTMETER AND GROUND DETECTOR.

We illustrate herewith a voltmeter and ground detector for switchboard use, which, as will be seen from the engravings, embodies a number of distinctive features.

FIG. 1.—VOLTMETER AND GROUND DETECTOR.

All contacts, connections, etc., are mounted on a separate slab of slate, which is located at the back of a switchboard. From this a rod passes to the front of the board and has attached to it the operating handle, which carries an indicating pointer over a suitably lettered dial plate. The parts of these switches are all indepenently capable of the finest adjustment before or after in place, by nuts and screws especially provided for the purpose.

The other main points in the design are clearly shown in the illustrations and need

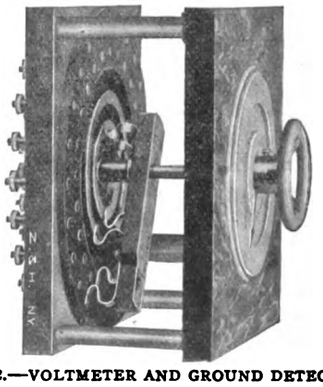

FIG. 2.—VOLTMETER AND GROUND DETECTOR.

no further comment. Great attention has been given to details, and, in contrast to many similar appliances of this class, these switches do not require constant tinkering to keep them in operating condition after they are installed.

The voltmeter switches are regularly made up to twenty circuits, and the differential galvanometer switches up to eight pairs of circuits. They are, however, made of greater range upon special order. The manufacturers are Zimdars & Hunt, 127 Fifth Avenue, New York.

### THE PRIESTMAN OIL ENGINE.

Until comparatively recently, certain obstacles met with, prevented the successful operation of engines using safe oils. Through the ingenuity of scientific men, however, these obstacles have now been overcome and the success of the safety oil engine is an accomplished fact.

The Aultman Company, of Canton, Ohio, have recently taken up the manufacture of the Priestman Safety Oil Engine, which, aside from the character of fuel used, differs from gas and gasoline engines in several important respects.

For fuel is employed high test, safe petroleum, such as is used in common house lamps, and generally known as kerosene or carbon oil.

The following is the mehod of operation: A fine kerosene spray is injected into the chamber shown directly underneath the cylinder head. Here this spray is mixed with the proper proportion of air, for supporting combustion, and the mixture heated by the hot exhaust gases, which are made to pass through an annular space surrounding this mixing chamber before being expelled into the atmosphere. The heated charge of oil spray and air is then drawn through the inlet valve into the cylinder by an outward stroke of the piston. The inlet valve is not mechanically operated but is opened automatically by suction, or, in other words, the pressure of the atmosphere. The return stroke of the piston compresses the charge, which is then ignited by an electric spark from an ordinary battery, and the resulting expansion of the heated products of combustion drives forward the piston, thus imparting the energy which is utilized for doing work. During the succeeding stroke of the piston, the exhaust valve is held open mechanically, and the dead gases are swept out of the cylinder, which is thus prepared for the reception of a fresh charge of oil and air. The cycle of events just described embraces two revolutions of the fly wheels.

PRIESTMAN OIL ENGINE.

The chief departure from the gas engine principle of operation is in the treatment of the fuel, a considerable portion of which, if not all, is burned as a liquid spray instead of as a gas. This fact is evidenced in two ways.

Firstly, the proportion of air and of a gas must be very exact to give an explosive mixture—about ten volumes of air to one of gas. If this proportion is not closely adhered to in gas and gasoline engines, no explosions, or very weak ones will result. This generally accounts for the difficulty sometimes experienced in starting gas and gasoline engines. The proportion of air necessary for burning a given quantity of liquid oil is many times the latter, and need not be so exact to obtain an explosion. The Priestman engine is very easy to start and no trouble is experienced from this source, as almost any mixture of air and oil will ignite.

Secondly, a very small portion of the oil spray within the cylinder coats the walls of the latter and so perfectly lubricates them that no other means is ever provided for this purpose. This is a most distinctive and important feature, for no special cylinder oil is ever used, and no attention to this point is ever necessary.

By reason of the positiveness of the cylinder lubrication, the cooling water surrounding the cylinder can be allowed to boil without increasing the friction, and with beneficial results. It is only necessary to have sufficient water for keeping the cylinder jacket full. This feature is very advantageous with portable engines, and in localities where small water tanks are advisable.

The oil, which is kept in a tank—located wherever convenient—is pumped into the spray maker under a pressure of about 8 pounds. The oil consumption is about 1¼ pints per brake horse power per hour. Looking at the question of consumption in another way; every time an engine receives an impulse, it requires the burning of only about 1½ drops of oil to produce each horse power. This fact is a good illustration of the astonishing amount of energy that is stored in a minute quantity of oil.

The steam engine method of governing, that is, by throttling the charge, is employed and impulses are taken regularly whether the engine be running empty or fully loaded, each charge of oil spray being exactly proportioned to the load carried. The excellent speed regulation of the engine especially adapts it for electric lighting, and a steady incandescent light can be obtained without the use of counter shafting or extra balance wheels. It is an interesting fact, and one possibly not generally known, that by using a given quantity of oil in the Priestman engine for operating incandescent electric lights, more illumination can be secured than if the same quantity of oil were burned in a common house lamp.

It may be of interest to the reader to also know the actual amount of work that can be secured from a small quantity of kerosene burned in a Priestman engine that is operating some of the most common classes of machinery. Take electric lighting, for instance, one pint of kerosene will run eight 16 c.p. incandescent lights, or one 1600 c.p. arc light for one hour. When operating an ice machine, a pint of oil will produce about 200 pounds of ice at 15° F. from water at 70° F. If attached to a hoist, 100 tons can be lifted four feet, or one ton four hundred feet by one pint of oil; and when used for pumping, the expenditure of this small quantity of oil will raise 1000 gallons of water 96 feet high. In computing these figures due allowances have been made for the average inefficiencies of all apparatus employed.

As the Priestman engine is very simple in its method of operation, and is entirely automatic in its action, it is admirably suited for places where there is desired a cheap, safe, and reliable motive power, which can be satisfactorily handled by unskilled labor, and which demands the least attention.

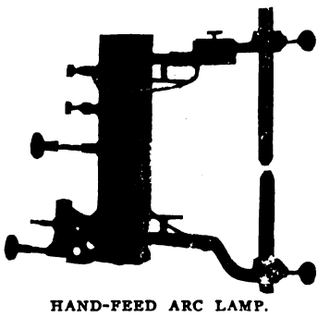
The Aultman Company have recently added a number of improvements to the engine, amongst them being an air storage system, whereby engines can be easily started without recourse to any preliminary hand pumping or turning of the fly wheels.

---

### POCKET BATTERY GAUGE.

The pocket battery gauge shown in the accompanying illustration, is of especial value to telephone inspectors and for use in testing telegraph and bell batteries and storage cells. The instrument is fitted in a case the size of an ordinary watch case, is dead beat in its indications, and easily attached to the cell to be tested. A special form is made for testing single cells of storage battery, in which use the indicator is of particular value, since with it may be detected a defective cell which, if left in circuit, might be ruined.

BATTERY GAUGE.



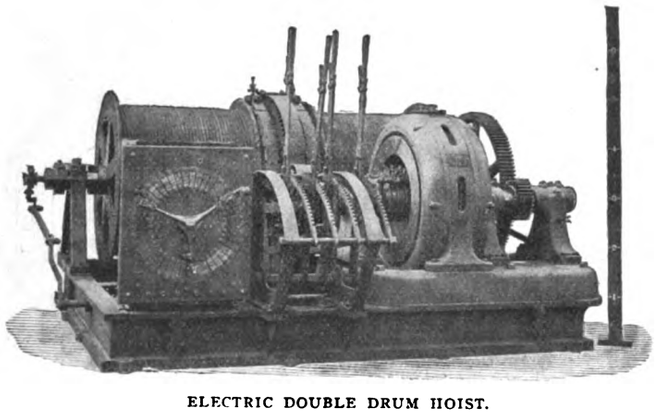
Digitized by Google

The maker of the Warner pocket battery gauge described is the Standard Electric Time Co., Waterbury, Conn.

### HAND-FEED ARC LAMPS.

The arc lamp shown in the accompanying illustration is intended for stereopticons, moving picture machines, scientific lecture work, and other purposes rendering the use of a hand-feed lamp necessary or desirable.

The carbon holders are adjustable to any

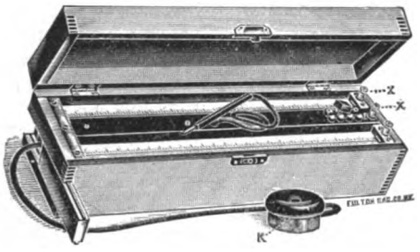


HAND-FEED ARC LAMP.

height independent of each other or the feed rod, and supplied with either plain or differential feed. As will be seen, there is no rack to get bent, and the feed rod is protected by being eased in a rectangular tube. Both carbon holders can be instantly returned to the starting position without the tedious operation of turning a feed screw backwards, as in the case of many other lamps. In regulating, but a slight movement of the feed handle is necessary, and then but once in every three to seven minutes, depending upon the size of carbon and the current used. The makers of the lamp described are Baker & Fox, 83 Schermerhorn Street, Brooklyn, N. Y.

### DOUBLE DRUM HOIST AND ELECTRIC MOTOR.

The electrical hoist, illustrated herewith, shows one of the recent applications of a General Electric induction motor to a double independent drum Lidgerwood mine hoist. It is compact in form, and the levers controlling the clutches and breaks and handle of rheostat are placed in the



ELECTRIC DOUBLE DRUM HOIST.

position most convenient for control by the operator standing on a platform above the floor, and having a clear view over the top of the hoist.

Each friction drum is driven through a single-reduction gearing by a 100-volt 12-pole induction motor of 30-h.p. capacity, running at 600 r.p.m. Each drum is independent and is 42 ins. in diameter by 40 ins. face. Together they hold about 420 ft. of ⅞-in. rope. The maximum hoisting speed is 300 ft. per minute, and the weight hoisted, including load, car and cage, is 2100 lbs. The depth from which the load is to be hoisted is 400 ft. from the surface.

### DIRECT-READING OHMMETER.

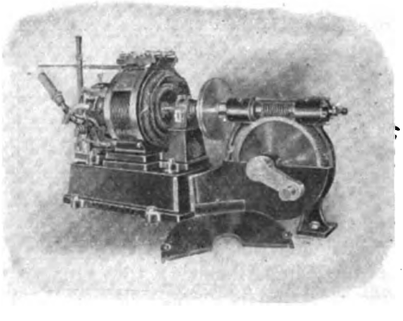
In the accompanying illustration is shown the '99 type of direct reading ohmmeter, manufactured by the American Electric Specialty Company, 123 Liberty Street, New York City. This instrument differs from its predecessor in many important improvements. There are four scales lettered in four colors instead of three, whereby the range is increased from zero to over one megohm. The scale is engine-divided and its accuracy is thereby so increased that its makers do not hesi-

DIRECT-READING OHMMETER.

tate to guarantee an accuracy of minimum error to considerably less than ½ per cent. The stylus which formerly carried a battery key has now been made much stronger and lighter and the battery key has been placed in the telephone receiver where it can be conveniently manipulated by the other hand. The delicacy of touch is thereby largely enhanced. A special telephone receiver is used, which is constructed for great sensitiveness to any disturbing current rather than for its speech-reproducing qualities.

The brass work and other construction have also been materially improved. The containing box is now built up of strongly dove-tailed and glued joints, and shrinkage or expansion from moisture is an impossibility. The bottom of the box is removable and the batteries can be removed and replaced in a few moments at an extremely low cost, and it is not necessary to send the instrument back to the makers for this purpose. The batteries are very long lived and will last a year with daily constant use.

### ORGAN PUMPING OUTFIT.



The need has long been felt for a reliable organ pumping outfit that can be operated by alternating currents, and recently such a combination has been placed on the market, as illustrated in the accompanying cut.

The outfit consists of a single-phase alternating current motor of 1 h.p., arranged with triple worm gear to directly transform the revolutions of the motor (1800 per minute) into the reciprocal crank motion required for an organ pump—45 strokes per minute.

In the system the motor is started and left running at a constant speed during an entire service or concert. The only disadvantage of this is the amount of current used while the pump is not in operation, and as this amounts to only 1 3/10 cents per hour with a rate of 10 cents per kw.-hour (power rates range from 5 to 20 cents per kw.-hour for this class of work) it will be seen to be an eligible factor, and in fact is fully compensated for by the absence of extra current incident to starting. Among the advantages are the absence of regulating rheostats and sparking of contacts on stopping and starting, and the simplicity and compactness of the outfit entailed.

The operation of this outfit is as follows: "The motor is started by the handle marked "Motor Starting Handle," and as the bellows of the organ is presumably empty, the friction clutch shown at the other end of the motor shaft is in contact with the worm disc and the motor begins pumping air into the air reservoir until filled. The natural rise of the top of the air reservoir to which the chain marked "connection to bellows" is attached through pulleys or bell-cranks, will release the friction disc at any desired point, and the pump mechanism will stop, leaving the motor running free, and thus taking almost no current.

As soon as the air reservoir begins to empty, the clutch operates again and as much or as little air is supplied as may be necessary to keep the reservoir charged with air. The action of the friction discs is positive and noiseless. The worm is of hardened steel. The worm wheel is run in a bath of oil and is therefore per-

ORGAN PUMPING OUTFIT.

Digitized by Google

fectly lubricated at all times, and the entire outfit is designed and manufactured to stand hard and continuous service with little or no attention.

The action of the outfit may be controlled to pump fast or slow, and to change the speed as the air reservoir fills by merely making a spring connection between air reservoir and the motor instead of solid connection; the solid connection is advised whenever practicable, as there is then very little or no wear on the friction clutch.

The outfit described is manufactured by the Emerson Electric Manufacturing Company 714 St. Charles Street, St. Louis, Mo.

### NEW TYPE OF GENERATOR.

The new "Triumph" generator illustrated herewith is a multipolar machine which differs from the usual type in that the armature windings are divided into distinct and separate circuits connected through a special commutator to separate distributing circuits with a common return, as shown in the accompanying diagram. The initial voltage of each circuit is 220 volts. The current is generated in each circuit for only one-third of the time, or in other words, each coil on the armature is active for only one-third of a revolution, being entirely cut out of circuit for the remaining two-thirds. Actual test has demonstrated that when a rate of 5400 impulses per minute has been reached, the light is absolutely steady.

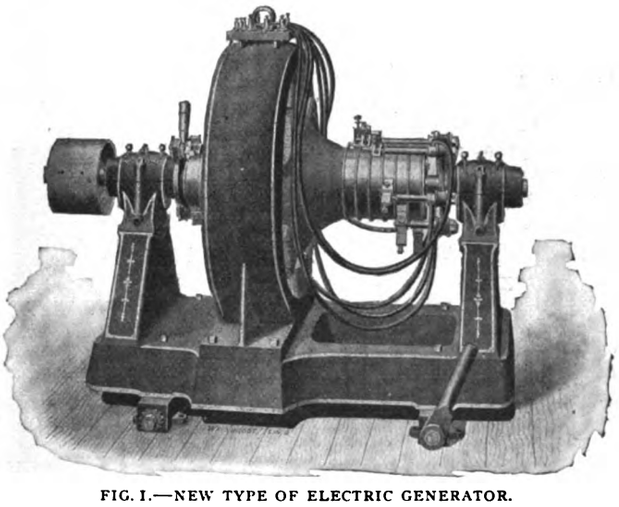


FIG. 1.—NEW TYPE OF ELECTRIC GENERATOR.

The manufacturers communicate to us the results of a recent test of a 300-light machine of this type, as follows:

Two new 16-c.p., 110-volt, 55-watt lamps were selected at random from a barrel of Buckeye lamps. and placed at each end of a Bunsen photometer. One was connected to the mains of a direct current machine and held at 115 volts, and the other connected with the dynamo being tested. The Bunsen disc was placed in the center of the scale and the current from the dynamo under test was regulated with a field rheostat until the lamp on that circuit was brought to the same candle power as that on the direct current. All readings were taken with a Weston portable voltmeter.

When the candle power of the lamp on the "interrupted current" generator was exactly the same as that on the direct current, the apparent voltage of the interrupted current was observed and the test began, the dynamo being belted to a countershaft, driven by a 12 x 14 automatic engine. Following are the results:

| | |
|---|---|
| Average of three cards, 33.35 h.p.; No. 16 c.p. lamps | 304 |
| Average of three cards, 24.43 h.p.; No. 16 c.p. lamps | 152 |
| Average of three cards, 13.82; fields open. | |
| No. 16 c.p. lamp, per h.p. delivered at full load. | 15.56 |
| No. 16. c.p. lamp, per h.p., delivered at half load | 14.32 |

It will be observed that these results are much better than claimed for any standard machine of the same capacity, and also that there is a surprisingly small drop in efficiency at half load.

As will be noticed from the photographic reproduction, the machine is simple and compact, and the manufacturers claim that the results obtained, while remarkable, can be demonstrated as theoretically possible from the principles embodied in the machine.

The manufacturers of this new type of machine are the Triumph Electric Company, Cincinnati, Ohio.

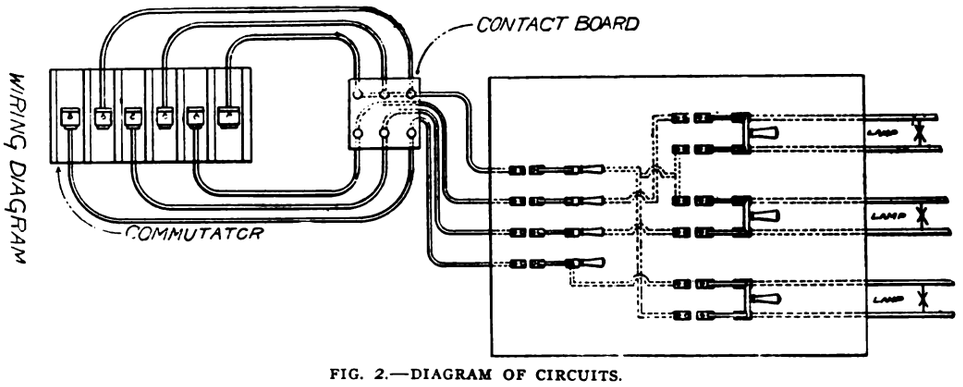

FIG. 2.—DIAGRAM OF CIRCUITS.

### INSULATING PAPER AND BOARD FROM ASBESTOS.

A product for insulating purposes and electrically indestructible, is now being manufactured by the Asbestos Insulating Company of Baltimore. The material is pure asbestos, so treated chemically as to remove all metallic particles, as well as other impurities, consisting of rock, lime and magnesia, which are found in the crude specimens. In the best Canadian specimens, the impurities removed amount to about 25 per cent of the bulk, leaving a base of two of the most indestructible factors found in nature.

The refined fibre is so improved by this process, that it can be employed in paper making, and spun into thread, which latter is used for insulating wire. Paper made from this material and rolled to eight one-thousandths of an in. thickness is stated to have a uniform resistance up to 1700 volts, and in blocks of an inch thick, made up of alternate layers of the paper, with thin rubber binding, and pressed to a solid mass, is equal to a resistance of 24,000 volts.

A desirable feature of this insulating material is, that it will not carbonize under any conditions, and cannot otherwise be affected by heat. The result of the purifying process gives virtually a new product, which is available for other than electrical purposes and should have a wide range in the arts, including fire-proof paints, and fire-proof material. On account of the extreme thinness of the sheet its use is claimed to reduce the size of armatures and other parts at least a third.

The process employed was the discovery of Mr. John F. Green, general manager of the company, who has given it a great deal of attention and experimented widely with samples of asbestos from almost all the regions where this material is found, up to as many as thirty-three different grades, many of the poorer grades being rendered commercially valuable by the process.

### AN ELECTRIC LIGHTER.

There has long been a demand for a practical electric lighter, which could be used on both electric light circuits and battery current. The type shown herewith, known as the "Matchless Electric Lighter," is made of the finest white china throughout, embodies these two essential points, and high efficiency, durability and economy are also claimed. The cost of maintenance is stated to be about one cent per month, and on electric light circuits no attention is required from one year's end to the other, save the moistening of the asbes-

Digitized by Google

tos packing in the torch about twice a month with ordinary usage. An attachment plug and cord is furnished and can be inserted in any lamp socket or attached to the wiring direct as may be most convenient. The lighter is then at once available for use.

The cut represents the lighter especially adapted for use in smoking rooms, hotels, cigar stores, marine work, palace cars, apartment houses, office buildings, private residences, and in fact in all places where

ELECTRIC LIGHTER.

cleanliness and freedom from danger from discarded matches is desired.

The lighter is available where there is no electric light current, by merely connecting two cells of dry battery, which is stated to require renewal perhaps once a year, and often less. The coil, of course, never wears out. A hundred or more lighters may be connected to the same set of batteries, or to the same circuit, and whenever a residence is equipped with electric gas lighting appliances, the lighter can be connected directly to the wiring already installed, and will call for no more attention than would an additional burner on a chandelier. The manufacturers are Stanley & Patterson, 32 Frankfort Street, New York.

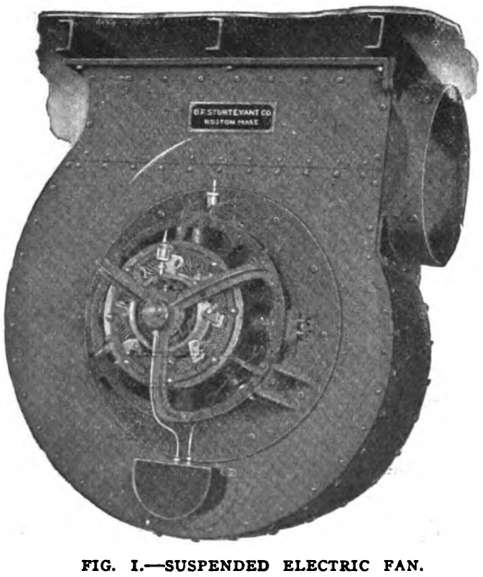

FIG. 1.—SUSPENDED ELECTRIC FAN.

### A SUSPENDED ELECTRIC FAN.

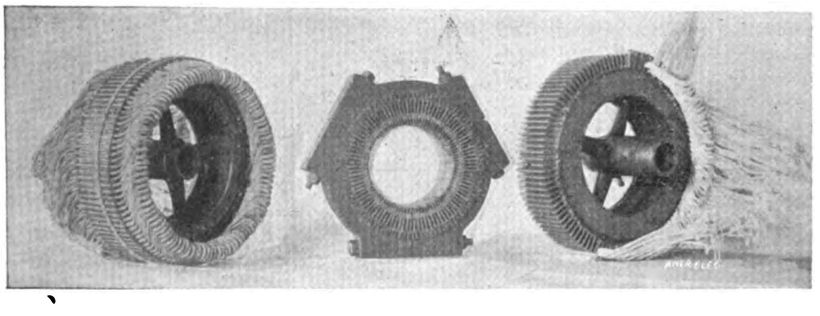
One of the prime advantages of an electric fan is its adjustability. Not only may it be located where most convenient for the adjustment of piping, but it may readily be constructed in such form as to be supported or suspended as may best suit the conditions. The accompanying illustration serves to make clear this point, for it represents an entirely new design built upon a special order by the B. F. Sturtevant Company, of Boston, Mass.

The fan as here shown was designed for use on shipboard, and is to be suspended from the deck. In general form the fan itself is of the usual steel plate construction, being an exhauster with its inlet upon the side furthest from the motor.

The motor itself is of entirely special construction, having eight poles, rendering it very compact, so that it extends the minimum distance from the side of the fan. In the size here shown the field ring was of wrought iron, although in larger sizes it is built of cast steel or cast iron.

The cast iron plate with projecting lugs, which is attached to the fan side, serves to center and hold in position the field ring of the motor, while tripod hangers extending from either side of this ring support the armature shaft in ring oiler boxes.

The field cores are of wrought iron, giving the highest efficiency in the field, and the pole shoes are of cast iron of such peculiar shape and size as to render the machine capable of extreme variation of load without sparking at brushes, and without any shifting or adjustment whatever. The field coils are machine wound, and thoroughly insulated, their form being thoroughly open. The windings present a maximum amount of radiating surface, which results in the most perfect ventilation, and prohibits any great accumulation of heat.

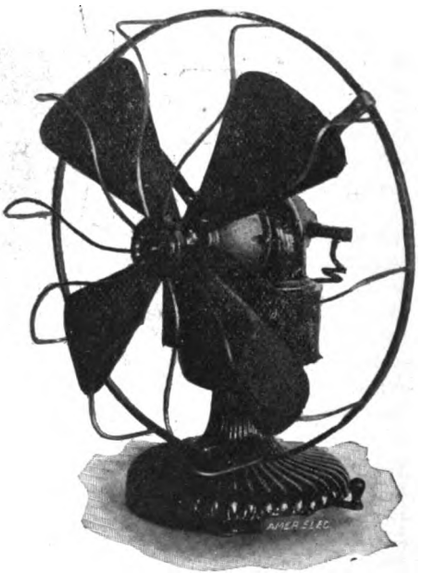


The armature cores are built up of laminated, slotted discs, mounted on a cast iron spider, having a hub projection for the reception of the commutator. These core discs are solidly clamped between two brass rings, which have corresponding core teeth.

The armature is of the coil wound drum type, and in the usual form has a two circuit winding, although in some cases multiple winding is used. This type of winding on machines of low speed and small output is of great advantage.

The commutator is of large diameter, and consists of pure rolled or drop forged copper segments, supported in a cast iron shell of spider construction, and thoroughly insulated. Reaction brushes of fiber graphite are used, and supported by special rigging.

These motors require no shifting of brushes from no load to full load, thereby greatly reducing the attention required.



Evidently fans of this type can be constructed in various sizes and forms, and may be provided with motors having capacities ranging from three to 125 h.p.

FIGS. 2, 3 AND 4.—DETAILS OF ARMATURE.

### A NEW FAN MOTOR.

The fan motor shown herewith, known as the "Peerless," is among the first of the 1899 models to be gotten ready for the market. The type shown carries a 12-in. fan. When running at 1850 revolutions per minute it is claimed to absorb but 35 watts of electrical energy, or considerably less than that taken by a high efficiency 16-c.p. lamp. The construction of the motor is such that it is impossible for dust to gain access to it or the commutator. The makers are the Warren Electric & Specialty Company, Warren, Ohio.

PEERLESS FAN MOTOR.

VICTOR TELEPHONE SWITCHBOARD.

The accompanying illustration gives a very good idea of the Victor metallic switchboard, being a reproduction of the photograph of an exhibit at the recent Northwestern Electrical Convention. One of the features of this board is that it has no conections on wood, all connections being mounted on rubber and soldered, thus obviating loose connection and cross talk. The simplicity of construction and fewness of parts of this board afford ample space for heavy installation and metallic parts, which tends to a double assurance of durability and high efficiency, with lowest cost of maintenance. The switchboard is built in five jack and drop sections, with entirely concealed wiring, tripolar single coil and low contact gravity drops, which, it is claimed, insure sensitive and positive action. The manufacturers of this switchboard claim that it is unrivalled in fewness, strength and simplicity of parts; in compactness, ease and rapidity of motion, and in durability and economy of maintenance. This apparatus is manufactured by the Victor Telephone Manufacturing Company, 166 to 174 S. Clinton Street, Chicago.

VICTOR TELEPHONE SWITCHBOARD.

## NEW BOOKS.

Twentieth Century Sketch Book for Schools, Colleges and Practical Men. Fifty leaves in block form. Woonsocket, R. I.: M. A. Avery. Price, 25 cents.

This convenience for engineers and draughtsmen consists of a block of sheets, each sheet having a marginal scale of inches. A sheet, therefore, has the advantage of sectional paper, without the disadvantage of sectional lines covering the object sketch. The size of the blank space surrounded by the marginal scale on four sides is 5 ins. x 8 ins. A similar sheet is made with the addition of an angle scale, which should be particularly useful in proving geometrical and trigonometrical calculations.

Fowler's Mechanical Engineer Pocket Book. Edited by William H. Fowler. Manchester, Eng.: Scientific Publishing Company. 324 pages, illustrated. Price, 1s. 8d.

This is an excellent manual of steam and mechanical engineering—in fact, comparing very favorably with the most pretentious hand-book on the same subject. The different sections have been prepared by competent engineers, and the data and other information appear to have been most judiciously selected. The section on electricity was prepared by Mr. H. A. Clark, of the Chelsea Polytechnic, and is an admirable collection of electrical engineering data and information having a direct practical bearing.

Hand-Book of the Corliss Steam Engines. By F. W. Shillitto, Jr. Bridgeport, Conn.: American Industrial Publishing Company. 197 pages, 54 illustrations. Price, $1.00.

This little book, embellished with a portrait of the author, purports to describe in a comprehensive manner the erection of engines, the adjustment of the Corliss valve gear, and the care and management of Corliss steam engines. While the information given can scarcely be termed comprehensive, it is yet clearly stated and eminently practical. The chapters on valve adjustment will be found particularly useful, and the same remark applies to a chapter on general repairs and management.

A Pocket Dictionary of Electrical Words, Terms and Phrases. By Edwin J. Houston, Ph. D. New York: American Technical Book Company. 945 pages. Price, $2.50.

In the preparation of this volume the author has not employed cross-references, but arranged the terms alphabetically in their natural order, thereby greatly enhancing the value of the book for ready reference. The definitions are concise, and the subject matter is up-to-date, all of the latest terms connected with polyphased currents being included. While not possessing the encyclopedic character of the author's larger dictionary, and though devoid of illustrations, the present work has the advantage of greater conciseness, more compact form and lower price.

Alternating Current Wiring and Distribution. By William Le Roy Emmet. Second edition, revised and extended. New York: The Electrical Engineer. 98 pages, 33 illustrations. Price, $1.

The second edition of this excellent little treatise has been thoroughly revised, and extended from 76 to 98 pages by the introduction of new matter. As a brief and concise exposition of the principles of alternating current working and their practical applications in distribution, this little book is of unusual value to both the engineer and the student. Those who desire to thoroughly understand the practical meaning of power factor, inductive load, reactance, etc., and to know how to apply the knowledge in actual cases, will find at present no other work to which they can refer with so much confidence.

Electrodynamics. The Direct-Current Motor. By Prof. C. A. Carns-Wilson. New York: Longmans, Green & Co. 298 pages, 71 illustrations. Price, $2.00.

The aim of this book is to apply the principles of electrodynamics to the electric motor, and the subject is very much simplified by the author's use of a so-called induction factor, or transformation of the fundamental equation applying in terms clearly showing the relation of the important factors, and enabling practical cases to be easily submitted to numerical calculation. The principles of shunt and series wound motors are developed, and chapters given on efficiency, acceleration, torque, control and armature reaction, special attention being paid to the street railway motor. An admirable feature of the book consists in the extensive use of numerical examples to illustrate the practical application of principles and formulas.

Twentieth Century Magic. The Construction of Modern Magical Apparatus, with the Introduction of New Experiments, Mechanical, Chemical and Electrical. New York: George Routledge & Sons. 160 pages, 100 illustrations. Price, $1.50.

Those seeking a means of amusing a company of friends, or even a public audience, will find in this book many ingenious methods, which, besides, have the advantage of being new. Chapter I. is on the design of the magician's stage and table. Chapter II. gives the details of five mechanical illusions, and the following chapter four tricks based on the use of chemicals. Chapter IV. is a reprint of five arti-

Digitized by Google

cles on electrical magic which appeared in the columns of this journal, and the final chapter is on equipment and working notes. The book is agreeably written, and all of the apparatus comes within the constructive powers of the amateur.

---

Electricity in the Diagnosis and Treatment of Diseases of the Nose, Throat and Ear. By W. Scheppegrell, A.M., M.D., New York: G. P. Putnam's Sons. Large octavo, 161 illustrations. Price, $4.50.

There has been no lack in recent years of works treating of the applications of electricity to medicine and surgery, but none has, until now, been devoted exclusively to a systematic consideration of the uses of this force in diseases of the nose, throat and ear—a branch of the healing art in which, at least as far as diagnosis is concerned, it is probably of greater service than in any other. The book, which is copiously illustrated, contains a concise account of the principles of electro-physics, descriptions of the numerous electrical instruments employed in diagnosis and treatment, and the indications for their use, as well as the modes of examination. The concluding chapters deal with the X-rays, from a physical and clinical point of view.

---

Matter, Energy, Force and Work. A Plain Presentation of Fundamental Physical Concepts, and of the Vortex-Atom and other Theories. By Prof. Silas W. Holman. New York: The Macmillan Company. 257 pages. Price, $2.00.

Were the principles so clearly enumerated in this book generally understood, the Patent Office would lose no small part of its revenue, electricity would no longer be considered the transcendant mystery in the realm of Nature, and vast sums of money spent on attempting the impossible would be spared. In other words, the book sets forth the distinctions between force, energy and work, classifies the different forms and clearly presents the principles of conservation and transformation of energy. The final portion of the book is devoted to a statement of the kinetic theory of gases, Le Sage's theory of gravitation, the vortex-atom theory and of other authoritative theories and speculations in the field of physics.

---

Magnets and Electric Currents. An Elementary Treatise for the use of Electrical Artisans and Science Teachers. By J. A. Fleming. New York: Spon & Chamberlain. 408 pages, 134 illustrations. Price, $3.00.

For many years one of the best books on the market for those desiring an introductory treatise to electrical science free of mathematics, has been Fleming's "Short Lectures to Electrical Artisans." After the issue of several editions of that book it became necessary to rewrite it, and the result is the present work. The several chapter headings are as follows: Magnets and Magnetism. — Measurements and Units.—Magnetic Force and Magnetic Flux.—Electric Currents and Electromotive Force.—The Measurement of Electric Currents. — Electromagnetic Induction.—Electromagnets.—Alternating Currents.—Electric Measuring Instruments.—Generation of Electric Currents. As a book to serve as an introduction to electrical science, and to prepare the way for the sound understanding of technical treatises on the various branches of electrical engineering, this work can be confidently recommended.

## PERSONALS.

LIEUT. S. DANA GREENE has been promoted to general sales manager of the General Electric Company.

COL. EUGENE GRIFFIN, first vice-president of the General Electric Company, has been promoted to Brigadier-General of Volunteers, in recognition of his excellent service in Puerto Rico while in command there of the First Regiment of Engineer Volunteers.

PROF. SIDNEY H. SHORT, in an article in the January number of the "Cosmopolitan," discusses the subjects of high-speed electric traction, and the employment of electricity on trunk lines. The "Evening Post," in an editorial based on Prof. Short's article, strongly indorses the position therein taken, which is that within a comparatively short period electric traction will reduce the time from New York to Chicago to nine hours, and trunk lines will be operated by electricity.

MR. JOHN McGHIE, for a number of years the advertising and newspaper representative of the General Electric Company, has resigned from that company to join the business staff of the "American Machinist," taking charge of the Western interests of that journal. Mr. McGhie made an enviable record when with the General Electric Company, and possesses both the ability and the social qualities to win success in his new field of work. The "American Machinist" ranks high among the ably conducted technical journals of the world—easily within the first dozen—and it is to be congratulated upon securing the services of one who, in every way, will worthily represent it.

## TRADE PUBLICATIONS.

ELECTRIC WELDING.—The Standard Tool Company, Cleveland, Ohio, has issued a pamphlet devoted to the electric welding line of its business, electrically welded bicycle parts being the subject.

REFLECTORS.—Numerous forms of electric reflectors are shown in a catalogue of the Western Reflector Company, 740 Grand Avenue, Chicago, ranging from types for desk use to reflectors for churches and theaters.

PENCILINGS.—With this title, the Joseph Dixon Crucible Company, Jersey City, Pa., have issued a pamphlet giving much interesting and useful information concerning lead pencils, and their selection for various uses.

LORICATED CONDUIT.—The Safety Conduit Company, Rankin Station, Pa., have issued several circulars giving a list of users of "Loricated" electric iron-armored conduit, and views of some large buildings in which this material has been installed.

EXACT TIME.—The Standard Electric Time Company, Waterbury, Conn., in a recent pamphlet, give much information concerning their system of transmitting by electrical means exact time from a master clock to any number of secondary clocks.

ELECTRIC VEHICLES.—With the title "The Twentieth Century Movement," the Electric Vehicle Company, 1545 Michigan Avenue, Chicago, has issued an attractive pamphlet containing extremely well-executed engravings of several types of electric motor vehicles.

A POCKET REMINDER.—The Sprague Electric Company is sending its friends a handsomely leather-bound ready reminder of daily engagements, which, in addition to the diary pages, includes a number of useful tables and considerable other matter for ready reference.

MULTIPOLAR MACHINES.—Circular No. 44, of the E. G. Bernard Company, Troy, N. Y., is devoted to the description and illustration of its multipolar slow-speed dynamos and motors. The description is a well-written technical account of the machine, not a mere collection of claims.

WARREN ALTERNATOR.—Bulletin No. 8, of the Warren Electric Company, Sandusky, Ohio, is a well-printed and illustrated brochure of sixteen pages, showing in detail the features of the Warren inductor alternator, and pointing out their merit. A number of flattering testimonials from users are included.

ELECTRIC HEATING.—In a fifty-page pamphlet the Simplex Electrical Company, Cambridgeport, Mass., (manufacturers under the patents of the American Electric Heating Corporation), illustrate numerous forms of electric heating apparatus, including radiators, portable stoves, teakettles, stew-pans, broilers, chopping-dishes, ovens, smoothing-irons, heating-pans, etc. An interesting feature of the text consists of tables giving the consumption in watts of all the apparatus listed.

LUNDELL MOTORS.—A beautiful catalogue recently issued by the Sprague Electric Company adds another to the growing list of edition de luxe trade publications. The title is "Electric Power," and the subject is divided into two portions—motors and applications. The numerous engravings are the highest expression of the half-tone art, and the cover is tasteful, both in design and illumination. Among the interesting technical matter is a series of curves, showing the variation of the efficiency of motors of different power, with different loads.

RECORDING WATTMETERS.—The latest achievement of the General Electric press is a beautiful large-page pamphlet on Thomson recording wattmeters, which more than maintains the reputation of this press as one without an equal in its line in this country. All of the various types of Thomson wattmeters are described and illustrated in detail, and diagrams of connections given. A valuable feature consists of a number of pages of general information regarding meters, which includes directions for reading and care, description of record book, price chart, etc.

STURTEVANT LITERATURE.—Bulletins H and I, of the B. F. Sturtevant Company, Boston, Mass., have for subjects electric fans and eight-pole motors and generators, respectively. The former contains fifteen excellent engravings of high-powered electric fans, with descriptions of the same, and the latter is devoted to the latest type of Sturtevant generator. A very handsome pamphlet issued by the same company has on the cover an illuminated title, "Who Uses Mechanical Draft," and on the inside pages lists covering seventeen large pages giving merely the names and addresses of users of Sturtevant fans for the purpose mentioned.

MECHANICAL STOKERS.—The new catalogue of the American Stoker Company, Washington Life building, New York, is executed in the highest style of the printers' and engravers' art; the paper and binding are in keeping. Besides a well-written and illustrated description of the American stoker, numerous views are given of its application to different boilers. An interesting series of engravings is from photographs of a large steam plant, taken at different hours of the day, which show at all hours an absence of smoke from chimneys serving boilers fitted with American stokers, while dense clouds pour out of two chimneys connected to boilers not thus fitted.

MECHANICAL DRAFT.—Among recent publications by the B. F. Sturtevant Company, Boston, Mass., are a second illustrated edition of the lecture on "Mechanical Draft for Steam Boilers," delivered at Cornell University by Mr. Walter B. Snow, of the engineering staff of the Sturtevant Company; an interesting circular entitled "Draft Without a Chimney," telling why the Sturtevant Company took down its tall chimney, how draft is now produced, and how an annual fuel saving of nearly $1000 is secured, and Bulletin G, illustrating and describing a unique generating set, in which both the engine and the generator are entirely

Digitized by Google

inclosed, although perfectly accessible through suitable doors. Such a device is of manifest utility wherever the atmosphere is laden with dust. Any of the above will be mailed on application.

CALENDARS.

Of the trade calendars of the year which have come to our desk, those of the Sprague Electric Company and the Okonite Company easily rank first as artistic productions. The former consists of a heavy mat, surrounded by an ebony frame. The lower portion of the mat frames a large calendar, in one corner of the sheets of which are neatly worded seasonable references to Lundell motors, fans, fan heaters, Sprague elevators, etc.—The Okonite calendar consists of an exquisite figure-picture in colors, surrounded by a neat mat; the calendar and word "Okonite" on the mat are unobtrusive, thus not marring the artistic effect.—The calendar of the G. F. Brunt Porcelain Works, East Liverpool, Ohio, consists of six lithographic sheets, each containing as a central piece the picture of a handsome young woman arrayed in an army or navy uniform. The coloring is brilliant and effective, and the effect both artistic and striking. —Another work of art in the proper sense of the phrase is the calendar of the Laclede Battery Company, Kokomo, consisting of a mat framing an etching of an agricultural subject by Peter Moran, entitled "Stacking Time." As in the case of the above-mentioned calendars, the name of the firm and the calendar do not detract from the artistic effect.—A large lithographic engraving in colors of "The Oregon Pursuing the Colon" ornaments the calendar of Geo. I. Roberts & Co., New York, which is printed on heavy cardboard.—The calendar of the Peckham Truck Company is, as in previous years, large in proportions, consisting of twelve monthly sheets 17 x 26 ins. in size. As usual, it is excellently executed in printing, engraving and paper.—The Wm. Powell Company, Cincinnati, Ohio, show in colors on their calendar a large illustration of the Powell regrinding "Star" valve, which is the subject of admiring glances from a female figure regarding it from a seat on the earth, represented by a globe. The Powell Company informs us that a copy of this calendar will be sent to any engineer upon application.—The Monarch Governor & Machine Company, Indianapolis, Ind., have been successful in producing an artistic effect in the decoration of its calendar, with a view in colors of the Monarch governor.—The La Favorite Rubber Manufacturing Company, Paterson, N. J., uses war subjects as a decoration for its calendar, the monthly sheets containing portraits of Dewey, Miles, Sampson, Shafter, and other naval and military leaders in the late war. A copy will be sent to any of our subscribers on application.—The calendar of the Phillips Insulated Wire Company, Pawtucket, R. I., is one of convenient size, and with the dates printed in white on a blue ground.—A small calendar for desk use is issued by the Stewart Heater Company, Buffalo, N. Y., containing views of the Stewart filter and heater.—Another calendar of convenient size is that of Machado & Roller, 203 Broadway, New York, to which an artistic appearance is lent by the handsome engraving used as a trade-mark by the Allgemeine Electricitats Gesellschaft, of which great German firm Machado & Roller are the American representatives.—The Ashton Valve Company, 271 Franklin Street, Boston, ornament their calendar with two portrait figures of children in handsome scrolls, underneath which is the title "Chips of the Old Block." —The calendar of the Joseph Dixon Crucible Company, Jersey City, N. J., has for its pictorial subject a lithograph in colors of an attractive young woman, in college gown, teasing an owl perched on a globe, the head of the bird of wisdom bearing a dunce cap.

## BUSINESS NEWS.

PECKHAM TRUCKS.—Among recent orders for Peckham trucks is one for 160 pairs for the Third Avenue Railroad of New York City.

THE EUREKA TEMPERED COPPER COMPANY has removed its office from 107 Liberty Street to 141 Broadway, corner Liberty Street, New York.

GLASSWARE.—At the recent Manufacturers' Annual Glass Exhibit at Pittsburgh, Pa., the Pittsburgh Glass Company was represented by D. W. Eyman, and showed a large exhibit of gas and electric shades of every description.

THE E. G. BERNARD COMPANY, 450 Fulton Street, Troy, at its annual meeting, held Jan. 10, unanimously re-elected the following officers: President, E. G. Bernard; vice-president, F. L. Stevens; secretary, H. T. Crissey.

THE RAMSDELL ELECTRIC CONSTRUCTION COMPANY, Salem, Mass., desires to receive catalogues from manufacturers of annunciators, automatic fire alarms, telephones for private lines, and electric house goods generally.

THE AMERICAN ENGINE COMPANY, Bound Brook, N. J., owing to the growth of its business, has opened a New York office in the White building, 95 Liberty Street, which will be in charge of Edwin S. Boyer, formerly of Philadelphia.

AMERICAN CATALOGUES WANTED.—We are requested to say that Gregg & Barrell, Standard building, Johannesburg, S. A. R., desire to receive catalogues from American manufacturers of electrical goods of all kinds, together with price lists.

THE C. & C. ELECTRIC COMPANY has removed its Philadelphia office from 633 Arch to much more commodious and attractive quarters at 45 North Seventh Street, where the manager, Mr. William Myers, will be glad to welcome the friends of his company.

MR. JOHN E. FULLER, 93 Maiden Lane, New York, has recently succeeded to the business of the North American Electric Company, of 181 William Street, New York. Mr. Fuller is sole owner and proprietor of the business, having no connection with any one else.

THE CENTRAL TELEPHONE AND ELECTRIC COMPANY, 909 Market Street, St. Louis, Mo., has in its new office, sample room and factory 8500 ft. of space entirely devoted to telephone goods. Everything, from telephones to fuse blocks, is carried in stock, and thus all orders can be promptly handled.

CARD GENERATORS AND MOTORS.—Among recent sales of Card apparatus by J. Holt Gates & Co., Western agents of the Card Electric Company, Mansfield, Ohio, were one 225-kw. 500-volt generator, two 150-kw. 500-volt generators, and twelve motors aggregating 880 h.p., all to be installed in the Armour glue works, Chicago.

JAMES McCREA & CO., 11 South Canal Street, Chicago, manufacturers of the Climax steam joint clamp, report a rushing business with the opening of the new year. An agency has been established with Messrs. McArdle & Co., 514 Camp Street, New Orleans, who carry a complete stock, and will look after the adjacent territory.

CRESCENT TELEPHONES.—The Pennsylvania Electric Company, Marietta, Pa., was awarded a bronze medal for its telephone apparatus exhibited at the Omaha Exposition. The award was the result of a special effort, but given on a line of samples exhibited by the company's local agent.

C. B. ARSINO finds, after eight months of successful business, that he has outgrown his present quarters at 125 Massachusetts Avenue, Boston, and he has taken a lease of 18 Cambria Street, Boston. In addition to his former work in electrical and mechanical repairing, Mr. Arsino will add an electro-plating branch to his business.

FERRACUTE MACHINES.—The demand on their manufacturing facilities has necessitated a considerable enlargement of the works of the Ferracute Machine Company, of Bridgeton, N. J. No small part of the business of this firm is the manufacture of presses and dies for electrical work, many shipments of which are on foreign orders.

FEED-WATER HEATERS.—That the Cochrane feed-water heaters, made by the Harrison Safety Boiler Works, Philadelphia, is appreciated by owners of electric railway and light plants is shown by a list of such users, recently issued. The most substantial plants in the country are represented in this, many of them having from 1000 to 3000-h.p. capacity installed.

THE GEO. C. TOWLE MANUFACTURING COMPANY, of Lancaster, Pa., have moved into new and much larger quarters, their new factory building being 150 x 75 ft. and two stories in height. Three months' orders are now in hand, among which is one for a complete equipment of fan motors for the new United States Mint building in Philadelphia.

THE CUTLER-HAMMER MANUFACTURING COMPANY, 70 West Jackson Boulevard, Chicago, Ill., has greatly increased its manufacturing facilities, and now claims to have the largest and the finest equipped factory devoted exclusively to the manufacturing of rheostats in the world. This, they say, with the large volume of business done, has enabled the price of rheostats to the trade to be materially reduced.

HARRISON PRIMARY CELL.—The Thermo-Electric Company, "Times" Building, is offering a primary battery having an e.m.f. of 2.45 volts, lead peroxide being the positive element and self-amalgamating zinc the negative. The capacity of a cell is 40 amp.-hours, and the makers claim that it is the most powerful and economical cell made for all open-circuit and semi-closed circuit work—such as bells, telephones, annunciators, burglar alarms, physicians' and dentists' lamps, etc.

FAN MOTORS FOR EXPORT.—The Emerson Electric Manufacturing Company, of St. Louis, received a few days ago an order from China for a number of desk and ceiling fans, amounting to about $1300, and the next day an order for a quantity of its alternating current ceiling fans, which were to be shipped to South America, amounting to about $675. In addition to these orders, the demand for Emerson fans has been unusually active from the larger cities in the United States.

ROEBLING CONSTRUCTION COMPANY.—Under this name a company has been incorporated under the laws of New Jersey, to engage in the manufacture of iron for fire-proof buildings. Of the 500 shares of the company, 260 are held by Frederick Roebling, 170 by Frank H. Croker (son of Richard Croker of New York), 50 by J. W. Hinkley, late chairman of the New York State Democratic Committee, and 10 each by Chas. G. Roebling and Frank O. Briggs.

INTERIOR TELEPHONES.—The Allen-Hussey Company, Chicago, Ill., the well-known manufacturers of interior telephones, have been meeting with such a gratifying demand for their product in the East that they have recently opened a New York office at 101 Beekman Street, where a complete line of their telephones will be kept in stock, and from which all Eastern orders can be filled promptly. Mr. W. R. Allen, of this company, will have charge of the Eastern office.

HANCOCK INSPIRATORS IN CUBA.—Mr. M. J. Martinez has received the appointment as resident agent at Havana, Cuba, for the Hancock Inspirator Company, manufacturers of injectors, ejectors, general jet apparatus and specialties for steam, water, air and gas. The business will be conducted under the style of M. J. Martinez, consulting and contracting engineer. Mr. Martinez will be prepared to submit estimates on all the different lines of apparatus manufactured by this company.

"COMMERCIAL" DYNAMOS IN JAPAN.—The Commercial Electric Company, Indianapolis, Ind., has recently installed a complete lighting and power plant for the Omi Mashi-Boseki Kwaisha, Kioto, Japan, which is a large flax spinning mill. All the machinery and supplies furnished were of American manufacture and installed through the Commercial Company's agent, Paul G. Fiedler, Yokohama. This is the fourth plant installed for the Commercial Company in Japan by Mr. Fiedler within the last few months.

FILER & STOWELL ENGINES.—Among recent sales of engines by Filer & Stowell, Milwaukee, Wis., are a 22-in. x 48-in. Corliss engine to the Menominee (Mich.) Electric Light, Railway & Power Company; a tandem compound engine, 10½ ins. x 20 ins. x 42 ins. stroke, to the Washburn & Moen Company, Worcester, Mass.; a

Digitized by Google

26-in. x 60-in. Corliss engine for the Whitney Iron Works, New Orleans; a 500-h.p. engine for the United States Glue Company, Milwaukee, and two 1000-h.p. engines, to Armour & Company, Chicago, for direct connection to generators.

MANHATTAN INCLOSED ARC LAMPS.—Mr. Stuart W. Wise, who was formerly treasurer of the Manhattan General Construction Company, has opened an office in the John Hancock building, 178 Devonshire Street, Boston, Mass., the former New England address of the Manhattan Company. Mr. Wise will push the sale of the Manhattan inclosed arc lamps from the above address. The company manufactures lamps for direct current circuits to operate singly on 110 to 220 volts, two or more in series on 220 to 550 volts, and to operate singly or in series on alternating current circuits.

BABCOCK & WILCOX BOILERS.—Sixty boilers of 520 h.p.—such is an order recently received by the Babcock & Wilcox Company, from Westinghouse, Church, Kerr & Co., which is said to be the largest single order for boilers ever given. The boilers are for the power house of the Third Avenue Railway Company, now being erected at 218th Street and Harlem River. The boilers will carry steam of 200 lbs. pressure, and, owing to the economy of the type of engine with which they will be used, now being designed by Westinghouse, Church, Kerr & Co., will be of sufficient capacity to supply steam to sixteen engines of 4000 h.p. each.

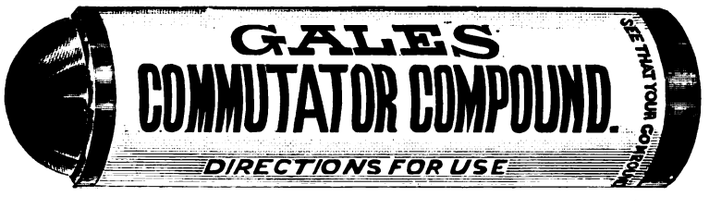
MR. H. W. WISWELL, electrical engineer, formerly with the General Electric Company, and who has been for the past year associated with the New York & Ohio Company as manager of its transformer department, makes the announcement that he has resigned his position with that company, his contract having expired, and has associated himself in a similar capacity with the Warren Electric & Specialty Company, Warren, Ohio. This company will place upon the market its new "peerless" transformers, which will be a distinct improvement upon anything now on the market, and expects to be able to make deliveries about April 1, 1899.

MURPHY AUTOMATIC SMOKELESS FURNACES are to be placed in connection with six water tube boilers of 250-h.p. rated capacity each, for the Union Iron & Steel Company, Youngstown, Ohio. Other recent sales are: Standard Plate Glass Company, Butler, Pa., three; Morrell & Company, Ottumwa, Iowa, an additional two; Northern Milling Company, Chicago, an additional two; Water Works, City of Detroit, additional four; Detroit Copper & Brass Rolling Mill, seven; Ford's New Plate Glass Works, Toledo, Ohio, eight; Michigan Alkali Company, Wyandotte, Mich., additional six, making forty-five in all sold this company within a year.

CAHALL BOILERS IN CUBA.—Mr. M. J. Martinez, member of the American Society of Mechanical Engineers, has received the appointment of resident agent at Havana, Cuba, for the Aultman & Taylor Machinery Company, Mansfield, Ohio, manufacturers of the "Cahall" vertical and the "Cahall" horizontal water tube boilers. Business will be conducted under the style of Mr. M. J. Martinez, consulting and contracting engineer. Mr. Martinez will be prepared to submit estimates on all the goods manufactured by the above named company, the vertical type of boiler being claimed by them to be especially adapted to the conditions and needs of the sugar industry in Cuba and Puerto Rico.

JENNEY MACHINES.—The Jenney Electric Manufacturing Company, of Indianapolis, Ind., now has its new plant well equipped for the manufacture of its well-known dynamos and motors, and while the plant which was destroyed by fire has only been rebuilt since about the 1st of September, the company is greatly crowded with work. Mr. Chas. D. Jenney, who is known the world over as one of the pioneer inventors and designers of electrical machinery, is at the head of the company, which insures the very latest improvements in electrical apparatus. This is undoubtedly the cause of the company meeting with such large demand for their apparatus, and inquiries from all over the country. They have had inquiries from Russia, England and Japan within the last ten days.

MURPHY STOKERS.—The Murphy Iron Works, of Detroit, Mich., has closed a contract with Armour & Co., of Chicago, for equipping the twelve 375-h.p. boilers in the latter company's new central station at the Stock Yards, Chicago. Many other installations have been recently made by the Murphy Company, and users of power are realizing more than ever the economy obtained by using the Murphy furnaces. Mr. O. D. Cotton, general sales manager of the Murphy Company, reports a greater number of installations on hand than ever before in its history, and he predicts an unusually heavy year's business in 1899 for his company. Mr. W. G. Amos, Chicago agent of this company, states that the prospects in and contingent to Chicago are unusually bright, and he is assured of a large number of new installations and perhaps a larger number of additions to plants in which the Murphy furnaces are already installed.



ORIENT INCANDESCENT LAMP.—A combined mechanical and chemical process is now employed by the Orient Electrical Company, of Youngstown, Ohio, for securing the vacuum in the bulbs of its incandescent lamps. The mercury pumps were thrown out a year ago, and mechanical pumps installed which, operating in connection with a chemical process, facilitate the gaining of the desired vacuum. By the new process an attendant is able to exhaust and seal 500 lamps in ten hours, or about 50 an hour. In the process a high tension-current is employed, which quickly drives the gases from the filament and produces a very efficient lamp, which maintains a practically uniform candle power throughout its entire life. Some of the peculiar features of the Orient lamp are that the filament is anchored from the mount, and the loop is made oblong, instead of circular. The Orient Company has opened a New York office in the Havemeyer Building, 26 Cortlandt Street, of which Mr. Francis Granger is manager.

CORRESPONDENCE INSTRUCTION.—The American School of Correspondence, Boston, Mass., offers special advantages to those desiring to pass Government examinations. Its object is to give the busy engineer or mechanic a thorough technical training in steam, electrical and mechanical engineering. The instruction is carefully graded, thoroughly practical and scientific, and is supervised by experts who are in close touch with the developments of the age. All instructors in the school are graduates of the leading technical schools, while the advisory board is composed of such well-known men as Dr. Robert Grimshaw, Charles Thom, Francis H. Boyer and others. The school is chartered by the Commonwealth of Massachusetts, and is warmly indorsed by the leading educators and engineers throughout the country. It is strictly an educational institution, founded for the "advancement of the American mechanic," and the tuition fee is therefore placed within the reach of all wage earners. Engineers would do well to write for a handbook.

A CLEARING HOUSE FOR BRAINS.—Under this unique title, the Technical Agency, 1360 Monadnock block, Chicago, announces to manufacturers and employers of engineering help that they can save them time, trouble and money in securing skilled and educated employees, such as electrical and mechanical engineers, draughtsmen, experienced superintendents and competent engineers and foremen. The Technical Agency charges the manufacturer nothing for their services, but solicits the privilege of putting before them the data and records of their candidates. The agency exercises great care in selecting each candidate for a position, and, as it will not knowingly recommend an applicant unless it feels assured that he is fully competent, the employer is thus put into communication with the exact class of employee he desires. We are informed that a large number of skilled men have been placed in good positions during the past few weeks, and that such manufacturers as have availed themselves of the Technical Agency's facilities express themselves well satisfied with this company's methods.

THE WARREN ELECTRIC MANUFACTURING COMPANY, of Sandusky, Ohio, has appointed J. Holt Gates & Co., 1426 and 1427 Marquette building, Chicago, general agents for its apparatus in the Western territory surrounding Chicago. The Warren Company has recently placed, through J. Holt Gates & Co., a 15,000-light alternating-current plant for the great new power and light plant of Armour & Co., at their extensive works at the Union Stock Yards, Chicago. This plant will consist of one machine of 7000 16-candle power light capacity, at 1100 volts and 7300 alternations; also two 3600 lighters, 1100 volts and 7200 alternations. These alternators, of the inductor type, will be operated by rope drive from Corliss engines of 2000 h.p. and 1100 h.p. each, to which engines will also be attached Walker direct-connected power generators. It is stated that the Warren alternators were selected on account of their close regulation, high efficiency, low temperature and ability to stand "grief." The Warren Electric Manufacturing Company is now prepared in its new factory to build 10,000 light machines, both single and two-phase. It has over sixty machines on order at the present time. Its new plant at Sandusky, O., is modern and up to date.

**SPARKING** reduces the working capacity of a motor or dynamo, wears out the commutator wastes power and may cause a fire. All of these may be avoided if you use

## CONVENTION NOTES.

MR. GEORGE CUTTER allowed no one to forget the Cutter specialties.

MR. J. H. FORD, consulting engineer, of Madison, attended the convention.

THE YARYAN COMPANY'S system of steam heating was explained by Mr. A. J. Stahl, of La Porte, Ind.

MR. JOSEPH B. CHAMBERS, superintendent of construction for Julius Andrae & Co., of Milwaukee, was present.

"POMERY-SEC," otherwise, J. G. Pomeroy, of the McGill-Pomeroy Company, Chicago, added lustre to the occasion.

PROF. DUGALD C. JACKSON greeted his many friends, and presented an able and interesting paper to the delegates.

"UNCLE" GEORGE SEARING bobbed up serenely the last day, and "switched" the conversation onto Hart & Hageman goods.

STANDARD TELEPHONE & ELECTRIC COMPANY, Madison, Wis., had two representatives present at the convention.

ILLINOIS ELECTRIC COMPANY, 239 Madison Street, Chicago, was represented by Mr. D. Dewey Newman and Mr. H. E. Adams.

MR. A. J. STAGG kept the interests of the Northern Electric & Manufacturing Company, of Madison, prominently before the convention.

THE WRIGHT DISCOUNT METER COMPANY was represented by Mr. Chas. D. Heile, of Chicago, and also comprised a part of Mr. Insull's exhibit.

CHICAGO GENERAL FIXTURE COMPANY, through their genial and courteous representative, F. A. Overbaugh, made many new friends and customers.

MR. CHARLES F. COOPER, superintendent of the Chicago Rockford Hosiery Company, of Kenosha, had an eye out for the good things in the electrical field.

WALLACE ELECTRIC COMPANY, 1506 Marquette building, Chicago, exhibited the Chicago inclosed arc lamp, and was represented by Edward L. Barr, the company's secretary.

CLOOS BROTHERS, manufacturing agents, 29-30 Calker building, Milwaukee, were represented in the person of Mr. Jacob Cloos, who greeted his many friends and renewed old acquaintances.

A. LOUIS KUEHMSTED AND FRANCIS B. RAYMOND were on hand, and, by no means, "second hand," in keeping the interest of the Charles E. Gregory Company prominently before the convention.

MR. A. C. JACKMAN, MR. CHARLES C. RUSSELL AND MR. VALENTINE, of the Rock County Telephone Company, Janesville, Wis., visited the convention and were very much interested in telephone exhibits.

MR. M. D. AUSTIN, 321 Dearborn Street, Chicago, was present, as was also Mr. W. A. Brown, of the M. D. Austin Company. These gentlemen showed a large line of specialties, safety wires and cables, Loricated conduit, and also the New York switch.

THE ELECTRIC APPLIANCE COMPANY, Chicago, through Mr. W. W. Low, dispensed hospitality hard to equal. Every one who knows "Billy" Low is his friend, and as nearly every one knows him his friends are legion. Mr. Low was assisted by Mr. B. B. Downs.

MR. GEORGE S. SEARING looked out for the interests of the Hart & Hegeman Manufacturing Company, of Hartford, and took every opportunity to convince delegates of the merits of the H. & H. switch. Mr. Searing was not overworked, as conviction was not difficult to secure.

JOHN A. ROEBLING'S SONS' COMPANY was represented by Mr. A. G. Conover, Jr., 171-173 Lake Street, Chicago. This company presented every attendant with a beautiful pocket-case and memorandum, a souvenir that was highly appreciated, and will be long prized by the recipients.

THE LIBRARY BUREAU, 215 Madison Street, Chicago, was present in the person of Roger A. Simmons. The system exhibited by Mr. Simmons was one of the most interesting exhibits made, and central-station men not acquainted with it would do well to investigate this system.

COLUMBIA INCANDESCENT LAMP COMPANY, St. Louis, added brilliance to the convention by the genial beams that radiated from the kindly countenance of George P. Rex, acting secretary of this company. A more popular salesman than Mr. Rex is not to be found in a long day's journey.

ELECTRICAL SUPPLY COMPANY, Madison, Wis.: Mr. L. W. Burch was, as usual, on exhibition. Mr. Burch did not make any new acquaintances at the convention, as he already knows everybody in the Northwest, and his many friends join us in wishing him long life, health and prosperity.

CLOOS ELECTRICAL ENGINEERING COMPANY had its interests well attended to by Mr. H. R. King, the treasurer of the company. Mr. E. A. Wurster, the secretary, also lent his presence to the brilliance of the assembly. Mr. James Asten, assistant engineer of the company, aided in exploiting the Cloos junction box, transformer, cut-out, etc.

MR. MARTIN J. INSULL, Monadnock block, Chicago, represented the Pittsburgh Transformer Company, Pittsburgh, Pa., with an exhibit of its new transformer, including accessories. Mr. Insull was much pleased with the favorable comment which he heard concerning the new transformer, whose special features appeared to appeal with force to the central-station men at the convention.

CENTRAL ELECTRIC COMPANY, Chicago, had on exhibition the Zeco arc lamp, which is claimed to be the latest type for direct and alternating current, and is easy to adjust and easy to install. A very strong point of this lamp is the clutch, which is very simple and positive. In most types of inclosed lamps the current is conveyed to the carbon through the clutch. This is not the case with the Zeco.

THE WESTERN ELECTRIC COMPANY, Chicago, had a large line of its handsome circular matter prominently displayed. The Stanley Electric Company's alternating current apparatus and Western Electric apparatus and supplies were well and ably presented to the attention of the visiting delegates by Mr. W. S. Hine and A. McNab Little. A beautiful souvenir pocket card-case was one of the features.

MR. MARTIN J. INSULL, manufacturers' agent, 1012 Monadnock block, Chicago, was present, and in his genial manner acquainted the

BELTS WILL SLIP

BUT CLING-SURFACE

WILL STOP THEM PERMANENTLY

CLING-SURFACE is to be applied to the inside of a belt. It has been so universally satisfactory for the past three years that we can safely guarantee that its use will not only stop all slipping but that the belts will become soft and pliable, yet firm; if of leather they will become as soft as calf-skin, and also absolutely water-proof; and furthermore we guarantee that the belts can be run slack, and the power will be increased so much that in a fair sized plant the cost of the sample can will be earned monthly.

This applies to all belts leather, cotton, rubber or a rope drive, whether new, old or oily. We will send you a sample can (25 lbs.), for trial, or if you prefer, we will advise you further as to its nature.

CLING-SURFACE MFG. CO.,

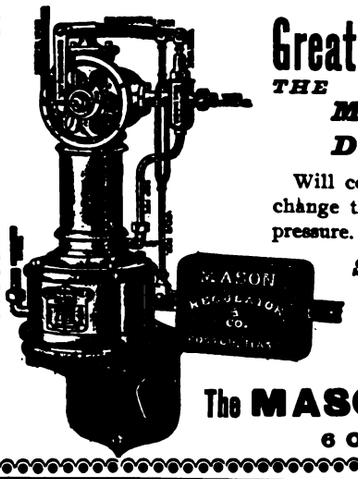
Digitized by Google

delegates present with the many good specialties which he handles, among which were C. & C. dynamos and motors, Paragon fans, Pittsburgh transformers, Chapman voltage regulator, Bergmann switches, Cling surface, etc., etc.

THE DEARBORN DRUG & CHEMICAL COMPANY, Chicago, through its assistant manager, Mr. W. J. Jameson, and Mr. J. M. Frye, its Milwaukee representative, presented some very interesting exhibits of samples of boiler tubes thickly incrusted with scale, and other cases showing their condition after using Dearborn compounds. Another feature was the exhibition of Dearborn lubricants. The gentlemen also made the delegates happy by their beautiful souvenirs, with which every delegate was supplied.

SPRAGUE ELECTRIC COMPANY, Parlor 7, was well looked after by Mr. E. D. Kittle and Mr. Chas. D. Burton, assisted by Julius Andrae & Co., the Wisconsin agents of the Sprague Electric Company. Of the latter company, Mr. Herman Andrae and Mr. J. S. Healy were present. These gentlemen talked Lundell fan motors, Sprague elevators and interior conduit with an ease and gracefulness of expression that pronounced them thoroughly acquainted with their subject, and it is almost unnecessary to state that they acquitted not only their company, but themselves, handsomely.



WAGNER ELECTRIC MANUFACTURING COMPANY, St. Louis, had on exhibition a single-phase, automatic, self-starting motor, connected to a dynamo, which in turn ran a direct current 24-in. blower; all connections were made through a switchboard of the Wagner Company's own make. The switchboard was handsomely mounted with a Wagner illuminated dial and instruments, watt-meter, ammeter and the popular Wagner break switches. It also exhibited its line of transformers, cut-outs, reinforced by a variety of printed matter. Mr. E. H. Abadie, general manager of sales, and Mr. A. D. Foster did the honors for this company.

THE VICTOR TELEPHONE COMPANY, Chicago, was represented in the persons of Mr. Wm. T. Blaine, president and manager; Mr. O. D. Rousseau and Mr. C. C. Caden, of their electrical corps. The latter gentleman has had a long connection with the Bell Company, and from his long experience with telephone interests his opinion is worthy of great weight and consideration when he pronounces the Victor metallic switchboard to be the most advanced from the standpoint of scientific correctness and mechanical perfection. This switchboard was on exhibition, and this company's telephone exhibit was the only complete one at the convention. These gentlemen and Mr. Blaine especially made many warm friends, and last, but not least, a number of sales of Victor apparatus during the three days they were present.

GENERAL ELECTRIC COMPANY had present Mr. F. N. Boyer, of Chicago; Mr. J. Scribner, Mr. R. A. Swain, Mr. Wilcox and the genial and irresistible Mr. Tom Ferris, of Milwaukee. For the first time in the history of the Northwestern Convention this company made no exhibit of apparatus, but it had at its headquarters in Parlor 5 a large amount of printed matter, and the courteous gentlemen present introduced to their many friends two new features of this company's production—a line of single induction motors and two-rate meters, both of which attracted much attention from the delegates, especially the operating central-station man. The meter mentioned supplies a long-felt want by placing the central-station man in the possession of an instrument whereby he can measure the amount of current consumed at the peak or the valley of the central-station load.

### IT BEATS THE BAND.

The newest and most inspiring piece of Sheet Music, arranged for piano, is "The Pioneer Limited March" composed by Capt. Frederick Phinney, Bandmaster United States Band, published by S. ## ELECTRICITY IN PRINTING, BINDING AND ENGRAVING.

### SPECIAL APPLICATIONS OF ELECTRIC POWER.

The application of electricity to the various processes employed in printing, binding, engraving and kindred arts has become so popular that electrical engineers are now much interested to become acquainted with data on this very important subject. The power and speed of motors which are well adapted to run various kinds of apparatus and the details of the various heating devices used in these arts, comprise valuable data. Further than this the details of application are much to be desired by those who contemplate or are even likely to have anything to do with such installations.

Without further excuses, it is therefore proposed to describe in this article the electrical equipment of the printing department of the Bradstreet Press and of the New York Life Insurance Company. Taken together, they probably represent the very highest development of the application of electricity to printing, binding and engraving.

The subject of electrically driven presses has been taken up before in these columns, and for this reason has received, in the case of these two plants, somewhat less attention than the apparatus in the other departments.

Fig. 6.—Smooth Shaver.

ELECTRICALLY DRIVEN ENGRAVING AND PAPER CUTTING MACHINERY.

Digitized by Google

Perhaps the first notable application of motors to printing presses was in the case of the larger sizes of cylinder presses, and all of the cylinder presses in both of these installations are so driven. Fig. 14 shows a motor directly connected to a press of this type in a manner with which most engineers are familiar. The motor shown is the Crocker-Wheeler, which type is used throughout the installations with but one exception, which is noted beyond.

This particular form of motor lends itself exceedingly well to the purpose for which it is intended. The inwardly pointing radial poles make the machine circumferentially iron clad, and this iron inclosure is somewhat enhanced by the overlapping sides of the yoke, which is of a U shaped section and partly includes the field winding. The armature of this machine is very short and of large diameter, giving a high conductor velocity and a correspondingly large output, weight and speed considered. This machine operates noiselessly and is amply sufficient to drive the press.

In the Bradstreet Press room there are eight presses driven in this manner. The following table of their dimensions is of interest in this connection:

| Press | Motor h.p | Motor speed | Form | Imp. per hour |
|---|---|---|---|---|
| Hoe ..... | 2. | 165 | 23x29½ | 1800 |
| Hoe ..... | 2.5 | 113 | 33x46 | 1700 |
| Cottrell ..... | 3. | 165 | 33x46 | 1700 |

The allowance of power has been found to be very liberal. These motors are controlled by a little cylindrical controller, the details of which are shown in Fig. 17. An adjustable resistance is also provided which is in series with the motor, and by means of which the speed of the controller can be varied between notches. This is a valuable adjunct, for it enables the speed of the press to be very finely graduated.

As is well known, fine half-tone work and color printing require a much slower speed than ordinary type printing, and it is important to be able to run the presses at the exact speed necessary to properly execute their work. A slight difference in the speed of the motor might mean several hours loss of time in running off the form.

In the Bradstreet press room are also three small presses of the Colt's armory type, run by little motors geared directly on the circumference of the large fly wheel. The application of the motor is extremely simple and is shown in Fig. 18. These motors are controlled by an automatic regulating box and switch. These presses use a bipolar motor rated at ½-h.p., the speed being 1200 r.p.m. They are geared to the presses by a rawhide pinion. These presses are for small work, and can make 2000 impressions of a 10-in. x 15-in. form per hour. The New York Life Insurance Company also uses presses of this same type and capacity. It is interesting to note that all of the presses of the Bradstreet

Company, and it may be added, all of their motor driven apparatus, are each provided with its individual circuit-breaker and fuse, even the smallest motors. These circuit-breakers are variously mounted, as shown in the illustrations. Some are conveniently mounted on adjacent pillars, and some are to be found on the back of the little board on which the starting box is mounted.

An interesting modification of motor practice in driving large presses is shown in the case of the stop cylinder press used by the New York Life Insurance Company. This is illustrated in Fig. 13. The feature of this arrangement is that it consists of a motor tucked away beneath the press, and connected thereto by a single reduction of gears. Inasmuch as the direct-connected motors are specially made for the purpose and are necessarily larger and more expensive, and, moreover, actually occupy more room than the geared motors, it becomes a question as to which practice is to be preferred, and whether or not the elimination of the noise of the gears from the multitude of other noises that a cylinder press produces, justifies the greater expense.

Motors direct-connected to printing presses were probably first used in the New York Life's printing department, having been introduced there as early as February, 1894. After five years' experience, the geared motor has been definitely fixed upon as the best and cheapest, under the conditions existing, and by use of a rawhide pinion the noise is reduced to a minimum.

An interesting example of the application of electric motors to printing presses is shown in Fig. 16. This little machine is intended for printing envelopes, which it can turn out at the rate of 10,000 per hour. It is a double cylinder press, the platen consisting of one cylinder, while the electrotype is bent smoothly about the other. The two run together and the envelopes are fed automatically between them. The speed is limited only by the number of impressions which it is possible to take from the plate in a given time. No difficulty is found in feeding the envelopes or receiving them. A large circular receiver is pivoted on an arm which projects from the back of the press, as shown in the figure. This receiver was removed in order to show the motor, which is of ½-h.p. capacity and runs at a speed of 1200 r.p.m.

These two establishments use a great deal of paper, which is cut to size on electrically driven paper cutters. A small cutter thus driven is to be found in the binding department of the Bradstreet Press and is typical of others installed there. This cutter (Fig. 1) is driven by a small motor suitably mounted on a bracket, and geared to the flywheel shaft. It is of 1-h.p. capacity and runs at a speed of 900 r.p.m., operating a cutter with a 32-in. blade. The power used is considerably less than the full load capacity of the motor.

An exceptionally large cutter of the Kent make (Fig. 5) is on the first floor of the printing department of the New York Life Insurance Company. This is direct driven by a multipolar motor of 3.5-h.p. capacity and running at 380 r.p.m.. The cutter has a 40-in. knife which the motor operates very rapidly indeed. It is shown in Fig. 5.

In the department of binding, both of these institutions furnish some very interesting applications of electricity. An electric embossing press is an object of interest and appears in Fig. 15. This machine is used for performing the heavy gilt embossing and printing on the covers of the large Bradstreet books, and similar work. The book or cover to be operated upon is placed on the lower table and forced against the upper one, which is electrically heated. The heating device has four grades of temperature as follows: First heat, 250 deg. to 300 deg. F.; second heat, 300 deg. F., approximately; third heat, 400 deg. to 500 deg. F.; fourth heat, 600 deg. F., approximately. The working temperature is about 300 deg. F. The heating head is made up of six coils, which are connected in various combinations by means of two switches.

FIGS. 19, 20 AND 21.—ELECTRIC GLUE HEATER, FINISHERS' HEATER AND GLUE POT.

This device is probably the first of its kind ever made, and its great success indicates that it will probably be widely adopted elsewhere. It was installed, together with the entire Bradstreet equipment, by the firm of Clark & MacMullen, consulting engineers.

The lower table is forced upwards by means of a heavy toggle joint which is operated from a shaft on which is mounted a large fly wheel. This machine is driven by a motor of 1 h.p. capacity, operating at a speed of 900 r.p.m. The power used is considerably less than this, however.

Another feature of the Bradstreet binding department is the electric glue heater, which is shown in Fig. 19. It contains two heating coils for warming the water bath, in which the glue pots are placed. There are two grades of heating, the highest of which will bring the water to boiling point in forty minutes. The lower heat maintains the temperature thus acquired. An insulating sheathing surrounds the exterior of the water bath.

A smaller device of the same character and principle is shown dismantled in Fig. 21. In this device there are two heating coils threading between each other. Either of the coils can be switched in service, thereby giving two degrees in temperature.

It remains to be said that the workmen in the binding department are particularly pleased with the electrical methods and declare them to be very convenient and reliable. The heating apparatus was designed by Mr. W. S. Hadaway.

Another interesting application of electrical heating is shown in Fig. 20, which illustrates a finisher's heater. This device is used to heat the various forming and ironing tools employed in fastening ornamental gilt work on high grade books. In this work the leather covering is heavily embossed with suitably shaped tools, which are heated to a certain temperature. These tools are also used for pressing in the gold leaf in the various ornamentations. In this work it is essential that the tools be heated to the proper temperature, and that they be perfectly clean and free from oxidation and foreign substances of any kind when used. For the purpose of properly heating these tools the electric heater is found very convenient. This stove is 10 ins. in diameter and its two heats furnish temperatures of 300 deg. and 600 deg. F., respectively.

For removing the impression on heavy bond paper the New York Life Insurance Company utilizes a hydraulic press, the pumps of which are worked electrically. These pumps are shown in Fig. 8. They consist of a pair of pumps such as are used on ordinary presses, and to the handles thereof are coupled two long rods which pass two crank discs mounted on a countershaft on the ceiling. To this countershaft is geared a bipolar motor of 3 h.p. capacity.

The New York Life Insurance Company produces from time to time a great many small pamphlets for advertising and for other purposes. These pamphlets are folded by motor-driven folding machines, one of which is shown in Fig. 11. The two machines in the New York Life binding department are driven with motors of ½-h.p. capacity.

The pamphlets are stapled together by electrically driven stapling machines. One of these is shown in Fig. 12, and is driven by 1-6-h.p. motor running at 830 r.p.m.

A device which properly belongs neither

Digitized by Google

to the department of printing nor that of binding, but which is interesting, nevertheless, is the ruling machine shown in Fig. 8. This machine rules the policy sheets with a fluid ink by means of pens, and though it is a large machine, it uses but very little power. A 1-6-h.p. motor run at 1600 r.p.m. is sufficient, and is connected to the machine through a worm gear.

In the art of electrotyping, electricity has been ingeniously applied by the New York Life Insurance Company

The routing machine is shown in Fig. 3. It is driven by a motor of ½-h.p. capacity, running at a speed of 1600 r.p.m. The peculiarity of the application of this motor lies in the fact that its shaft is vertical and the bearings and field frame have been redesigned to accommodate this arrangement. The motor is belted by two multiplying belts to the routing tool, which runs at a speed of 12,000 r.p.m.

In Fig. 4 are shown the rough shaver and the beveler. These require 2¼ h.p. respectively. Each has its separate motor. The speed of the motor on the rough shaver is 1000 r.p.m. The beveler has a small motor running at 1300 r.p.m. The smooth shaver requires only a moderate power, the motor having an output of 1 h.p. and a speed of 1000 r.p.m. This machine is shown in Fig. 6.

The little jig saw, shown in Fig. 7, is driven by a ¼-h.p. motor of the Lundell type, manufactured by the Sprague Electric Company. This type of machine is very compact and efficient, and will undoubtedly find many uses among other wood working artisans.

Fig. 2 is devoted to the illustration of the moulding press for making the wax impressions in electrotyping. This machine employs a 2-h.p. motor, running at 813 r.p.m.

These devices are typical of a number of others which are contained in the same department, and each of the various machines, it will be noted, is driven by its own separate motor.

In Fig. 10 is illustrated a little electric elevator used by the Bradstreet Press, which, while not a direct application of electricity to the book producing art, is nevertheless very convenient. It is intended for lowering and raising forms from the composing room to the press room. It is entirely automatic in its action. The pressure of a button on the door jamb starts the elevator up or down and takes the control from all other buttons. The door is automatically locked unless the elevator is directly opposite, and the elevator cannot be started or stopped from any point of contact when the door is open. This elevator is the production of the Sprague Electric Company.

The building in which these extensive equipments are located is a model of its kind. It stands on Elm Street, directly in the rear of the New York Life Insurance Building, and is light, airy, well heated and ventilated, and thoroughly fireproof. The current used for the numerous purposes is generated on the premises by a large Crocker-Wheeler plant which, being standard in design and construction, does not require description. All of the wiring is done in iron-armored conduit.

To the superintendents of the printing departments of the two companies—Mr. W. H. Van Wart, of the New York Life, and Mr. John Oliver, of Bradstreets—much of the credit is due for the completeness of the electric power application and for many of the special features included.

The plants described, having been gradually evolved, contain no experimental features, and are therefore particularly instructive. In fact, as an example of the capabilities of the electric motor we know of no installation comparable with those here noticed.

# The Induction Generator.

## TESTS OF AN INDUCTION GENERATOR.

The principle of reversibility of electrical generators also applies to the induction motor, which, when driven at a speed above synchronism, will act as a generator. In order to do so, however, there must be connected in circuit with it either an alternator or a synchronous motor.

The following tests, described in a paper by Prof. A. F. McKissick before the American Institute of Electrical Engineers, June 29, 1898, were made with a General Electric 5-h.p., three-phase 220-volt, six-pole, 60-cycle induction motor, with starting resistance in secondary rotating element (see Figs. 1, 2 and 3), driven by a 10-h.p. 110-volt Thomson-Houston direct current motor.

The machine used as an alternator and synchronous motor in the tests was an "Ideal" 5-k.w. three-phase, 60-cycle, 10-pole, 220-volt machine (see Fig. 4), and could be belted either to a jack-shaft or to a 3 kw. Edison 125-volt dynamo. The curves in Fig. 5 show the operation of the induction machine as a motor with varying output.

The tests were divided into two series, one with the belt connecting the alternator to the jack-shaft thrown off after starting; in the other the belt was not removed.

In the first series of tests, the belt connecting the Ideal alternator to the jack-shaft was in each case thrown off after starting, and the alternator run as a synchronous motor, either without load or driving the 3-kw. Edison dynamo.

The method of obtaining the magnetization curves shown in Fig. 6 was to start the induction motor from the Ideal alternator, the 10-h.p. direct current motor being belted to the induction machine when up to speed; current was supplied to the 10-h.p. direct current motor, driving induction machine near synchronism, and then the belt thrown off connecting the alternator to the jack-shaft. This alternator then ran as a synchronous motor, receiving its current from the induction machine, which is now driven as a generator by the 10-h.p. direct current motor belted to it.

By varying the exciting field current of the synchronous motor, the voltage of the induction generator is varied, and from the readings of the field current in the synchronous motor and the voltage at the terminals of the induction generator, the curve marked "Induction generator" in Fig. 6 was obtained. The magnetization of the Ideal alternator is also given in Fig. 2, which is almost identical with the magnetization curve of the induction generator.

In a test with the induction generator driving the synchronous motor loaded, the alternator was made to run as a synchronous motor by the induction generator as before, and then belted to the 3-kw. Edison machine, driving it as a dynamo. The results of this test are shown in Fig. 7. In making the calculations for efficiency, the energy required for the excitation of the synchronous motor fields was charged up against the synchronous motor.

Fig. 8 gives the results of the following test: With the connections the same as in the preceding test, and the load on the 3-kw. Edison machine maintained constant, the voltage of the induction generator was varied, and corresponding current, watt and speed readings recorded.

The voltage was varied from 260 to 125, the synchronous motor falling out of step on attempting to lower the voltage to 100. Curve A gives the variations of the supply current with the field current; curve B, the variation of the supply current with the voltage of supply; and curve C is plotted between the power factor and the voltage of supply.

In a test of the induction generator with a lamp load, the induction generator was started as before, and a lamp load that could be varied was put on, it of course being necessary to run the synchronous motor empty. The load in lamps was varied from zero to the full load of the induction generator, with the result shown in Figs. 9 and 10.

In calculating the results shown in Fig. 9, the watts supplied to the alternator running as a motor, and to the lamps, were taken as the output of the induction generator, the efficiency being this output divided by the input to the induction generator; and the power factor, this output divided by the total apparent watts from the induction generator.

In Fig. 10 the fact that the energy delivered to the alternator, and that required for the excitation of the alternator fields, does no useful work is taken into account. So in calculating the results in Fig. 10, the watts supplied to the lamps were considered as the output, the efficiency being this output divided by the input; and the power factor of this output divided by the total apparent watts from the induction generator.

In testing the synchronous operation of the alternator, the speed of the induction generator was varied, the voltage of supply being maintained constant, and corresponding readings of speed taken on the alternator running as a synchronous motor, which showed that motor ran

Digitized by Google

in synchronism with the induction generator. The results are shown in Fig. 11, the full line representing the synchronous speed line, the small circles the points found from readings. In this test, and all preceding tests, the belt connecting alternator to jack-shaft was thrown off after the starting up of the induction generator.

In the following tests, the belt connecting the Ideal alternator to the jack-shaft was not removed.

In a test of the induction generator when furnishing current to the alternator, the induction generator was started up as usual, and its speed gradually increased from below synchronism to about six per cent. above synchronism, readings taken as usual. The alternator was therefore run as a motor and helped to drive the jack-shaft.

The results are plotted in Fig. 12, which will be found by comparison to resemble the curves constructed by Mr. Steinmetz. It is interesting to note in connection with this test the readings on the two wattmeters, as shown in Fig. 13.

At the beginning of the test and before the induction motor was speeded up, readings were taken on the two wattmeters, but as the power factor was below 50 per cent., the reading on one wattmeter (No. 2) was negative; hence, its connections had to be reversed, and with its connections thus reversed the difference of the two wattmeter readings represented the total true watts. As soon as current was turned on the shunt motor (insufficient however to make this machine act as a motor and drive the induction machine), the load on the induction motor was decreased, the power factor decreased, and the corresponding wattmeter readings are shown in Fig. 13.

On furnishing sufficient potential to the shunt motor to make it act as a motor and drive the induction motor as a generator, the readings on wattmeter No. 1 diminished and finally became negative (necessitating a changing of its connections), while the readings on wattmeter No. 2 continue to increase as shown, but were always negative. Under these conditions, the total watts were the sum of the two wattmeter readings, and as the sum is negative the induction generator was supplying energy to the Ideal alternator.

A test with the induction generator furnishing current to the Ideal alternator and to a bank of lamps was the same as the preceding one, except that a bank of lamps was connected to the three-phase terminals. At the beginning of the test, the alternator furnished current to both induction motor and lamps, but on speeding up, the induction motor, now running as a generator, supplied current to both lamps and alternator, which latter acted as a motor, helping to drive the jack-shaft.

The results of these tests are shown in Fig. 14. Curve B is plotted with the induction motor output as ordinates and the number of revolutions per minute above synchronism as abscissæ. At first the output is negative, which indicates that the motor was receiving energy from the alternator; at eleven revolutions per minute above synchronism it commenced to act as a generator, and at twenty-two revolutions it furnished energy to both alternator and lamps.

As pointed out by Mr. Steinmetz, the induction generator can be run at different speeds and still the same frequency obtained from it. For proof of this, a small induction motor was connected in the above test to the three-phase mains and run with no load. Variation of the speed of the induction generator from synchronism to 20 per cent above synchronism did not in any way affect the speed of the little induction motor, its speed remaining constant, and almost synchronous with the Ideal alternator. Of course, this will not hold true when the conditions are as described in Fig. 11.

On attempting to make some tests with this induction generator as a single-phase instead of a three-phase machine, it was found that the current required by the motor when running as a synchronous motor (with the belt connecting the alternator to the jack-shaft thrown off), was excessive, so that this test had to be abandoned.

### USES OF THE INDUCTION GENERATOR.

The most probable use of the induction generator will be for boosting. Mr. Kelly has discovered that an induction generator, having its field coils in series with the mains, will act as a booster or feeder regulator, and that this action as a booster at any particular speed above synchronism will depend upon the amount of current supplied by the field magnets.

In order to use an induction generator

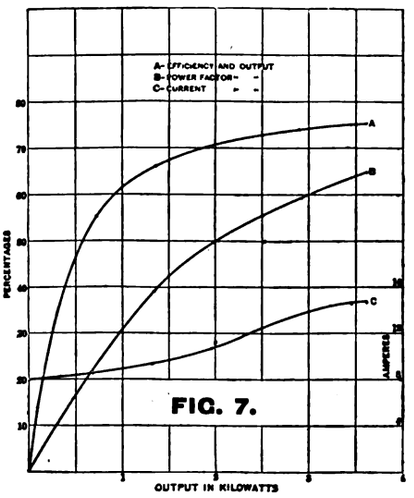

FIG. 7.

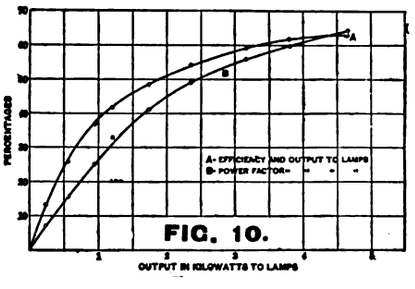

FIG. 10.

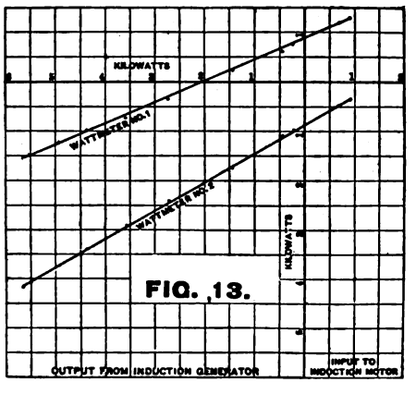

FIG. 13.

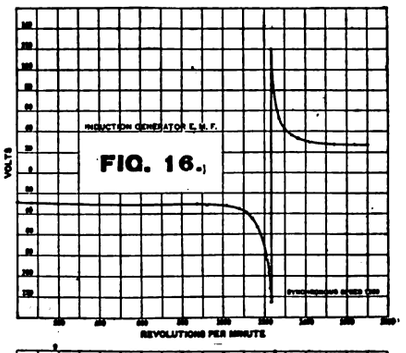

FIG. 16.

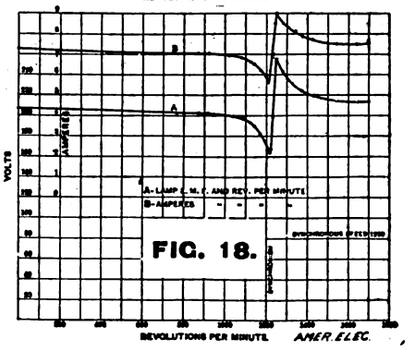

FIG. 18.

Digitized by Google

as a booster, the fields are connected in series with the main line, and the induction generator driven above synchronism. With no current flowing, there will be no boosting action, but as soon as current flows the boosting action commences, its amount depending upon the current flowing in the mains, and this amount for a given current may be varied by varying the speed of the induction generator. So that by the use of an induction machine as a booster we get a generator with no brushes, collector rings or commutator.

In case the induction motor should ever be used for the propulsion of street cars, its action as an induction generator, when driven above synchronism, could be taken advantage of in descending grades, thus pumping back energy into the line, and doing away with braking to a great extent.

In a test of the induction generator as a booster, the generator and alternator used in the above experiments were connected in series as single-phase machines, and with a bank of lamps, and readings taken to determine its boosting action.

In the first test as a booster the speed was maintained constant at 1300 revolutions per minute (synchronous speed 1230), and the current flowing in the mains varied from zero to the full load current of the alternator by adding lamps. The results obtained are shown in Fig. 15.

In the second test of the speed of the induction generator was varied between wide limits, the alternator e.m.f. being maintained constant, and also the number of lamps connected in series with the two machines. The results are shown in Figs. 16, 17 and 18.

## AN ELECTRIC PYROMETER.

BY H. L. MUNNOCH.

In order to measure high temperatures numerous pyrometers have been devised at various times more or less adapted for the purpose, the most reliable one in use until a few years ago being the Siemens copper ball pyrometer. In careful hands this pyrometer gives very accurate results, but for many purposes it is inconvenient to use, and the time required is not less than about five minutes when a temperature is taken.

The electric pyrometer here described is generally known as the Chatelier pyrometer, which has many advantages. The results can be read off at any time the same as with a pressure gage, it is reliable and accurate, it will work for years with very little attention as it seldom gets out of order, and it can be adapted for almost any purpose. It has been successfully used in England for indicating the temperature of the blast passing along the hot blast mains into the blast furnace, and I will describe one that has been in use at a Cleveland works for this purpose continuously since 1893 with excellent results.

The pyrometer consists essentially of three parts. (1.) A thermo couple consisting of two wires, one being pure platinum and the other an alloy of platinum with 10 per cent rhodium, this combination being the result of researches of M. le Chatelier. (2.) A mirror galvanometer, preferably of the d'Arsonval type, with lamp and scale. (3.) A copper wire line connecting the thermo couple and galvanometer. The principle of its action is the measurement of the voltage produced by heating the thermo couple.

We have two sets of apparatus, one for the use of the foremen and stovemen, the galvanometer being fixed in an office behind the furnaces, convenient for constant use; the other is a recording apparatus which was designed by Professor Roberts Austen and made by J. Pitkin, London. The former will now be described in detail.

The galvanometer is a Desprez-d'Arsonval, and is placed in a wood case to exclude

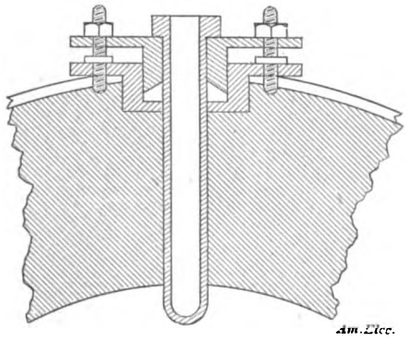

FIG. 1.—RECEPTACLE FOR COUPLE.

dust as much as possible, and the wires of the galvanometer terminate in a plug. There are four furnaces, and for each of these a plug switch is placed close to the galvanometer. A pair of No. 16 insulated wires are run from each switch to the respective furnaces, and these wires are connected to the two wires of the thermo couple. The temperature at either furnace can thus be readily taken.

Fig. 1 shows the arrangement for inserting the couple into the hot blast main, which is a wrought iron tubing lined with 9 ins. of firebrick. A hole about 1 in. in diameter is drilled through the plate and firebrick, and through this a Dresden porcelain tube about 12 ins. long is inserted, the tube being closed at one end and having a collar at the other. As the blast in the main is under pressure, a stuffing box is studded to the iron tubing and a packing of asbestos is used to make the joint tight. The porcelain tube projects about an inch into the main. The platinum and platinum-rhodium wires were at first merely twisted together at the end, but in time the contact between them became poor, which was a source of trouble. In order to overcome this difficulty the wires are now fused together in a flame obtained by blowing an oxygen jet through a spirit lamp flame. The wires are placed in the porcelain tube, and in order to insulate them they are threaded through fireclay cylinders about 3 ins. long, which have fine holes running longitudinally. The cylinders fit loosely into the porcelain tube, and reach nearly to the top, which is closed with an ordinary cork; the couple wires are led through the cork to the outside, where they are connected to the line wires by suitable clamps.

Now when the fused end of the couple is heated, an electric current is generated which varies according to the difference between the temperature of the points of contact and that of the ends joined to the line, and this is shown on the scale of the galvanometer. In order to give the reading a definite nature, the wires require to be standardized, which is done by heating them to several known temperatures and taking the readings on the galvanometer. From these results a definite value in degrees is given to each division on the galvanometer scale.

Before the couple is fixed it is standardized in the laboratory at the following temperatures:

| | Fahrenheit. |
|---|---|
| Boiling point of water | 212 |
| Melting point of tin | 441 |
| Melting point of lead | 618 |
| Boiling point of sulphur | 838 |
| Melting point of aluminum | 1158 |
| Melting point of potassium carbonate | 1592 |
| Melting point of potassium sulphate | 1860 |

The couples are placed in the boiling water and deflection noted. For the tests with tin, lead and aluminum a crucible about 2 ins. high is used, of which Fig. 2 is a section, the wires being placed in the hollow recess at the bottom of the crucible. The metals are melted in an ordinary crucible in a muffle furnace and then poured into the special crucible, the reading of the galvanometer being taken just as the metals are becoming pasty and beginning to set. The sulphur is melted in an iron tube closed at one end and the wires held in the sulphur vapor; this test requires a little care on account of the liability of the vapors to take fire, and should be continued for a little time so as to get a constant reading. The potassium carbonate and sulphate are melted in platinum crucibles, and when they are quite fluid the wires are stirred about in the molten salt until it becomes pasty and begins to set, the reading being then taken.

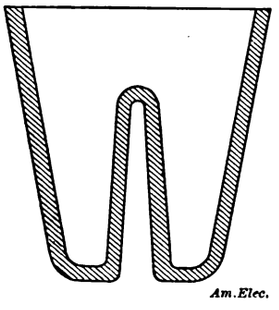

FIG. 2.—TESTING CRUCIBLE.

When taking the readings of the metals and salts it is a peculiarity that the deflection of the galvanometer will remain steady from the time when they begin to set until a minute or two after they are set completely, so that it is easy to get an accurate reading. From the readings thus obtained a scale of temperature is calculated for all the divisions of the galvanometer scale, a copy of which is hung up near the galvanometer. By means of this apparatus temperatures can be taken at any time to within 10 degs. F.

If two lengths of wire are obtained suffi-

Digitized by Google

cient for several couples, it will only be necessary to cut off one couple and standardize it, as the others will be the same; but if wire is obtained at different times the new wires should be standardized, as a slight variation in the alloy wire makes a difference in the deflection. A couple originally fixed in September, 1893, was taken out in September, 1898, and on being standardized it gave exactly the same results as when originally tested. The electric pyrometer has frequently been checked with a Siemen's copper ball pyrometer, and almost invariably found to agree within a few degrees.

Besides the special use of this pyrometer which I have just described, it is used for other purposes, such as taking the temperature of molten slags, molten metal and the heat of various kinds of furnaces. In fact, it can be used anywhere if the wires are protected by a fireclay or porcelain tube.

The recording apparatus (Fig. 3) consists of two rectangular light tight boxes. One is 15 ins. long, 7 ins. broad and 10 ins. high, and contains a brass drum (D) about

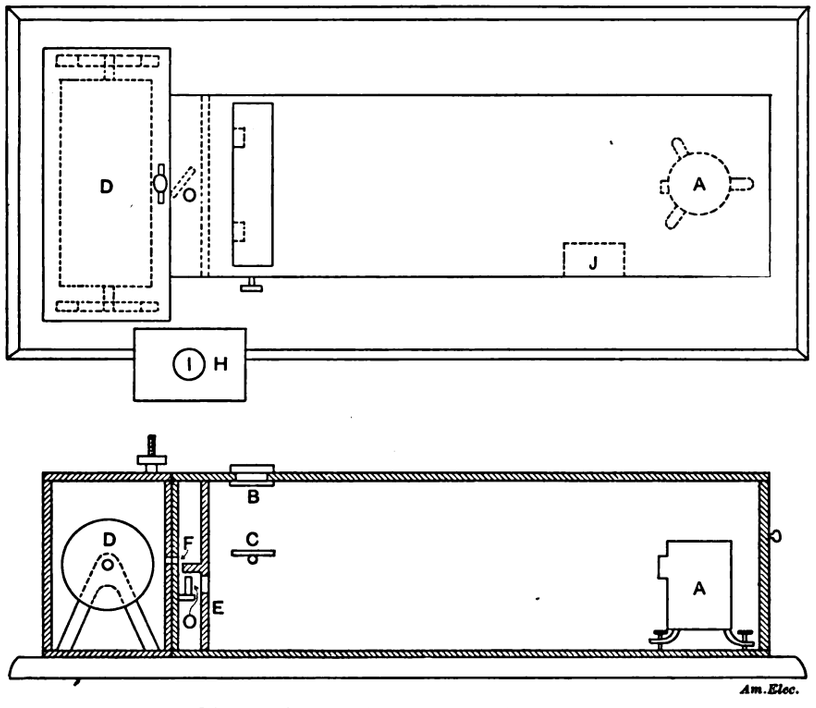

FIG. 3.—PLAN VIEW AND SECTION OF RECORDING APPARATUS.

5 ins. in diameter, around which a sheet of rapid bromide paper, 8 ins. wide and 16 ins. long, is wrapped. The drum is driven by clockwork and makes one revolution in 24 hours. A fine slit (F) is made in one side of the box, and runs horizontally opposite the center of the drum, which slit can be closed by means of a screw on the top of the box.

The other box is 2 ft. 9 ins. long, 10 ins. broad and 10 ins. high, and is mounted on a base board. At one end is placed a 250-turn Holden-d'Arsonval galvanometer (A), and at the other end there is a slit corresponding with that in the box containing the drum. The light for the galvanometer is supplied by a paraffin lamp or gas burner (H), placed at the side of the box near the end containing the slit; the light travels through an aperture in the box half way across, and is there reflected through a narrow vertical slit (E) to the galvanometer mirror (C), whence the narrow vertical beam of light is reflected across the horizontal slit at the other end, and a small spot of light thus passes through to the bromide paper, the position varying according to the deflection of the galvanometer.

Close to the slit in the box there is a plane mirror (O) about one inch wide, extending across the box, and by means of a knob outside this mirror can be turned down so as to intercept the ray of light from the galvanometer and reflect it on to a transparent scale (B), which is let into the top of the box and is closed with a lid when not in use; this scale enables independent readings to be taken any time. The box also contains a clock (J) which acts as a two-way switch by making alternate contacts of a minute duration to two lines, so that records from two furnaces can be obtained at the same time; every hour for one minute there is no contact made with either line and the galvanometer returns to zero, thus giving hour marks on the paper and also a zero mark.

The recording galvanometer is standardized in the manner already described, at the same time taking records of the tests on the bromide paper and readings on the scale on the top of the box. From these results a temperature scale is constructed for the bromide paper and for the scale on the box. After the records are taken on the bromide paper the box containing it is carried to a dark room, a new paper is put on the drum and the apparatus started for another 24 hours' record. The bromide paper taken off is then developed and fixed in the usual way; when the paper is dry it is ruled at the hour marks and also ruled for each 100 degs. of temperature.

Some six years' experience with this electrical pyrometer has proved it to be accurate and reliable if standardized with care, and its application may be termed universal, as with a little ingenuity it can be modified to suit almost any purpose.

## THE CANDLE POWER OF ARC AND INCANDESCENT LAMPS.

### THE DEFINITION OF SOME PHOTOMETRIC TERMS.

BY PROF. WILBUR M. STINE.

Candle Power.—The candle power is a unit for expressing the intensity of light sources and illumination, and is in general use principally in Germany, England and the United States. In France the unit most widely employed is termed the *carcel*.

The origin of the c.p. unit is clearly indicated by its name. In the early days there was no great variation in the size of the molds for making candles, and though there was no apparent design about the matter, yet the result was that there existed comparative uniformity in the character of the materials, size of wick and finished candle.

A candle flame much exceeding 2 ins. in height begins to smoke; consequently the wick would be snuffed before the flame reached the smoking length, and this condition, together with the close resemblance of candles wherever made, insured a greater uniformity of illuminating power from candles than has been obtained from any light source since employed. It is thus readily understood why the candle came into use as a simple concrete unit of light when people began to compare illuminations and the intensities of light sources.

Accordingly, to-day, we speak of the light of an incandescent lamp being a certain c.p. But this adherence to the use of an obsolete term has more to commend it than the use of the foot as a unit of length; for, though in the metric system we have a unit much superior to the foot, there is really no photometric unit to displace the candle.

The English Candle.—The specifications for this standard are a wick of three strands, having eighteen to twenty-one threads to the strand. (Note that nothing is said about the size of the threads, one of the many uncertainties connected with this standard.) The material of the candle is spermaceti. The finished candle is 10 ins. long and has a diameter at the top of 0.8 ins. and at the bottom 0.9 ins., and its weight is six candles to the pound. The wick must be of such a character that with the flame of normal height the candle shall consume 120 grains of material, wick and spermaceti, per hour. Should the weight of material consumed be greater or less than that just given, the amount of light emitted by the candle will vary within certain limits, proportionately.

When burning under normal atmospheric conditions, with clean wick and a flame-height of 1.8 ins., such a candle is

Digitized by Google

supposed to emit unit intensity of light, or 1 c.p.

However precise these specifications may appear, when one comes to practice with such a unit, he is reminded of the description of a certain length-standard in the London Exchecquer, which was broken on an occasion and repaired by riveting, so carelessly, that the parts had as much play about the joint as a blacksmith's tongs.

It is to be noted that a candle is supposed to give unit light when the flame has a height of 1.8 ins., and careful tests show that a change of even 1-10-in. from this height may alter the intensity of the light by 3 to 5 per cent. One of the things a candle does not do is to burn with a constant length of flame, so that readings with it can be made only at such time when the proper flame height is indicated.

A candle flame is sensitive to the slightest air current, and as its readings are valueless unless the flame is perfectly steady, every precaution must be taken against disturbing the air about the flame. This condition is trying, for even a slight movement of the arm a few feet distant will distort the flame. In fact, it is almost impossible to maintain the air about the candle so undisturbed, that the flame will be perfectly steady. Then too, the candle wick untwisting as it burns, adds its disturbance to the flame. All open flames are sensitive to air currents, but the candle flame is especially unstable from the added effects of the burning of the wick, and the continual change in the height of the flame.

Other sources of uncertainty of the value of the light are the character of the wick and the quality of the spermaceti. The care with which the cotton has been cleaned from which the wick is woven, and the tightness of the stranding are not without influence on the amount of light. The degree of purity of the spermaceti affects the flame very considerably. The barometric pressure and the amount of moisture in the air have, too, a marked influence; increase of pressure makes the flame more luminous, while increase of moisture in the air lowers the amount of light emitted. Practically none of these causes of variation can be removed. It will not do to place a box about the candle flame, nor enclose it with a chimney. In either case the light is uncertainly affected.

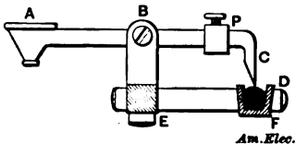
When using a candle in photometric work, at least two observers are needed, one to observe the flame height and the other to adjust the screen. The length of flame should be observed through a telescope. Before making a measurement the wick should be cleaned and trimmed; then as the flame steadies and increases in length, at the moment it reaches 1.8 ins., the screen is adjusted and its position read off. Unless the screen is handled dexterously, scarcely more than one reliable reading can be made without retrimming the wick.

The German Candle.—In Germany the Gas-Lighting Association early gave close attention to the specifications for a standard candle. Their specifications are very minute, and the manufacture of the candles is done under their supervision. With such care the German candle (Vereinskerze) is probably more reliable than the English candle. It differs but slightly from the English standard in its dimensions, but is made from a different material, paraffine. The height of the flame taken for unit illuminating power is 2 ins.

The light-value of the German candle in terms of the English candle, if *two uncertainties* can be spoken of as being in *constant ratio*, is, say, one German candle equals 1.15 English candles. One practical application is to note that German incandescent lamps are usually marked in "Kerzen." Thus, "10 K" means 10 German c.p., which is equal to 1.15 English c.p.

In succeeding articles the photometric measurement of the arc and incandescent will be considered.

# Among our Foreign Contemporaries



Edited by CHARLES T. CHILD

**Modified Bunsen Cells.**—According to "Engineering," Mr. Emil Petersen has devised some promising modifications of the Bunsen cell. The original form of this battery is well known to consist of an outer zinc element, in dilute sulphuric acid, and an inner carbon element in a porous cup containing strong nitric acid. The sulphuric acid may be replaced by a solution of common salt, in which case neither the e.m.f. nor the internal resistance is affected, and the zinc need not be amalgamated. Several depolarizing agents, such as potassium permanganate, hydrogen peroxide, etc., actually give a higher e.m.f. than nitric acid, but have an insufficient constancy and yield of current.

Mr. Petersen discovered that chloride of iron answered the purpose admirably. Cells made with the zinc in a solution of common salt and the carbon in chloride of iron have all the good properties of Leclanché cells. The e.m.f. is 1.72 volts and the internal resistance of ordinary sized cells from 0.3 to 0.4 ohms. The same arrangement, using an iron plate instead of the carbon plate, yielded for 72 hours a constant current of 1.2 amps. at 0.54 volts.

---

**Electric Oil-Shortage Alarm.**—An ingenious little instrument for giving warning of the failure of a steady supply of oil to a bearing or journal is described in "L'Electricien," by M. Aliamet. The accompanying illustration shows its construction very distinctly. A B C is a lever, pivoted at the point B, and carrying at A a little funnel provided with a small orifice; this is mounted directly over the bearing which is to be oiled, and into it drips the oil, from an ordinary sight-feed cup. The size of the outlet hole in the funnel and the regulator of the oil cup are so proportioned that when everything is working normally the funnel is kept partly filled with oil, which drops into it from above and out below into the bearing. If the oil cup is clogged, or empty, the oil in the funnel will run out in a few moments, and the counterbalance P, will cause the lever to deflect so that the point C will plunge into mercury

ELECTRIC ALARM FOR OIL-SHORTAGE.

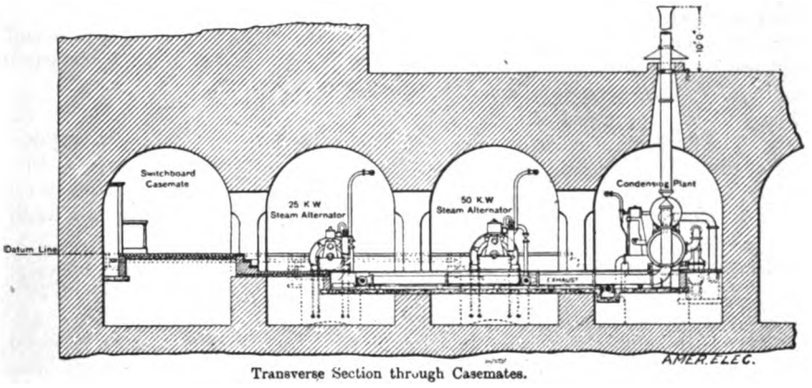
contained in the insulating cup D, thus closing a circuit connected with an annunciator and bell.

The apparatus is so simple that something on the same principle may be made in any shop, and it seems that it should be reliable and not apt to get out of order.

---

**Electrolytic Production of Bleaching Solutions.**—Electrolysis plays an important part in Germany in the preparation of bleaching solutions, says the (London) "Electrical Engineer," especially those for bleaching finer goods. In former days, when solution of chloride of lime found exclusive employment for this purpose, the most careful mixing with water gave imperfect results, since particles of the chloride were liable to remain undissolved, and, being retained by the material to be bleached, gave rise to blemishes and even to holes in it. The electrically-prepared bleaching-lye is, however, quite free from this defect. By subjecting a solution of ordinary salt to the action of the electric current a perfectly clean bleaching fluid of any desired strength, containing no corrosive spots in suspension, may be obtained. Uniformity and freedom from blemishes are thus secured, even if the material to be bleached is not carefully handled during the process.

Another advantage, generally overlooked, is that a solution of any strength, even so strong as to be injurious to the fabric, may be made from bleaching powder, but it is impossible by the electric process to make solutions of harmful intensity. The latest method for producing these solutions, which comes from Germany, is to use no metal for electrodes at all, save at the cathode end of the apparatus.



The tank consists of a single wooden box, containing grooves in its sides, into which are slid the specially prepared electrodes. Current is fed only to the end electrodes, the others acting bi-polar fashion, one side as anode and the other as cathode. In this way the number of elements in series may be so increased that the current from ordinary dynamos used for lighting by night may be used to electrolyze salt water by day. Under a pressure of from 65 to 110 volts, it is possible

Digitized by Google

to prepare 100 cu. ft. of bleaching-lye from 300 or 400 lbs. of salt in ten hours.

**The Electric Lighting of Gibraltar.** —The famous fortification of the Rock of Gibraltar has been provided with a modern electric light station, which was installed under some curious difficulties due to the extraordinary location on which it was necessary to place it. The site of the station, which is very fully described and illustrated in the "Electrician," is what is known as the King's Bastion. This was originally an artillery barracks, and was built in the solid rock. The accompanying illustration shows how the old casemates of the fortification were utilized for the installation of electrical machinery. There is nothing especially remarkable about the electrical installation itself, which consists of three locomotive boilers and four Siemen's alternators, direct connected to Belliss engines. The distribution is effected at 2000 volts, single-phase, and the ordinary 110-volt, two-wire secondary for incandescent lighting. Street lighting in the town is from a 220-volt, three-wire network, mostly incandescent lights being used for this purpose. The condensing plant was extremely difficult to install. Water for the condenser circulation was obtained from the sea, the suction and ejection pipes having been passed through brick work 12 ft. thick and thence 100 yds. out to the water. Of course, the condensers are of the surface pattern, and are supplemented by an evaporator plant to make up losses in the feed water. Another peculiarity of the plant is that the whole of the mains throughout the system consist of concentric cables. The insulation is bitumenized fibre and the cables are lead-sheathed and further protected by coatings of hemp and steel tapes. They are laid directly in the ground, under the sidewalks. Five substations are connected to the high tension mains, and supply the two-wire and three-wire systems for general supply and street lighting respectively. The incandescent street lamps are arranged alternately on opposite sides of the three-wire circuit, and at midnight switches in the sub-stations are thrown so as to cut out one side of each circuit.

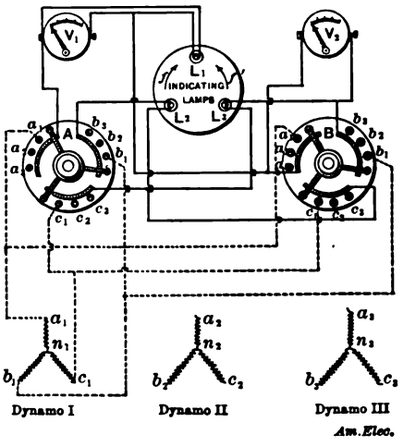
The plant is not a very large one, but there is probably no other electric light plant installed in casemates cut in the solid rock.

SECTION THROUGH CASEMATES, GIBRALTAR ELECTRIC LIGHT STATION.

**Wireless Telegraphy.** — M. Albert Nodon, writing in "L'Electricien," rather criticises the Zickler system of wireless telegraphy, described in these columns in the October, 1898, number, in which ultra-violet light is used to increase the conductivity of a vacuum-tube at the receiving station. The principal objection, according to M. Nodon, to this system is that the very short radiations of the ultra-violet light are readily absorbed by water-vapor, and even by the atmosphere itself. Experiments made by the author at the Meudon observatory demonstrated that the short wave-length radiations of the electric arc were readily absorbed by thick layers of air, a fact already well known in connection with solar and other radiation. He suggests that instead of utilizing the short radiations of violet light, long radiations, or so-called radiant heat, would form a far more satisfactory medium for this variety of communication. It is already known that the relatively long Hertz waves readily traverse not only air and water-vapor, but the greater majority of solid and liquid bodies as well. The obscure rays of intermediate wave-length between these and visible light have equally the property of easily traversing atmosphere charged with water-vapor and dust. For the reception of signals sent by such a method, either a sensitive thermopile or a bolometer, which consists of an extremely thin platinum wire whose electrical resistances is minutely affected by temperature changes, may be used.

This suggestion is interesting in two ways; not only as showing the ingenuity of its author, but also as a specimen of the many utterly impracticable schemes that have been suggested by the widespread interest in wireless telegraphy. Contrary to the author's assumption, the radiations of hot bodies, not necessarily luminous, are readily stopped by moist air, while the instruments that he proposes as receivers are almost unmanageably sensitive, and can only work to any advantage under the most refined conditions of the laboratory.

**A Phase Comparator.**—An ingenious modification of the ordinary phase lamp arrangement, used for paralleling alternators, is described in "L'Electricien." The illustration herewith is a schematic diagram of the arrangement utilized for connecting three-phase dynamos in parallel. The dynamos are shown at the bottom of the drawing, and, for the sake of simplicity, the connections from only one of them are indicated. These are led through the circular three-point switches, shown at the right and left of the diagram, to three phase-lamps and to volt meters. The three lamps, $L_1$, $L_2$ and $L_3$, are so connected by means of the switches, A and B, that they are bridged across points of the armature windings of the two machines having a simple cyclical order, readily understood by reference to the diagram, but exceedingly difficult to explain in



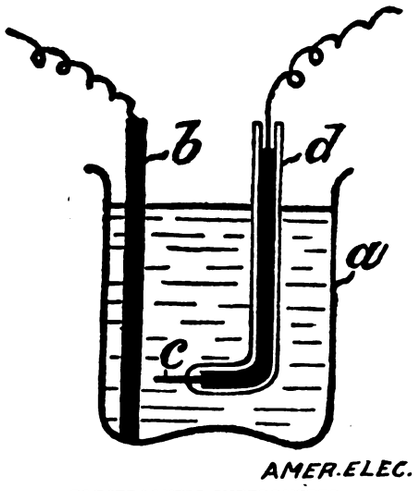


DIAGRAM OF PHASE COMPARATOR.

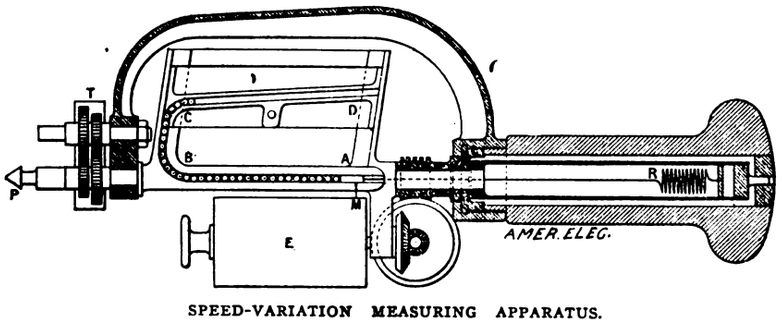
words. Under these conditions, if the two machines to be connected are not in exact synchronism, the phase lamps will be lit and extinguished in the usual way, but in regular cyclical order. A round sheet of ground glass is mounted over the three lamps, and if the machines, when it is desirable to parallel them, are not in precise synchronism, the light due to the rapid illumination and extinction of the three lamps in order, will appear to run circularly, in one way or the other, around the ground glass. According to the direction of its rotation it is determined whether the incoming machine is running too fast or too slow, and the necessary regulation of its speed is made until the rotation of the light becomes very slow, about once in four or five seconds. When this partial synchronism is reached, the machines are thrown together at the instant when the upper lamp, $L_1$, is entirely extinguished. The intervention of the switches A and B is simply to connect together any running and incoming machine and the phase-lamps. This arrangement possesses points of considerable merit, not the least being its remarkable simplicity and ease of operation.

**Induction Coil Interrupter.** — It would appear from an article by Dr. Wehnelt in the "Elektrotechnische Zeitschrift" that an ideal interrupter for the induction coil has at last been realized, and in a most inexpensive form. The device consists merely of a glass receptacle. a, containing dilute sulphuric acid, in which is immersed a lead or other metal plate, b, and a platinum wire, c, fused in a glass tube, d, filled with mercury to conduct the current.

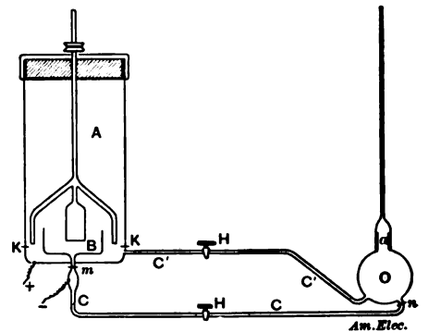


Digitized by Google

By connecting this device in the circuit of the secondary of an induction coil it acted as a remarkably perfect interrupter, giving quick breaks of great frequency; frequencies were measured ranging from 200 to 1700 per second. With this interrupter an induction coil does not require a condenser, and instead of inductance in the primary being a detriment it is an advantage, actually favoring the sharpness of breaks. The platinum electrode should be connected to the positive side of the battery or line, as it will be melted if connected to the negative side. It was found that by its means a 12-in. coil would have the spark increased to almost 24 ins., and that a 6-in. coil could be used with a Roentgen ray tube designed for a 12-in. coil. The interrupter gives admirable results in Roentgen- ray work, there being no flickering on the fluorescent screen, and the time for photographing is reduced. From the description, a voltage of at least 12 would appear necessary for good working.

ELECTROLYTIC INTERRUPTER.

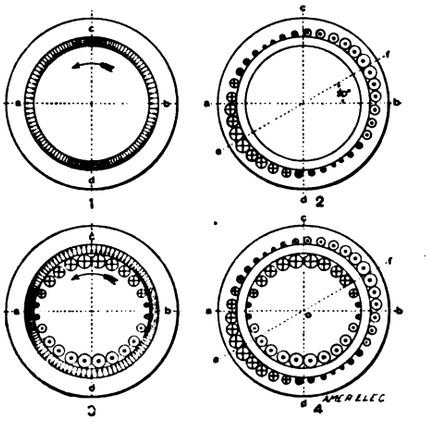
**Apparatus for Registering Speed Variations.**—At a recent meeting of the Société Internationale des Electriciens, M. Boucherot, in the course of a paper upon speed and torque curves of polyphase motors, described a highly ingenious instrument for measuring variations of speed. The illustration herewith is a cross-section showing the working parts. The instrument is used like the ordinary speed-counter, by being thrust into the center-mark on the end of the motor bearing. Centrifugal force is made use of, as in the ordinary tachometer, to measure the speed, but instead of utilizing any time-measuring device to obtain the ordinate of the curve drawn by it, the actual rotations of the machine itself are used to drive the cylinder E, shown at the lower part of the illustration.



SPEED-VARIATION MEASURING APPARATUS.

A roller-chain is encased in a run-way in the middle of the apparatus, one end of it being attached to the spring R, in the handle. The part of the chain B C, is, of course, subject to centrifugal force when the machine rotates, and runs over into the run-way C D, pulling up the part of the chain A B, and extending the spring. The inclination given to C D is just sufficient to compensate for the friction of the chain against the walls of the run-way. It will be seen from this that the extension of the spring is almost strictly proportional to the square of the speed. The cylinder E is turned by the worm and bevel gear shown in the illustration and a pointer, M, traces upon it a curve, of which the ordinates are angular distance traversed and the abscissæ are proportional to the squares of the speeds.

The results which can be obtained with a machine of this character are very interesting. Among others, the author quotes some speed tests upon a Corliss engine, to note the variations in its speed and the relation of the maxima of speeds to the point of admission of steam and cut-off—results which would have been extremely difficult to obtain by any ordinary method of calculation.



**A New Mercury Voltameter.**—In "L'Electricien," M. L. Gourwitch describes a novel and ingenious form of a voltameter which can be made practically a direct reading instrument, and which is free from most of the difficulties inherent in the ordinary silver, copper or hydrogen instruments. The illustration shows the essential parts of the instrument.

A glass vessel, A, is provided with a 3-pronged agitator coming down through its lid, and has one of the leading-in wires sealed in its bottom. Into this vessel projects a small dish, B, also of glass, connected with the capillary tube c c, and the bulb O. This bulb is also connected by another capillary tube, c' c', with the vessel A. In the outlet tube, below the bottom of the large vessel, is blown a small enlargement, m, into which is sealed the other leading-in wire. The whole apparatus is mounted on a board (not shown in the illustration), provided with screws, so that its level can be properly altered. Mercury is poured into the apparatus until it stands at the level K K in the outer vessel and at an equal level in the inner dish B, and is then allowed to run into the bulb O through the stop cocks shown in the two small tubes. Above the level of the mercury in the bulb colored alcohol is placed, and this is allowed to extend some distance up the capillary tube shown at the right of the illustration. Into the vessel A is put a quantity of water, containing 5 per cent of nitrate of mercury and 10 per cent of nitrate of potassium; the stop cocks are then closed and current allowed to flow through the apparatus in such a way that the mercury in the dish B is the cathode. The natural result is that the quantity of mercury in this dish is increased at the expense of that in the outer vessel, and upon the completion of the operation an opening of the stop cock in the lower tube allows the excess to run into the bulb O and force the colored alcohol up the capillary tube. This may be graduated to read directly in ampere hours or coulombs. It is said that the fall of e.m.f. through the apparatus is only 0.2 volt.

SKETCH ELEVATION OF MERCURY VOLTAMETER.

**Induction Motor Diagrams.**—The graphics of induction motors have always been more or less difficult. Some suggestions contained in an article by Mr. C. C. Hawkins, in the "Electrician," are extremely elegant. Four of his proposed diagrams are here reproduced. They are intended to represent load diagrams when magnetic leakage is absent.

FIGS. 1, 2, 3 AND 4.—INDUCTION MOTOR DIAGRAMS.

Fig. 1 represents a resultant two-pole field, such as would exist in an induction motor at any moment as it rotates in the

Digitized by Google

direction shown by the arrow. Then the instantaneous currents induced in a squirrel-cage armature are as shown in Fig. 3, where the relative strength of the currents at different positions are indicated by the size of the circles. The secondary ampere-turns so produced, would, if acting alone, produce a magnetic field, of which the line of maximum induction *a b* (Fig. 3) would be at right angles to the line at maximum induction *c d* of the resultant field at the same moment.

Fig. 2 shows the general disposition of primary ampere-turns which must be produced by the several phases of current in the field winding. Fig. 4 represents both sets of ampere-turns filled in, or a combination of those shown in Figs. 2 and 3.

These diagrams are interesting on several accounts. If properly printed on circular card sheets, so that they could be superposed, they would unquestionably afford a very satisfactory assistance in understanding many problems connected with induction motors.

---

**Mixed Traction Tramways in Paris.**—An interesting paper was read by M. de-Marchéna before the Société Internationale des Electriciens, upon the tramline running between Paris, Pantin and Aubervilliers. This line is the first in France to be equipped with a mixed trolley and accumulator system, and its operation, while appearing to also furnish an elegant solution for the difficulties encountered by electric tramways in Paris, is exceedingly interesting from many points of view.

The total length of the line is about 7½ miles, of which about 5½ miles are within the city limits. There is a secondary feeder system comprising about 3 miles, entirely outside the city limits, on which the trolley alone is used. Grades as high as 3.3 per cent are encountered on the part operated by accumulators, and these are unfortunately so situated that their ascent is made when the accumulators have already been partly discharged by use on other parts of the tracks.

It was decided from the beginning not to attempt to remove the accumulators from the cars at any point, but to charge them while the cars were running on the trolley part of the line and to discharge them in the city on those portions of the tracks where the municipal regulations forbade overhead wires.

The equipment of the cars consists of 224 cells upon each, carried in a special box swung under the body of the car, and carefully ventilated to avoid any fumes entering the vehicle itself. Each element weighs 28½ lbs. and contains four negative and three positive plates. The total weight of the batteries, including their box and connections, is 8,386 lbs. The cells are permanently connected in series, all of the joints being burned together. The positive plates are of the usual "grid" type, with composition pellets, while the negative plates are of the chloride type. Double truck cars are used, the trucks being of the "maximum traction" variety. The cars in running order, without passengers, weigh about 10 tons, two 25-h.p. motors being used on each. Including the seats on the roof (an arrangement very usual in France, and which would be highly desirable in this country), the vehicle seats fifty-six people. The track is solidly built of 90-lb. girder rails.

There is nothing unusual about the power stations requiring description. The charge of the batteries for each run is made during about thirty minutes, while the car is on the trolley section. When the car first enters this section the current taken by the accumulators ranges from 80 to 100 amps., falling in about five minutes to 60 amps., and running down gradually to about 20 amps. As the power station is at the end of the trolley line opposite to that at which the cars enter, the conditions for charging are very favorable, the voltage gradually increasing as the car nears the station. Some remarkable results are claimed for the total energy consumption of the road at the power station. For an average of three months the watt-hours generated per car-mile run were only 1,828. About one-third of the car-miles were run on the trolley section, without the intervention of the accumulators. It is stated that an efficiency as high as 60 per cent between the terminals of the dynamos and motors has been attained on this system, but that it may easily fall below 50 per cent if the batteries are allowed to get into bad condition. It is thought that it would be well to augment the weight of the batteries carried on each car, despite the increase of total dead weight which this would entail, on account of being able to obtain in this way a more satisfactory regulation of charge and discharge for the cells. The whole installation, however, furnishes an extremely interesting experience, and in spite of the inevitable troubles encountered by a system of this revolutionary character, its results have been very satisfactory to its promotors.

The conditions of electric traction at Paris are very difficult. To be of any public service the lines must run from central points to the suburbs, but an iron-clad municipal regulation absolutely forbids the use of the overhead trolley within the fortifications, that is, the city limits. The new line now under construction between the Place de la Bastile and Charenton has undertaken to solve this problem by the use of a conduit, very much like those in New York city, at the city end, and overhead trolley in the outskirts. The completion and operation of this line will furnish a valuable comparison with the method described above. It seems reasonable to suppose that in cities where the streets are nearly level, this mixed trolley and accumulator system, already in highly successful operation in Germany, may prove a more satisfactory solution of these problems imposed by municipal governments than even the conduit. The British Isles and the continent of Europe at present furnish a very large field for the exploitation of systems of this character.

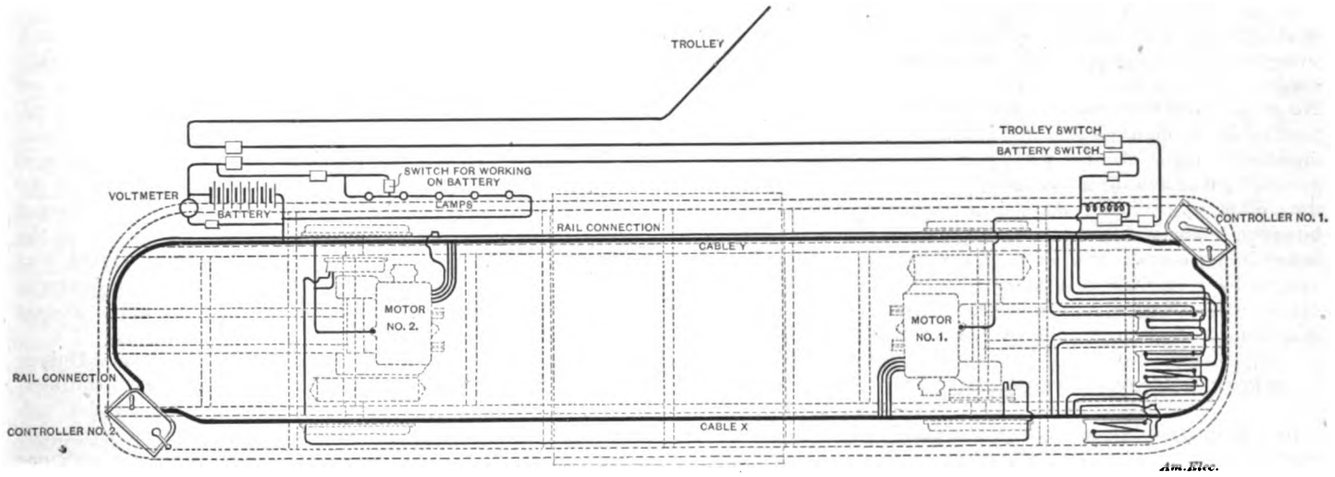


DIAGRAM OF CIRCUITS ON ACCUMULATOR TROLLEY CAR.

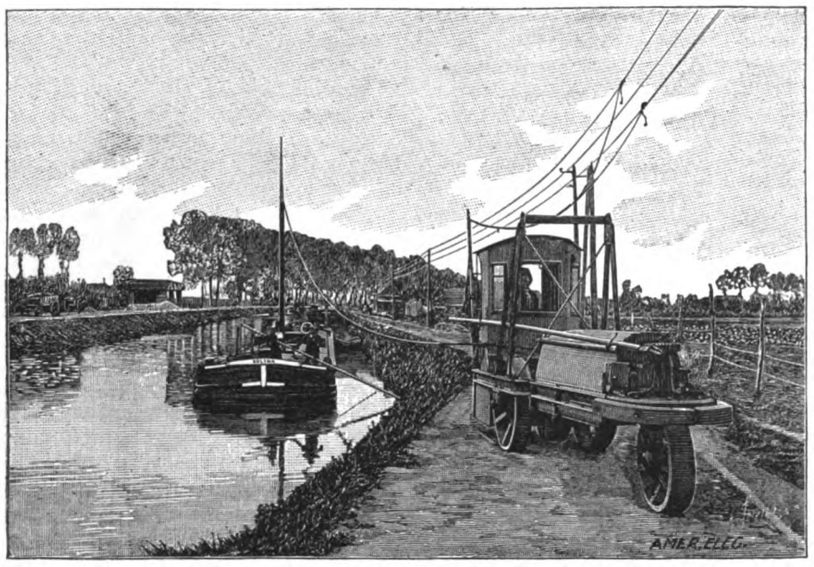

---

**Electric Towage on Canals.**—Some very interesting work has recently been done upon the canals between Bethune and Pont-à-Vendin, in the north of France, in the way of electric towage of canal boats. The method used is excellently illustrated in the accompanying engraving, taken from "La Nature."

It was desirable to neither encumber the tow-path of these canals with cross-ties and rails, or any other structure over which the familiar tow-horse could not readily pass,

Digitized by Google

and in other ways to approach as nearly as possible the conditions of horse-towage with the new apparatus. The tractor is a variety of tricycle, or road locomotive, having broad tires and a sufficient weight to give it the necessary adherence to the tow-road. A two-pole series motor of about 6 kw. is used, geared to the rear wheels while the machine is steered by the front wheel. The generating stations are situated at points about 9 miles apart along

ELECTRIC TOW-HORSE ON A FRENCH CANAL.

the path; the total distance over which this system is in operation being 50 miles.

As the illustration very clearly shows, a double-trolley wire system is used, and over-running trolleys are hauled along behind this electric horse by flexible cables. No attempt has been made in this installation to attain high speeds, the apparatus crawling along at about 2 miles per hour, at which speed it hauls a boat carrying 185 tons of freight. Under these conditions, however, it almost doubles the speed of the horse-drawn boats. The experiments are said to have resulted in a most excellent economic showing, as well as in great success from a commercial point of view.

## ELECTRICITY DIRECT FROM COAL.

In a paper read before the recent annual meeting of the Northwestern Electrical Association, Prof. A. J. Rogers gave an interesting review of authoritative investigations made to date in the endeavor to obtain electrical energy direct from coal, or, more generally, from carbon and some of its compounds.

Early attempts were made to get a practical carbon battery by using a rod of carbon dipping into a vessel of molten nitrate of potash or other powerful oxidizing agent. As early as 1855 Becquerel had used various molten electrolytes with carbon as an electrode and a platinum dish as a containing vessel and serving as the other electrode.

In 1877 Jablochkoff procured a patent on the use of a solid electrolyte in a state of fusion which would act upon a carbon electrode. Thomson, Edison and others proposed practically the same method. In 1882 J. A. Davis proposed to infuse air into the electrolyte, and in 1883 A. M. Clarke used potash or soda hydrate regenerated with air.

A cell by C. S. Bradley had a fused electrolyte of $Na_2 Mn O_4$ contained in an iron vessel serving as the negative electrode and a carbon rod dipping nearly to the bottom of the liquid mass, as the other electrode. With an iron pot at a red heat it is stated that an e.m.f. of 1 volt and 3 amps. was given by 1 cell. In attempting to verify these results, Prof. Rogers could only obtain from .1 to .2 of a volt, and this did not materially change by the addition of a blast of air. The same voltage can be obtained even when the carbon rod touches the bottom of the iron pot, seeming to indicate a thermoelectric rather than an electrochemical action.

In June, 1894, Prof. Ostwald proposed an ideal carbon monoxide (CO) consuming cell. He proposed the use of an outer copper containing vessel which should serve as an anode. Within this vessel is a porous cup containing the carbon cathode with lumps of carbon. Surrounding the porous cup is a saturated solution of copper chloride, and a constant supply of carbon monoxide is forced into the solution and absorbed by it. A stream of air is also supplied to the cathode compartment.

Following out this line of investigation Dr. Borchers, some five years ago, undertook a series of experiments, using carbon monoxide and air in an electrolyte of copper chloride, which readily absorbs oxygen and carbon monoxide. Since the heat energy of the latter with oxygen is 75 per cent of the told energy of the two, if the gases can be caused to combine either directly or indirectly, setting free electrical energy instead of heat, a tremendous step would be gained.

Borchers thought he had accomplished the desired result. He claimed to obtain as high as 27 per cent of the calculated energy of combination of the two gases to form carbonic acid gas, and with gas from bituminous coal he obtained as high as .64 amps. on short circuit, and .56 volts on high resistance with his apparatus, giving an efficiency of 38 per cent. Many experimenters, including C. J. Reed in this country, H. H. Barnes, E. Vesemmeyer of Stuttgart, Rhodin of Manchester, Eng.; Robert Mond, William Tatlow and others have repeated Borcher's experiments, varying his conditions and criticizing his results. They consider the e.m.f. as due not to the union of carbon monoxide and carbon, but rather as the result of the oxidation of the copper and the copper chloride.

In July, 1897, Borchers read a paper before the Electrical Society of Germany, in which he claims that he has eliminated all sources of error in his carbon element. By the use of glass plates instead of porous diaphrams, he separates the copper and copper chlorides and prevents diffusion. These glass plates extend into mercury, covering the bottom of the cell. The electrodes are made to receive in the carbon monoxide, and in the copper chloride to absorb the former in the best possible manner. By using plates of lead peroxide or manganese peroxide, instead of metal he obtained an e.m.f. of .5 volts.

Since it is still questioned whether Borcher's experiments are conclusive that an e.m.f. is possible with carbon monoxide and oxygen, Prof. Rogers strongly heated two like plates of carbon in an oven, then immersed one of the plates and allowed it to cool in an atmosphere of carbon monoxide, the other remaining in air. After cooling they were partially immersed in a vessel of ordinary lake water, and the e.m.f. noted was as high as .4 volt. The experiment was also repeated, using a dilute solution of sulphuric acid, with similar results except that the e.m.f. would more rapidly diminish, probably from decreased internal resistance. The direction of the current was from the monoxide charged plate through the external circuit to the oxygen or air plate. To what extent, if at all, the copper chloride acts as a conveyor of monoxide to oxygen, Prof. Rogers thinks is still a matter of doubt.

As early as 1883 Carl Hering and Dobrowolsky reported having obtained considerable current with carbon electrodes, sulphuric acid being used as an electrolyte and coal gas brought in contact with one plate and air with the other.

As an aid and a guide to experimental investigation it would seem to be desirable to determine if the element carbon can exist in an electrolyte in the ionic state. With this end in view, Dr. Alfred Koehne has attempted to show that carbon does form ions and, therefore, it is theoretically possible to oxidize the element at ordinary temperatures and obtain electrical energy instead of heat.

He used pure carbon as anode, hot sulphuric acid as electrolyte and platinum as cathode. The liquid became yellow, then dark brown and black, and a thin layer of graphite was deposited on the cathode. Using carbon and lead peroxide as elec-

Digitized by Google

trodes and hot sulphuric acid as electrolyte, he obtained a galvanic cell giving an e.m.f. of 1 volt on a resistance of 100 ohms.

Bartoli and Pasogli had previously found that using sulphuric as an electrolyte and carbon electrodes, carbon monoxide, dioxide and oxygen formed at the anode. Of these Koehne obtained 29 per cent, 70 per cent and 1 per cent, respectively.

Franz Vogel thinks that Koehne did not obtain carbon in solution, that deposited being of mechanical and not electrochemical origin. So it is, perhaps, hardly yet proven that carbon does form from free ions in electrolytes at ordinary temperatures. If it does not, the field for investigation in this direction would not seem promising of great practical results.

Within the last few years experimenters have returned again to the fused electrolyte for the carbon consuming cell. W. W. Jacques employs fused caustic soda as the electrolyte contained in an iron melting-pot. This vessel also serves as an electrode. Air is admitted at the bottom of the iron vessel and mixes with the carbon electrode suspended in the liquid. Carbonic acid gas passes off through an opening in the top of the iron tank.

To produce fusion the caustic soda is heated to 400 deg. to 500 deg. Peroxide of manganese and magnesium oxide are added, and magnesium carbonate forms and decomposes so that only a small amount of the oxide is necessary. Jacques states that he used 100 cells each 12 ins. deep and 12 ins. in diameter, and obtained a current of 18 amps. at 30 volts for 18¾ hours with a consumption of 8 lbs. of carbon. In another experiment he reports that with 100 cells he obtained 90 volts and 16 amps., giving him an efficiency of 85 per cent of the energy of the carbon consumed.

C. J. Reed says the process is electrothermic and not electrolytic. He finds that illuminating gas will also produce the same effect as air. He also finds that the carbon may be replaced by a metal and that the polarity changes at a red heat.

Prof. Rogers adds that without having carried these experiments to the same extent as reported by Jacques, he, nevertheless, has been able to get only a maximum of about .3 volt e.m.f. with an iron containing vesel and electrode, and he questions Jacques' results, even though they are reported to be supported by the authority of Profs. Cross and Rowland. Employing a platinum crucible instead of one of iron as the containing vessel and electrode, Prof. Rogers found an e.m.f. of nearly .5 volt at a red heat of the caustic soda.

According to a United States patent issued to Blumenberg nearly a year ago, superheated steam is injected into the fused electrolyte consisting of lime, caustic soda and cryolite. He claims these oxides to give up a part of their oxygen to the carbon electrode, forming carbon monoxide and dioxide, and then receive back their oxygen from the steam, setting free hydrogen. If this is the end of the process, it would hardly seem probable that heat or electrical energy would be liberated.

Prof. Rogers concludes that while the problem of obtaining electricity from carbon direct has not yet received a practical solution, it can not yet be regarded as insoluble. The chance of success, however, would seem much better in endeavoring to oxidize the easily obtained hydro-carbons and carbon monoxide.

If we keep closely to the theory of the galvanic cell as worked out by Nernst and others, we cannot get far astray and are likely to reach valuable results in the solution of this greatest of technical problems.

If any approach to 100 per cent of the energy of the coal can be secured an industrial revolution would follow, in comparison with which the invention and perfection of the steam engine is almost insignificant.

## DROP IN ALTERNATING CURRENT CIRCUITS.

At the recent meeting of the Northwestern Electrical Association, Mr. Geo. L. Thayer read a paper on "The Design of Secondary Circuits in Alternating Plants," which was without question the most important contribution of the meeting from the standpoint of the central station man. Owing to lack of space the paper unfortunately cannot be reprinted in our columns, but we make an abstract of that portion which dealt with drop in alternating current lines.

| 4 | 8.1 | 2.019 | 2.024 | 2.027 | 2.49 | 2.55 | 2.62 |
| 6 | 6.4 | 2.011 | 2.016 | 2.018 | 2.38 | 2.45 | 2.49 |
| 8 | 5.1 | 2.009 | 2.011 | 2.012 | 2.30 | 2.35 | 2.39 |

The accompanying tables enable a comparison to be made between the effects on drop of the frequency, distance apart of line wires, and the size of conductors. It should, however, be borne in mind that the increased drop with large conductors is not due to the size of the conductor, but to the large current carried. In fact, for the same current the inductive drop becomes smaller as the diameter of the conductor is increased.

Both tables are based on a 2 per cent drop with direct current over a line 500 ft. long, the voltage being 100. Table I. is for a frequency of 60 cycles, and Table II. for a frequency of 125 cycles. The first division in each table refers to alternating current in a non-inductive (incandescent lamp) circuit, and the second division to an inductive circuit having a power factor of 95 per cent.

A study of the tables affords some interesting information. As long as lamps form the only load—that is, when the power factor is 100—the line losses do not differ appreciably from what they would be with direct currents. If, however, a portion of the load is in small motors or in arc lamps, the inductive drop in the lines begins to assume importance. With a power factor of 95 per cent, the drop in a No. 4-0 wire is increased 50 per cent at 60 cycles and 100 per cent at 125 cycles, the lines being 12 ins. apart. It is also evident that the lower the power factor the poorer the regulation of the secondaries. The inductive effects can be kept down by subdividing the heavy circuits, bringing the wires closer together, using lower frequencies and by operating motors with good power factors. Although the inductive effects decrease quite rapidly when the conductors are brought within 12 ins., it is hardly practicable to make the distance less than this on overhead work. On the underground work at St. Louis, where the wires are very close together, the effects of inductance are very small. Beyond 36 ins., the limits of the tables, the increase in inductive effect is not very great, with increased distance apart.

It will be noticed how rapidly the inductive drop decreases with the size of wire. For example, in a 4-0 circuit at 125 cycles, and with wires separated 36 ins., the direct-current drop is 2 volts; the drop with a load having a power factor of 100 per cent is 2.527 volts; and the drop with a load having a power factor of 95 per cent is 5.70 volts. With a No. 8 wire the same drops are 2, 2.012 and 2.39 volts respectively. With lower power factors the drop becomes correspondingly greater, and as some arc lamps and motors have a power factor below 70 per cent, they may be extremely large.

## Electricity in a Medical Clinic.

In the description of the generating plant of the Polhemus Memorial Clinic which appeared in the February issue, it is stated that the Ball & Wood engines have cylinders 13 ins. x 12 ins., a horsepower of 90 at 275 r.p.m., and that they are equipped with Rite's governor. The engines in question are three Ball & Wood simple engines, with cylinders 13½ ins. x 11 ins., and proportioned to give 80 h.p at 275 r.p.m. at 80 lbs., with 5 lbs. back pressure. The engines are equipped with the Ball & Wood standard governor, and not with the governor mentioned in the article. The medical apparatus described in the article was designed and furnished by Louis M. Pignolet.

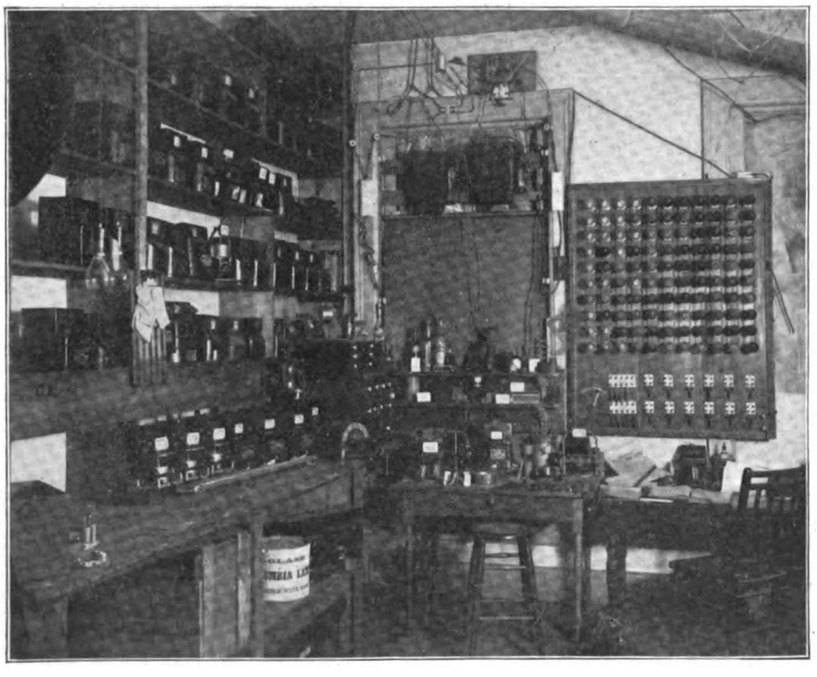
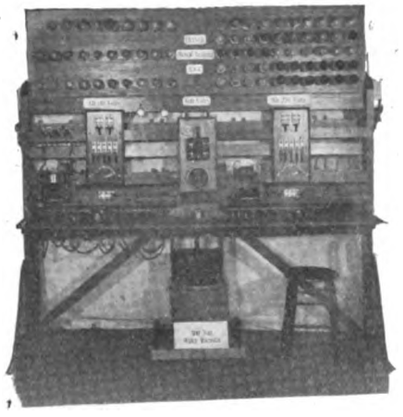
## METER TESTING AND HANDLING.



BY JAMES E. JUDD.

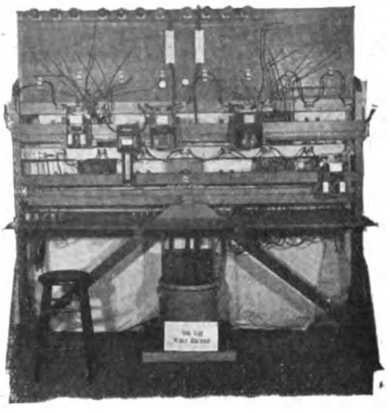
A meter testing department has come to be one of the prime requisites for a modern central station, and hardly any station can be called thoroughly up-to-date which does not make provisions to insure the satisfactory operation of the meters used, from the standpoint of the customer, as well as of the station.

One of the greatest defects in the present meter system is the inability of the meters on the market to remain absolutely constant; and it is the exception, rather than the rule, that a meter which is accurate when installed, will be accurate after a year's service. For this reason it is highly important that each instrument should be thoroughly tested and calibrated, not only when it comes from the factory, but also at definite intervals during use.



There are few central station managers who will not readily see the advisability of such tests, but there are many who are slow to introduce a meter testing department, owing to the immediate expense involved.

A testing department when properly planned and operated can take care of a large number of meters with comparatively small cost, and with a decided gain to the station. It is the purpose to call attention here to the meter testing department which has been developed after considerable study and use, and operated in connection with a station supplying light and power in a city having a population of 18,000. The equipment here described, however, is amply large for stations supplying ten times that number of inhabitants.



TESTING RACK.

Meter testing is a very delicate operation, and should be done with the greatest care. The best measuring instruments should be employed, which should be calibrated from time to time to insure their accuracy. The testing laboratory should be far removed from all jar or vibrations which would tend to interfere with the calibration of the meter. The utmost cleanliness must be observed, and dust covers should be provided for standard meter and other measuring apparatus. The rack on which the meters are placed during the test should be substantial, and very carefully constructed. The one here shown in photograph was built of good grained oak, 7 ft. 8 ins. long, by 7 ft. 6 ins. high, and of skeleton form. One side is used for testing ampere-hour meters, and is arranged so that sixteen meters can be tested at one time, if necessary. It is provided with flexible cords and plugs, so that one meter may be removed at any time without disturbing the others. A standard ampere-hour meter, which has been carefully calibrated, is mounted permanently at the head of the board, and is provided with a special cover with movable mica windows, so that fans, dial and tell-tale hands may be seen at any time. The dial window may be opened at will, thus facilitating the resetting of hands before starting the test. The instruments used on this side of the rack consist of one low reading and one high reading ammeter, the smaller reading from 0 to 2 amps., and the higher from 0 to 25 amps. Either instrument may be thrown in or out of circuit without opening the circuit of the meters under test, also by the use of a third switch, both instruments may be cut out without interfering with the test, the instruments being only cut in from time to time

WATTMETER SIDE OF RACK.

AMPERE-HOUR SIDE OF RACK.

to see that the load has not changed. A shunt is placed around the low reading instrument, and is always left closed, except when the instrument is in use, so that should a heavy load be accidentally thrown on, no damage will result.

The other side of the rack is used to test wattmeters, and is divided into three sections, one each for 108 and 220 alternating, and the third for 500 volts direct. As may be seen in Fig. 1, a lamp bank is used for load on the 108-volt and 220-volt sections, and a water rheostat for the 500-volt. The meters on this side are held in position by clamps, and have a leveling piece beneath, which may be raised or lowered with a thumb-screw, while the meter may be given an in or out motion with clamp screws, which are shown on side in Fig. 1. The leads or meters are of flexible cable with special terminals, which are arranged to sink to the level of the board when not in use. The lamp banks on this side of the board are so arranged that any load from ten lamps in series to forty lamps in multiple, may be thrown on the meter, without making it necesary for the operator to leave his chair.

Each of the alternating current sections is provided with two portable, direct reading watt-meters, one for light loads, and the other for heavy loads. The instruments used in connection with the 500-volt section consist of two ammeters, one reading from 0 to 10 amps., and the other from 0 to 100 amps.; also a 650-volt voltmeter.

The water rheostat used for the 500-volt section is somewhat different from that ordinarily used, in that both its terminals are fixed for various loads; that is, the positive side consists of several elements, each connected by different wires to various switches on the board, so that by properly manipulating the switches, almost any load

Digitized by Google

required may be obtained. This rheostat requires occasional addition of water and salt, or other substance used to make the water conduct to replace that lost by decomposition or evaporation, which would cause the resistance of the solution to vary. As will be seen in Fig. 2, a smaller water rheostat is placed under the center of the board, consisting of a 20-gal. jar, in which two movable iron plates are fitted in a frame work built in the jar; these being adjusted from the operator's seat at the board by cords passing up over a pulley, which is direct connected to a wheel on the front of the board.

The smaller water rheostat is used only to adjust any difference in load caused by poor regulation, or otherwise, after having approximately adjusted the load required. The board being built of skeleton form, can be readily adjusted to hold any make of meter on the market, there being several different kinds shown connected in circuit in Figs. 1 and 2, viz: Shallenberger, Scheeffer, T. H., Fort Wayne, and a Hale discount meter.

# The Induction Motor.

## HOW ENERGY IS TRANSFERRED FROM THE PRIMARY TO THE SECONDARY IN INDUCTION MOTORS.

BY WM. BAXTER, JR.

There are many men, well informed in relation to the actions of continuous current machinery, who cannot fathom the mysteries of alternating currents. This condition of things is due, in part, to the fact that the latter subject is more difficult to understand, and in part to the prevailing notion that the difficulties are more formidable than they really are. The latter impression has been created, to a very great extent, by the abstruse manner in which alternating current problems are generally treated. There are certain points in connection with the action of continuous currents that were regarded as very complicated only a few years ago, as, for example, the theory of compound winding for constant potential generators, which formed the basis for numerous lengthy and more or less complicated mathematical demonstrations; but at the present time this subject has become so well understood that simple explanations are found sufficient to elucidate the principles involved.

It is not probable that alternating current actions will ever be interpreted with the same degree of simplicity as the continuous, since, in many cases, they are more complicated; but many of the present difficulties will eventually be brushed aside. In fact, even now it is not unusual to read occasionally a simple explanation of some action previously regarded as only capable of being demonstrated by the aid of the higher mathematics.

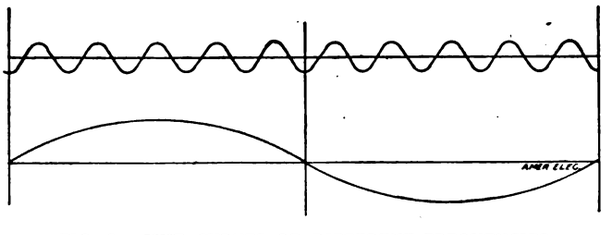


FIG. 1.—SINE CURVES OF DIFFERENT FREQUENCIES.

The theory of the polyphase induction motor is generally regarded with profound respect, but in this article an effort will be made to show that it is, after all, quite simple. When a man concludes to familiarize himself with the operation of induction motors, he starts by reading some elementary explanation of the subject. From this he learns that the effect of magnetizing the field by means of two or more alternating currents of the same frequency, but out of phase with each other, is to produce a magnetic flux that rotates at a velocity proportional to the frequency of the currents, and that if the phase displacement is properly adjusted to the number of currents, and the currents are equal, the flux will rotate at a uniform rate, and the strength of the field will be constant. From this he can see at once that if an armature is placed within this rotating field it will be dragged around, since the conductors on the armature will be cut by the lines of force of the flux, and the e.m.f. so induced will set up currents that will endeavor to set themselves at right angles to the magnetic field. But as the field rotates, the currents induced in the armature conductors must also rotate to preserve the right angular position, and as the conductors are fixed in the armature they cannot rotate without carrying the latter with them.

Thus the explanation makes the cause of the rotation of the armature quite clear, but it does not throw any light upon the manner in which the energy of the primary currents is transferred to the rotating secondary, and since the latter cannot develop a torque without such a transfer, it is obvious that a compensating inductive action must be set up in the primary or field coils. The seeker for knowledge begins to study the subject with a view to clearing up this mystery, and naturally concludes that the armature currents in some way set up e.m.fs. in the field coils that are the equivalents of the energy appearing in the armature.

The description of the action of the motor tells him that the armature currents alternate with a frequency much lower than that of the primary currents, and when he begins to contemplate this statement he finds himself completely bewildered, for at once an effort is made to reason out the nature of the inductive action that a current of low frequency can have upon one of much higher frequency. A picture of two such currents is drawn in the mind something like that shown in Fig. 1, and then the effect of the lower current upon the upper one is studied. The more the picture is studied the deeper the mystery grows, because all that can be made out of it is that while the lower current is diminishing it will put an induction in the upper current in one direction, and while it is increasing it will put an induction in the upper current in the opposite direction; but as one wave of the lower current laps over several waves of the upper one, each one of its inductive actions will be against one set of the impulses of the upper current, say the positive, and in the same direction as the other set. The other half of the lower wave will effect the upper current in just the opposite order, hence the two effects will neutralize each other, and only result in producing a distortion of the upper current.

All this confusion, which is due to an improper interpretation of the action, can be cleared away by a simple statement of the fact that the armature current, as a whole, when considered with reference to its position relative to the rotating field, does not alternate, but is continuous and of constant strength so long as the primary currents remain constant.

That this statement is true can be made evident by the aid of Fig. 2, which represents a type of armature winding commonly used in induction motors. This winding consists of two end discs, connected by means of the rods marked a, b, n, m, etc.

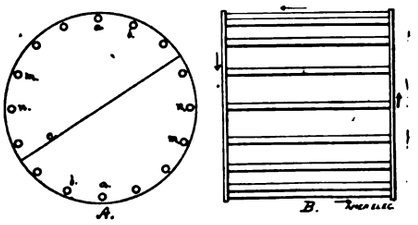

FIG. 2.—TYPE OF INDUCTION ARMATURE WINDING.

Suppose an armature provided with such a winding is placed in a magnetic field and is caused to revolve; then it is evident that when the rods a, a, are passing the center of the magnetic flux, they will have induced in them an e.m.f. that will be higher than that induced in any of the other rods. At this same instant the e.m.f. induced in the rods n, n, will be zero, as these will be moving parallel with the lines of force. As each pair of rods comes successively into the position of rods a, a, it will be the seat of the highest e.m.f. The action, as can be seen, is that which is explained in any elementary book upon dynamo-electric machinery; and as we know

Digitized by Google

the currents induced in any individual pair of rods, as a, a, b, b, etc., will alternate with a frequency equal to the velocity of rotation of the armature, but the currents flowing in all the pairs of rods, taken with reference to their position in space, will be continuous. That is, in all the rods above n, n, the currents will flow in the same direction; and in those below they will flow in the opposite direction, and this order will not be disturbed, no matter what the velocity of the armature may be.

Since, in this illustration, the field is stationary, it follows that as the armature currents are always in the same direction with reference to a fixed point in space, they are in the same direction with reference to the magnetic flux, for this is also taken as fixed in space. If the field rotates, the continuous current in the armature will also rotate and at the same velocity as the field. That is, the points n, n, at which the induction is zero, will always be on a line at right angles to the direction of the flux; and the points a, a, at which the induction is maximum, will always be on a line parallel and coincident with the center line of the flux. If the field remains stationary and the armature revolves, the only effect of changes in velocity will be that the e.m.f. will vary, increasing and decreasing with the speed.

If the armature remains stationary and the field flux revolves the result will be the same; that is, the e.m.f. induced in the conductors will increase and decrease with the velocity with which the field rotates. In a continuous current motor the field remains stationary and the armature revolves, and in the multiphase motor the field, as well as the armature, rotates. If both parts rotate at the same velocity the effect upon the armature conductors is the same as if both stood still, for in this case the latter are not cut by the lines of force. A continuous current motor at a standstill does no work, hence an induction motor, when running at synchronins, can do no work. When the armature of an induction motor runs at a lower velocity than the rotating field the effect upon the conductors is the same as if the armature stood still and the field rotated with a velocity equal to the difference between the field and armature; that is, with a velocity equal to the slip.

From the foregoing it can be seen that whatever the velocity of the armature of an induction motor may be the inductive action therein is precisely the same as that in the armature of a simple continuous-current motor, and the only difference between the two machines is in the manner in which the inductive action which compensates for the energy of the motor is impressed upon the main currents. In the continuous current motor the main current passes through the armature, and the c. e.m.f. induced therein is the representative, so to speak, of the work done. But in the induction motor the main current does not pass through the armature, and therefore the e.m.f. induced therein does not account for the work done. The current induced by this e.m.f., however, sets up a magnetization which reacts upon the field coils, and thus sets up therein an induction that accounts for the work done.

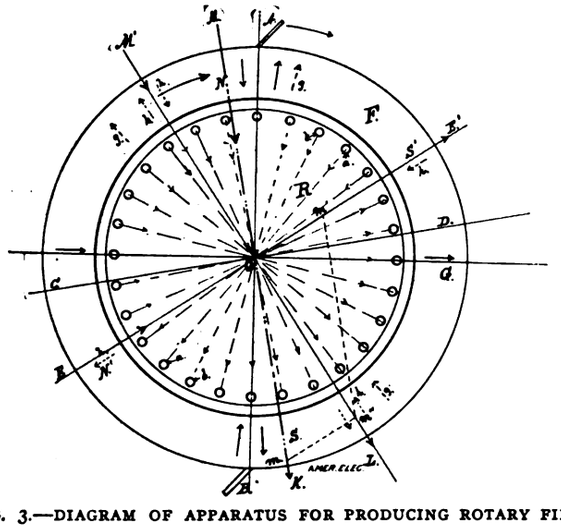

FIG. 3.—DIAGRAM OF APPARATUS FOR PRODUCING ROTARY FIELD.

This part of the action can be made clear by means of Fig. 3, which represents an apparatus by means of which a rotating magnetic field can be obtained with a continuous current, thus simplifying the subject by removing the complication arising from an effort to conceive of the manner in which the currents of a polyphase system produce the rotating magnetization. The ring F is supposed to be wound like a Gramme armature, and to be provided with a commutator face on the periphery, after the fashion of a Siemens & Halske generator.

With such a device it is evident that if the continuous current is admitted through the brushes A, B, and flows through the wire in the direction indicated by the solid arrows, that N and S poles will be developed at top and bottom, as shown, and lines of force will traverse the inner space from N to S. If the brushes A, B, are rotated, the points at which the current enters and leaves the wire will rotate; therefore the poles N and S will rotate, and so will the lines of force within the ring; that is, we will by this process obtain a rotating field within the ring F. If the magnetic polarity of the iron could change instantly the poles would always remain upon the diametrical line joining the brushes, no matter what the velocity of rotation might be; but as it requires a certain amount of time for the polarity of the iron to change, the poles will lag behind the line upon which the brushes rest and be on some other line, as M K. The angle M O K, formed by the line through the poles and the line through the brushes, will increase as the velocity of rotation of the brushes is increased.

As the brushes rotate the lines of force within F must necessarily cut through the wires upon the inner side of the ring, and thus induce e.m.fs. therein. If the poles N S did not lag behind the brushes, these e.m.fs. would neutralize themselves, for one-half would be in one direction and the other half in the opposite direction; but in consequence of the lag of the poles this neutralizing action is not completed, for while the wires in the arc A D are the seat of an induction in one direction, those in the arc D B are the seat of an opposite induction, and the two arcs are of unequal lengths. Hence, the net inductive action upon the wire wound upon F is the difference between these two opposing actions. This inductive action appears in the circuits wound around F, as a counter e.m.f., and represents the energy absorbed in eddy currents and hysteresis.

We will now consider the effect of the rotating field upon the wires wound upon the drum, R, which represents an armature arranged to revolve within F. As we have already explained in connection with Fig. 2, if R revolved at the same velocity as the field—that is, at the same velocity as the brushes A B—there would be no inductive action. But if R revolves at a lower velocity there will be an inductive action. If R stands still, the inductive action will be the same as if it ran at a lower velocity than the rotating field, the only difference being that the e.m.f. will be greater. This being the case, we will regard R as stationary, as by so doing the action can be made clearer. Let the wires upon R be connected with each other at both ends, as shown by the broken lines, so as to form independent closed loops.

If we consider the instant when the brushes are in the position shown in the figure, it will be evident that the rotating flux, whose center line is M, K, will cut the armature wires and induce therein e.m.fs. in the direction indicated by the arrow heads upon the broken lines; the induction in all the wires above the line C D being in one direction, and in those below it in the opposite direction. In consequence of these e.m.fs., currents will flow in all the loops, and these will develop an armature magnetization in the direction of the line C D. But, as was shown in connection with Fig. 2, this magnetization will rotate with the field flux, always retaining the same relative position; therefore it will cut the conductors upon R, and thus induce e.m.fs. therein. These e.m.fs. will be zero, or nearly so, in the wires near the line M K, but will have the maximum value in the wires near the line C D. The

Digitized by Google

e.m.fs. induced by the field flux will be nearly zero in the wires near the line C D. Now the e.m.fs. induced by the armature magnetization will be in the same direction as those induced by the field flux in the wires below the line C D, on the right side of R, and in the wires above this line on the left side of R, but they will be in opposite directions in the wires above the line on the right and in those below the line on the left. The effect of this will be that in some of the loops near the line C D the e.m.fs. induced by the field flux will be overpowered by the e.m.fs. induced by the armature flux, and as a consequence the currents will be reversed. On this account the line that divides the positive from the negative inductions upon the armature will be shifted back of C D to a position E $E^1$.

The faster the brushes A B revolve the higher the e.m.fs. induced in the wires upon R, therefore the stronger the currents developed, and the stronger the armature magnetization. The stronger the armature magnetization the higher the e.m.fs. induced in the armature wires by it, and the greater the angle through which the line E $E^1$ will be shifted. From this we see that the greater the velocity of the brushes, or, what is the same thing, of the rotating field, the greater the lag of the field magnetization M K, and the greater the lag of the armature magnetization E $E^1$.

The armature flux along the line E $E^1$ not only cuts through the wire wound upon the armature, but also through the wires upon the inner surface of ring F. The rotating field flux M K, as we have seen, has but a small effect upon the field wires, and would have none at all if the line M K did not lag behind the brushes. The armature magnetization along the line E $E^1$ lags much more than the field flux, and its effect upon the field wires is correspondingly increased. As can be plainly seen, the armature as well as the field ring F, wires, are now subjected to the action of two magnetizations, one along the line M K, and the other along the line E $E^1$. We can consider the action of each one of these separately, or we can regard them as the components of the resultant magnetization along the line $M^1$ $L^1$, either method will lead to the same result.

Considering the action of the resultant, $M^1$ L, the first thing we notice is that it lags behind the brushes by a greater angle than M K, hence it will set up a greater counter e.m.f. in the field coil than the latter. The inductive action of $M^1$ L in ring F will be in one direction above the line E $E^1$, and in the opposite direction below this line. The coils constituting the circuits between the brushes A B are not equally divided by this line, the arc A $E^1$ being much shorter than the arc $E^1$ B. The e.m.fs. induced by the magnetization $M^1$ L will be in the direction of the arrows g, and this, as can be seen, is in opposition to the current from A to E, and with the current from A to $E^1$. The difference between these two arcs, which is equal to twice the arc $M^1$ A, represents the preponderance of the counter over the direct e.m.f. induced in F by the rotating flux $M^1$ L.

This c. e.m.f. induced in the primary compensates for the energy transferred to the armature, B, and actual measurements would show that this e.m.f., multiplied by the current in F, would be equal to the energy appearing in the armature in every form.

If we investigate the action of each flux separately, that is, of the rotating field flux M K and the armature flux E $E^1$ we will find that the action of the latter upon the wire on the field ring F will be such as to develop a counter e.m.f. from A to L, and a direct e.m.f. from A to $M^1$. The arc in which a c. e.m.f. is impressed is greater in this case than when the resultant $M^1$ L is considered, but to offset this the magnetization E $E^1$ is smaller, as can be seen by comparing the lengths of the lines Om' and Om''. If the diagram were accurately drawn, it would be found that the product of Om' by the arc A L, minus the arc A $M^1$, would be just equal to the product of Om'' by the difference between the arcs A E and A $E^1$.

As Fig. 3 is a simple continuous current device, it is not difficult to trace out the inductive actions of the magnetizations M K, and E $E^1$, and we can readily see that the c. e.m.f. induced in F by E $E^1$ is proportional to the energy transferred to R, and in fact is an accurate measure of it. The flux M K has little effect upon F, simply because the points where the current enters and leaves the wire rotate, and always are in the same position relative to this flux. If F were magnetized by the two alternating currents of a two-phase system, the result would be different as regards the flux M K, but the same as regards the flux E $E^1$. If alternating currents passed through the wire on F the coils in the quadrant to the left of brush A and those in the quadrant to the right of B would be traversed by one of the currents, and the remaining coils would be traversed by the other current.

With this arrangement the points where the currents would enter and leave would be fixed, and as a result the inductive action of the flux M K would not be neutralized. Under these conditions if R were rotated at the same velocity as the flux—that is, in synchronism with it—no induction would be set up in its wires, as these would not be cut by the lines of force; therefore, the only flux that would cut the wires on the inner side of F would be M K. This induction would be alternating, and owing to the angular relation of M K with reference to the field coils and the phase of the currents flowing therein, it would act nearly in opposition to the e.m.f. of the current, the impressed e.m.f, and result in causing the current to lag very much behind its e.m.f., and therefore to have but a small energy value. The action of the flux M K upon the field coils would be the same as that which takes place in a choking coil, the energy in the circuits would be cut down, but none of it would be transferred or abstracted from the circuits in any way.

If R is allowed to run at a slower velocity than the rotating field M K, then currents will be developed in its coils, and the flux E $E^1$ will appear, and this cutting through the inner sides of the field coils will induce therein c. e.m.fs. which would have the effect of reducing the lag of the current and increasing the energy thereof. The increase of energy in the field circuits would be directly proportional to the e.m.f. induced therein by the flux E $E^1$, and as in the case of the field developed by the continuous current and the rotating brushes, this e.m.f. would be a true measure of the energy transferred from the field coils to the armature. The flux M K, therefore, simply acts as a regulator of the amount of energy appearing in the field coils, while the flux E $E^1$ represents the transfer of energy from field to armature, and is a measure of the total work done; that is, the e.m.f. induced by E $E^1$ in the field coils multiplied by the current in phase with it is equal to the energy abstracted from these coils, which appears in the armature as electrical, mechanical and thermal energy.

## NOTES.

**Worcester Polytechnic Alumni Dinner.**—The annual dinner of the Worcester Polytechnic Alumni Association of New York took place in New York on Feb. 3. In an address President Mendenhall called attention to the great growth of the institute from a single building, besides the shops, and thirty students, to a teaching force of forty and an equipment which has involved an expenditure of $112,000 on apparatus alone during the past ten years.

**New England Electric Railways.**—A recent map published by Mr. R. H. D. Derrah, of the Boston Elevated Railway Company, plots 2157 miles of electric railways in the States of Massachusetts, Rhode Island and Connecticut. The map has a special interest from showing the network of systems developed in these States, which in time will be duplicated everywhere in the United States where there are thickly populated districts. One can now make an uninterrupted journey in New England on electric railways between towns in New Hampshire and in southern Massachusetts, Connecticut and Rhode Island.

**Y. M. C. A. Electrical Club.**—The Young Men's Christian Association of Chicago has a flourishing electrical club, which holds stated meetings for the discussion of electrical questions. Among topics recently announced is "Do electrical occupations pay," and to obtain data for its discussion. Mr. George A. Damon, director of the club, has addressed a letter to a large number of men of acknowledged reputation who have attained success in various electrical lines, submitting a comprehensive list of questions for answer. In other large cities it would appear desirable for the Y. M. C. A. to extend its usefulness by the addition of a similar branch.

Digitized by Google

**Two Electrical Journals Combined.**—Beginning with the issue of March 11, the two weekly electrical journals now published under the names of "The Electrical World" and the "Electrical Engineer" will be issued as one publication, under the name of the "Electrical World and Electrical Engineer." The issue of March 4—the last under its present name—of the first-mentioned journal commemorated its quarter-century of existence, having been founded as the "Operator" in 1874, and transformed into "The Electrical World" in 1883. The "Electrical Engineer" was founded in 1882 as a monthly, becoming a weekly in 1889.

**Electric Platform Railway at Paris Exposition.**—Our Paris correspondent writes that after a six months' experimental trial, just finished of a 1000-ft. section, the administration of the Paris Exposition of 1900 has given a contract for a movable platform for passenger traffic between the Esplanade des Invalides and Champs de Mars. The platform will consist of two parts, one having a speed of 2.4 miles per hour, and the other a speed double this. Power will be furnished by three-phase motors, of which 28 were used in the successful trial mentioned, four in series on a 212-volt circuit, the frequency being 25. The platforms will carry a central rail, articulated at intervals of 13 ft. This rail will bear on pulleys which will be geared to three-phase motors, the shaft carrying a large and a small pulley to give the proper relative speeds to the two platforms.

**National Association of Municipal Electricians.**—A meeting of the executive committee of the Fire and Police Telegraph Superintendents' Association was held at Boston on Jan. 28, at which the name of the body was changed to the National Association of Municipal Electricians, and the annual meeting fixed for Sept. 5, at Wilmington, Del. In connection with this meeting there will be held an exhibition of electrical and mechanical apparatus used in various departments of electrical work. Among the papers already promised are the following: "The Laws and Government of the Wire Department of Boston," by Commissioner Thomas W. Flood; "Licensing of Employees Engaged in Electrical Work and the Improvement of the Quality of Work and Material," by Capt. William Brophy, of Boston; "Advisability of Concentrating the Control of all Municipal Electrical Interests Under One Head," by Morris W. Meed, of Pittsburgh; "The Underground System as Applied to the Fire Alarm Telegraph," by S. L. Wheeler, city electrician, Springfield, Mass; "The Police Signal System of Boston," by John Weigal, superintendent police telegraph, Boston; "Aerial Construction of Fire and Police Telegraph Lines," by W. H. Thompson, city electrician, Richmond, Va.; "Progress and Development of the Municipal Electrical Interests of Canada," by G. F. MacDonald, Ottawa, Canada.

**Elevated Railway Electric Traction.**—The president of the South Side Elevated Railway Company of Chicago, in his annual report, speaks in the highest terms concerning the favorable experience during the past years with electric traction on his road, the Sprague multiple-unit system being used. Owing to the reduction of operating expenses incident to the use of electricity and the increased traffic attracted by the improvement in service entailed, the net earnings were double what they had been during the same period of time just previous to electric operation. The reliability of the Sprague system, he states, had been fully tested this winter, when 150 cars (the entire rolling stock) were in daily operation, Sundays excepted, for many weeks. The storage battery auxiliary is also highly praised, the battery reducing the fluctuations, enabling the generating plant to be worked more economically, and obviating the necessity which would otherwise have existed for putting in more machinery. The cost per annual maximum h.p., it is stated, did not exceed $15, general expenses, insurance, depreciation, interest and taxes being included. Taking the months of November and December, 1897 and 1898, for comparison, steam being used during the first period and electricity during the second, we have the following remarkably favorable showing for electric traction:

| November— | (a) | (b) | (c) |
|---|---|---|---|
| 1897, steam ..... | 87.3 | 77.7 | $10,603.80 |
| 1898, electric ..... | 57.3 | 47.7 | 39,448.56 |
| December— | | | |
| 1897, steam ..... | 83.6 | 73.8 | 14,691.69 |
| 1897, electric ..... | 55.0 | 45.4 | 45,355.68 |

Here (a) is the ratio of expenses to earnings, including "Loop" rental, taxes and licenses; (b), ratio of expenses to earnings, excluding "Loop" rental, but including taxes and licenses; (c), net earnings. The road included in "Loop" operation consists of 19.44 miles of track.

**The Electrical Exhibition.**—One of the features of the electrical exhibition to be held May 8 to June 3 at Madison Square Garden, New York, in connection with the twenty-second convention of the National Electric Light Association, is an exhibit of automobiles, which will be the most complete thus far held in the country, the space set aside for this purpose having already been oversubscribed for. Another new feature is a special section for models of new inventions, which will give inventors an ideal opportunity and at nominal cost, to bring their patents before those most likely to be interested. The exhibits of boilers, engines and steam specialties, which at former shows were located in the basement, will be placed on the main floor, and the space allotted for these classes is almost entirely disposed of at this early date. Arrangements are being made for the meeting in the garden of engineering societies during the time of the exhibition, and special days are being appointed for the attendance of various classes, one having been fixed for exporters in and around New York City. Judging from present indications, late comers applying for space will have to be turned away; the contracts already closed are far in excess of previous years, and space in the garden, large as it is, promises soon to be filled to overflowing.

**Municipal Ownership.**—The Jackson, Mich., "Sunday Herald" says that if Jackson's water system is to be taken as an illustration of the "superior benefits" conferred by municipal ownership, it is not likely that the citizens will exhibit eagerness or undue haste to acquire electric lighting or railway plants. Detroit, it says, furnishes as much water for $5 as Jackson does for $16, and proposes to reduce the tax still lower. Jackson compels its water patrons to pay the entire cost of water for fire and other public purposes, and then takes $16,000 of their money annually and turns it into the contingent fund to help out the taxpayers who do not patronize the water works. Gas has been reduced since the city engaged in the water furnishing business, from $3 per 1000 ft. to $1, but water still holds inexorably to the old rates.

**Electric Light Consolidation.**—As we go to press announcement is made of the consolidation of all the electric lighting central stations in the counties of Essex, Hudson, Passaic, Bergen, Morris, Union and Middlesex, New Jersey. The capital stock of the new company, which is called the United Electric Company of New Jersey, will be $20,000,000, and all of the plants will be under one management. It is planned to build a central power plant on the bank of the Passaic River, from which current will be transmitted to all lighting centers within a radius of 16 or 18 miles. Within the territory affected are the cities of Newark, Jersey City, Paterson, Elizabeth, Passaic and Hoboken. The consolidation was brought about by Mr. Philip N. Jackson, representing the United Gas Improvement Company of Philadelphia. The plants absorbed will be kept as reserve stations for cases of emergency.

**Ether Waves.**—In an address before the recent annual alumni dinner of Worcester Polytechnic Institute, Prof. Hallock referred to the fact that all modern investigation points to the ether and its waves as the seat of force and power. In the case of the ocean, the surface waves range in size from those of the tide which have crests thousands of miles apart and a rate of two in twenty-four hours, to the little choppy waves, a few feet long and with a period of a few seconds. So in the case of the ether, the waves vary from the long, slow waves of Hertz, having a length of several yards and a measurable time of motion, to those of Roentgen, which have a length of less than one-twenty-thousandth of an inch, and which are so rapid that they will travel seven and one-half times around the earth in a single second. Through this wide range, there are an infinite number of separate and distinct forms of waves, each of which has its peculiar characteristics by which it can be recognized as completely as can a well-known face in a crowd of thousands of persons, and each of which is so tenacious of its individuality that some

Digitized by Google

of them, coming to us from the distant fixed stars, and having traveled thousands of years, do not lose their own length of time or vibration and can be so accurately determined as to tell the material from which they came, and its condition at the time when they started on their long journey. The waves are so numerous that those coming from the sun, which are not more than from one-thirty-thousandth to one five-thousandth of an inch long and one-millionth of an inch high, pounding away millions of millions of times per second, expend upon each acre of the earth's surface 10,000-h.p. continually. The source of the energy shown in the thunder storm and the cyclone is sometimes a matter of wonder, but when it is considered that one-third of this 10,000-h.p. per acre is absorbed by the atmosphere, it is seen what a vast amount of energy is waiting in the air to be drawn upon in case of disturbances. It is well known that the particles of an electrified body are in motion; in the case of the Roentgen ray tubes, these moving particles set up a bombardment of the cathode, and this in turn sets up the ether wave known as the Roentgen ray. It is certain that in the upper layers of the atmosphere, the density of the air is so small as to approach the condition in the Crookes tubes. Physicists are beginning to think that it is possible that the ether waves from the sun set up a motion in the rarefied air, and this produces the electrification which is manifest in the lightning and always exists even when not so manifested, as is shown by the fact that a flame standing at a distance of only 6 ft. from the wall of a building will show an electrification of 1300 volts above that of the earth.

---

**Snow Storms and Electric Traction.**—After the first snow storm of the winter, the New York daily press published what purported to be an interview with President Vreeland of the Metropolitan Railway Company, in which a statement was made that the electric car service was delayed on account of snow on the tracks preventing electric contact with the rails. This led to a number of inquiries to this office from subscribers who had thought—and correctly—that the underground trolley system did not use the ground. It appears that the reporter had misinterpreted a comparison between cable and electric cars, made to bring out the fact that the former, not depending upon wheel friction, were not affected by snow on the track. After the recent storm, the newspapers fell into another error, and attributed the delay in service on some of the new electric lines to failure of electrical apparatus, whereas it was due to the track cause above mentioned. The New York company was evidently unprepared to keep the rails clear, for in Washington, D. C., Manager Coleman by constant and energetic work kept the tracks clear during the same storm, and the running of cars suffered no interruption. though 12 ins. of snow fell. The same underground trolley system is in use in Washington and New York.

---

**Portraits of Coulomb and Ampere.**—An eminent member of the French Academie des Sciences writes us concerning a portrait of Coulomb, that the only one known to exist is a painting in the audience room of the Academie, and the authenticity of this is not established. A search was made in the print department of the Bibliotheque Nationale and among publications likely to contain a portrait of Coulomb, but without success. We are indebted to the same

ANDRE MARIE AMPÈRE.

source for a portrait of Ampère, from which the accompanying engraving was made. There are some yet living who knew Ampère, and we are informed that several of these, to whom the original of the engraving was submitted, pronounced the portrait an excellent likeness. Arrangements have been made for obtaining a photograph of the Coulomb portrait above referred to, and when received an engraving from it will be printed in these columns.

---

**Electricity on Board Ship.**—In a paper read before the January meeting of the American Institute of Electrical Engineers by Lieutenant-Commander S. Dana Greene facts and figures were given showing the indisputable economy of electric power for driving auxiliary machinery aboard ship. The recent position reported to have been taken by one of the Naval Bureau chiefs that such applications should not be further extended on our warships at present, because we did not have the trained men to care for the machinery, is pronounced absolutely untenable. If, it is added, it is demonstrated that an electric motor is better adapted to drive a deck winch, for example, than a steam or hydraulic or compressed air motor, then it should be installed, and the necessary men to operate it can and should be obtained. If the course suggested by the naval officer referred to had been followed in our navy for the past fifty years, Lieutenant-Commander Greene truly says that we would still have sailing vessels (the frigates and line-of-battle ships of Nelson's day), and our recent unpleasantness with Spain would have terminated very differently.

Referring to experience in the late war, it was stated that all of our regular war vessels were fitted with electric lighting plants, and many of the larger ships were supplied as well with certain electric auxiliaries, such as ventilating fans and ammunition hoists. Two of the "Brooklyn's" turrets were controlled by steam motors, and two by electric motors, and from both official and unofficial sources all of the electrical apparatus on these ships stood the supreme test of battle admirably, and the officers of the "Brooklyn" are enthusiastic over the performance of the electrically controlled turrets. They report that with respect to ease of manipulation and fineness of control, there is no comparison, but rather a contrast. This is high praise from competent authority, for the officers referred to had actual command of the turrets in battle, and their judgment is not only unprejudiced and impartial—it is final and conclusive.

Tests made on the auxiliary machinery of the U. S. S. "Indianapolis" are discussed, and it is shown that the average weight of steam used by the main engines per hour was 33,620.6 lbs., and by the auxiliaries, 10,146.7 lbs. That is, the auxiliaries consumed nearly 25 per cent of the total coal used. The main engines consumed an average of 20.63 lbs. of steam per i.h.p. per hour, and the auxiliaries an average of 119 lbs. per i.h.p. per hour (the lowest being 55.06 lbs., and the highest 318.68 lbs. per i.h.p. per hour). These results are not exceptional; in fact, they are probably better than the average obtained on most warships or merchant vessels. The new British cruiser "Powerful" (14,000 tons displacement), is reported to have used 8,300 tons of coal from England to Hong Kong, of which 3,400 tons (or over 40 per cent) were required for the auxiliaries. Under the most favorable conditions the auxiliaries of a large ship probably consume at least 20 per cent of the total coal and water used. This is more than twice as great as the consumption in a modern central station, and there is no good reason why as good results should not be obtained afloat as ashore.

A calculation is made for a first-class battleship on the basis of 1000 h.p effective at the motors, and the conclusion arrived at, that it is fair to assume that while the average steam consumption can be reduced to 75 lbs. per hour, this is 100 per cent in excess of that required for an electric drive. Assuming the average daily use of 800 h.p. effective at the auxiliaries at sea, this means a saving of 45 tons of coal per day, or that with a given coal endurance (or "steaming radius") a vessel can carry from 10 to 20 per cent less coal; or, expressed in another way, with the same coal capacity she will have from 10 to 20 per cent greater steaming radius. The average price paid in the navy for coal (including stations in all parts of the world) is probably at least $7 per ton, so that in the case assumed there is a direct saving in running expense of $315 per day for coal alone. The use of the present voltage of 80 in the navy is condemned as entirely unsuited for a large generating plant, and the three-wire system, or a standard 220 to 250 volt two-wire system, is recommended instead.

### The Single-Phase Induction Motor.

The article in another column on the design of a single-phase induction motor will be found of much interest even by those who would not care to construct the machine described, as it involves an excellent illustration not only of the application of various alternating current principles, but of the principles themselves. Inductance, power factor, slip, hysteresis, as well as the principles of the closed-circuit secondary, here appear in a concrete form that enables the mind easily to grasp their significance. We knew, in fact, of no contribution to the subject which so clearly sets in relief the principles of the inductive motor as the article by Mr. Heldt to which we refer. To those taking up the subject of induction motors, the reading of this article, followed by the reading of the articles in two preceding numbers by Mr. Berg, can be recommended as offering a means of making a full acquaintance with a subject that heretofore has been treated in a manner not easy to follow by those lacking an acquaintance with higher mathematics.

### One Hundred Years of Electricity.

An exhibition is to be held at Como, Italy, from May to November of the present year, to celebrate the discovery a century ago by Volta of the primary cell. There have been few or no discoveries more worthy of being thus marked than that of the great Italian. Up to the day of his great discovery there was no knowledge of current electricity, the only form with which acquaintance had been made being the static; and the only source of electricity was the static machine, which is utterly insignificant as a generator of electrical energy. The voltaic cell furnished the first practical source of electrical energy, and in a form that enabled experiments to be made which culminated in that of Faraday —the base of all our present electrical development. Whether we gage the discovery by what has sprung from it, or by its originality, or by its vastly greater importance over any previous discovery in electrical science, it stands forth as one worthy of centennial celebration even unto the end of time.

### Central Station Associations.

A few years ago it was evident from the discussions at the meetings of the Northwestern Electrical Association that few members were selling current on other than flat rates. In view of the generally small size of the plants represented, it was consequently encouraging to learn at the late meeting that not only were meter rates now considered a necessity, but that attention has been strongly turned toward differential charges. There can be no doubt but that the progress made in this direction has been due to the instruction given at conventions, which illustrates the great value of such associations, particularly when representative of the smaller stations, whose owners have not the aid of the technical staff employed in large plants. Even in the case of the latter the comparison of notes among managers and engineers leads to beneficial results, as has been illustrated in the history of the Association of Edison Illuminating Companies, which body has been an important factor in placing these companies far in the lead of most others of similar rank.

### Conductivity of Lamp Filaments.

It is well known that the conductivity of an incandescent lamp filament increases during the first few hours of the operation of a lamp, and that after this first increase it decreases steadily during the entire life of the lamp. According to an authority on the subject, this initial increase in conductivity is due to the perfection of the carbonization of the filament by the temperature of operation. The process of carbonization converts the cellulose thread, which is a combination of carbon, hydrogen and oxygen, into almost pure carbon, thus making a conductor of the perfectly non-conducting cellulose. The conversion, however, is not complete, and in the finished filament there is still some hydrogen. This process continues in the filament after the lamp has been placed in service, and this completion of the carbonization process is the principal cause of the increase of conductivity during the early hours of a lamp's life. As soon as this is completed there is a decrease in conductivity, due probably to a slight wasting away of the filament, as is made evident by the sooty deposit upon the globe of the lamp.

### Electrolytic Interrupter.

In "Among Our Foreign Contemporaries" will be found a description of a new form of interrupter for induction coils, which forms undoubtedly the most important improvement in connection with such coils that has appeared since the day of Ruhmkorff. The device referred to is remarkable both for its extreme simplicity and the perfection of its action, and appears to definitely and ideally solve the difficult interrupter problem. Heretofore

Digitized by Google

a weak point of induction coils has been the interrupter, and such forms that have been devised which have approached being satisfactory have also been both complicated and expensive.

---

One of the most valuable points of the new interrupter is that it does not involve a low inductance in the primary to obtain the best results, as in the case of all other interrupters. Indeed, the presence of considerable inductance was found by Dr. Wehnelt to be an advantage, actually causing the break to be more abrupt. This will enable the primary of large coils to be wound to almost any desired resistance, whereas at present such coils, to give the best results, should not have more than a single layer, which necessitates often an unduly large current in order to saturate the core.

---

**Two-rate Metering.**

We print on another page an article (misplaced in position through the exigencies of "make-up") in which the writer, Mr. Lyman E. Reed, considers the subject of two-rate metering from the consumers' standpoint. The main argument offered would, if well founded, have considerable weight, but it rests upon the assumption that there is a close similarity between the functions of a central station and that of a retailer of merchandise. While the selling of current may be compared to the selling of any other commodity, and in the eyes of the consumer be considered an identity in fact, there nevertheless exists a wide difference between the two functions.

---

A central station is primarily a manufacturer of a commodity, and while it also retails its product, this does not necessarily require that it should not be governed by the same considerations that apply in other manufactures. During a dull season a manufacturer will, in order to keep his plant employed, sell his product at a figure far below the average rate, and at no time permit small orders to interfere with the profitable working of his plant. But aside from analogies, which are notoriously unsafe criteria, a central station should, as far as possible, obtain from every consumer a price for the service rendered based upon the cost of that service. There is nothing unreasonable in this view, and as the supply of current is almost necessarily a monopoly, the central station manager is in a far different position from the retail merchant in asking that each consumer shall pay the actual cost of the current furnished, together with a fair profit, instead of overcharging those who should receive consideration, in order to sell at a loss to the small or short-hour consumer.

---

A system of discounts on bills is a very rough way of attempting to do justice to the deserving, for it does not necessarily differentiate the long-hour from the short-hour users. The nearest approach to the ideal system appears to be that devised by Mr. Arthur Wright, in which the user is charged the cost price on the use of the part of plant kept for his particular service, and the cost of producing the current consumed, with a profit added. The only objection that appears tenable against this system is that it does not make allowance for those whose maximum demand occurs at other than the hour of maximum load.

---

**Engineering Education.**

The day is not very far distant when the engineer graduate was almost invariably regarded askance by the employer, and, indeed, received but little encouragement from any quarter. He was apt to be characterized in terms little complimentary for the fault of his college education—for at times it assumed the aspect of a fault—not only by those who merely echoed the opinion of the time, but in good faith by others who had, without systematic education attained high rank in the engineering world. Even to-day we occasionally hear of one who says he would not employ a college graduate, but in view of the present consensus of opinion, based upon a generation of experience, that systematic engineering education is necessary to engineering success, such cases, instead of doing ill, are more likely to recall Æsop's fable of the sour grapes.

---

There were, of course, reasons, though mostly illogical, for the prejudice which formerly existed against the educated engineer. Many—perhaps most—of the great engineers of the day had risen to eminence without the aid of the education decried, and few stopped to think that great minds will reach the goal, whatever the handicap. The profession was based upon methods due to a long line of men whose habits of thought had little in common with those of the college graduate, and the latter, because these methods did not appeal to him, was often condemned as lacking the engineering instinct. Engineering then rested largely on empirical grounds, and the successful exercise of the profession required even a greater exercise of the judgment than at the present day, when this branch of knowledge is thoroughly systematized and its data no longer the dicta of authority but consisting of scientific fact. The lack of the seasoned judgment necessary under the then condition was probably the strongest reason for the unpopularity of the graduate, who, because he possessed a degree, doubtless thought he was a full-fledged engineer.

---

Experience through a sufficient length of time has vindicated systematic engineering education, but no small factor in such vindication has been the growth in the formerly vituperated graduate of the faculty of judgment, without which his education would have been of little avail, and the possession of which in a high degree enabled the early engineers with but little scholastic education to accomplish feats that remain the pride of the profession. Engineering education, in a broad sense does not, then, consist in merely a college education, for it implies the seasoning of the judgment, a seasoning that only comes from experience with practical affairs in which every exercise of the judgment is inexorably checked.

---

Any attempt to impart this faculty of judgment to the youth at college would appear futile, and the graduate goes into the world rather as a candidate for engineer, using that term in its older sense, than as a full-fledged engineer, as his degree may lead him to believe. The engineering course would therefore appear to have for its object the teaching of principles, the time for which should not be entrenched upon by practical work that does not materially aid such teaching. For practical work in college shops and laboratories is not apt to have much influence on the judgment, and the practical instruction imparted will either not be utilized at all after graduation, or form but a very slender portion of what it is necesary to know in any line taken up profesionally. Every employer has his own methods, and every line of work its special features—as a rule, not arbitrarily fixed, but due to the conditions existing in each case. Consequently, the young graduate has necessarily a period of apprenticeship before him—a period in which he will learn in an infinitely more thorough manner all the practical details of the particular line of work upon which his livelihood is dependent. On the other hand, once graduated he will ordinarily have little opportunity and less desire to continue the systematic study of principle, the habit of mind for which is ideally created and maintained in the academic atmosphere of a college.

## DESIGN OF A ¼ H.P. SINGLE-PHASE INDUCTION MOTOR.

BY P. M. HELDT.

The induction motor described in this article was designed to be built by amateurs, and the aim has been to make it simple and easy to construct.

The motor is designed for a single-phase alternating circuit of 104 volts and a frequency of 60 cycles per second. It has four poles, and, therefore, its synchronous speed would be 1800 revolutions per minute. The actual speed of the motor at load will be about 10 per cent less than the synchronous speed.

The primary or stator has a plain ring winding, and the secondary or rotor a so-called cage winding, consisting of bare copper conductors, embedded without insulation in an iron core, all conductors being connected at the ends. The bearing supports are provided with an oil chamber, and either a ring or felt self-oiler may be used.

In making the calculations for the motor we will follow the method much used in transformer calculation, which consists in assuming the various losses, and from these losses determine the dimensions of the parts in which they occur. We will set down the efficiency of our machine at 60 per cent and the power factor at 75, figures which obtain in machines of this size on the market. The output being ¼ h.p., or 186 watts, the intake will be $\frac{186}{.6} = 310$ watts, and the total losses are, therefore, 124 watts. We will make a preliminary division of this loss as follows:

Primary $C^2R$ loss, 25 watts.
Secondary $C^2R$ loss, 15 watts.
Hysteresis, 40 watts.
Friction and eddycurrents, 34 watts.

The primary current at full load will be $\frac{310}{140 \times .75} = 4$ amperes. From the $C^2R$ loss and the current strength we may now find the resistance of the primary circuit, $R = \frac{25}{4^2} = 1.56$ ohms.

Alowing a current density in the primary winding of 2000 amperes per sq. in., we find that the wire to be used is No. 16 B. & S. The length of this wire, which will have a resistance, when warm, of 1.56 ohms, is 354 ft.

The ohmic component of the e.m.f. in the primary circuit is 1.56x4 = 6.24 volts, and the induction or counter e.m.f., therefore $\sqrt{104^2 + 6.24^2 - 2 \times 104 \times 6.24 \times .75} = 99.42$ volts.

In a single-phase induction motor the strength of the rotating field is not constant, but fluctuates. We will base our calculations, however, on an equivalent rotating field of constant strength.

Fig. 1 shows a diagram of the magnetic field in the motor. Let N be the flux of magnetism that passes through the teeth of the stator, between A and B. Then, as the magnetic field rotates with a velocity of 1800 r.p.m., and the conductors are stationary, each conductor cuts this number of lines 120 times per second. The mean value of the e.m.f. induced in one conductor will be $\frac{N \times 120}{10^8}$, and the $\sqrt{}$ mean square, $\frac{N \times 120 \times 1.1}{10^8}$ But this value, multiplied by the number of conductors, is the maximum e.m.f. induced in the primary winding. Representing by n the number of cycles per second (60), we may write:

$$E\sqrt{2} = \frac{2.2\ n\ N\ C}{10^8} \quad (1)$$

We will allow a maximum magnetic density in the stator core of 25,000 lines to the sq. in., and make the axial width of the core double its radial depth. The maximum magnetic flux at any cross section of the core is $\frac{N}{2}$. The area of the cross section will, therefore, be $\frac{N}{50000}$. The periphery of this area is $6\sqrt{\frac{N}{100000}}$ and taking the length of turn 10 per cent greater than the periphery of the core, we have for it the value, $l = 6.6\sqrt{\frac{N}{100000}}$.

The number of conductors is equal to the total length of wire divided by the length of one turn:

$$C = \frac{L}{6.6\sqrt{\frac{N}{100000}}}$$

By substituting this value of C in equation (1), transforming and reducing, we obtain

$$N = \frac{1.8\ E^2.\ 10^{12}}{n^2\ L^2}$$

We may now substitute as follows: E = 99.4, n = 60, L = 4248 (inches). This gives N = 275000.

The magnetic cross section of the field core is $\frac{N}{50000} = 5.5$ sq. in., and the length of one turn, $6.6\sqrt{\frac{N}{100000}} = 11$ ins.

The number of conductors is $\frac{4248}{11} = 386$. As we have four poles, the number of conductors should be divisible by four, and we will, therefore, take 384 conductors.

These conductors may be distributed in 32 slots, giving 12 conductors per slot. We will wind these conductors 2 wide and 6 deep. The diameter of No. 16 double cotton-covered magnet wire is 61 mils. For insulation we allow 30 mils on each side of the slot and 30 mils at the bottom; also a clearance space of 30 mils below the surface of the teeth. This gives for the dimensions of the slots a depth of 426 mils and a width of 182 mils.

The cross sectional area of the core was 5.5 sq. ins., and the ratio of axial length to radial depth, 100. We will make the core 3½ ins. long by 1 9/16 ins. deep, which approximately satisfies the above two conditions.

The mean magnetic density in the teeth may be taken at 32,000 lines per sq. in. There are in all 550,000 lines, each passing through the teeth twice, which is equivalent to 1,100,000 passing once. The magnetic cross section of the teeth should, therefore, be $\frac{1,100000}{32000} = 34.4$ sq. ins. Dividing this area by 3.5 ins., the length of the teeth, we obtain 9.83 ins., the circumferential space taken up by the teeth. The circumferential space taken up by the slots is $32 \times .182 = 5.82$ ins. The total inner circumference of the stator is, therefore, 15.65 ins., and the diameter practically 5 ins.

Some of the lines of force that pass through the primary circuit do not enter the secondary circuit, but leak around it. The leakage coefficient is about 1.2. The total lines of force crossing the gap number, therefore, $\frac{1,100000}{1.2} = 916.600$. By dividing this number by the surface of the gap we obtain the mean magnetic density in it, $\frac{916.600}{55} = 16600$

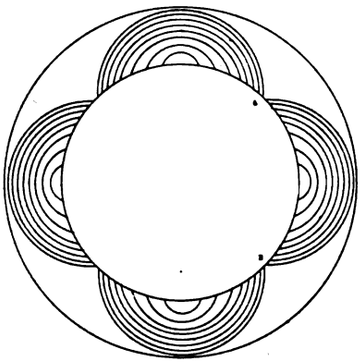

FIG. 1.—MAGNETIC CIRCUIT.

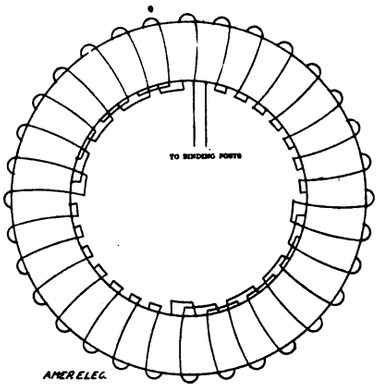

FIG. 2.—DIAGRAM OF STATOR WINDING.

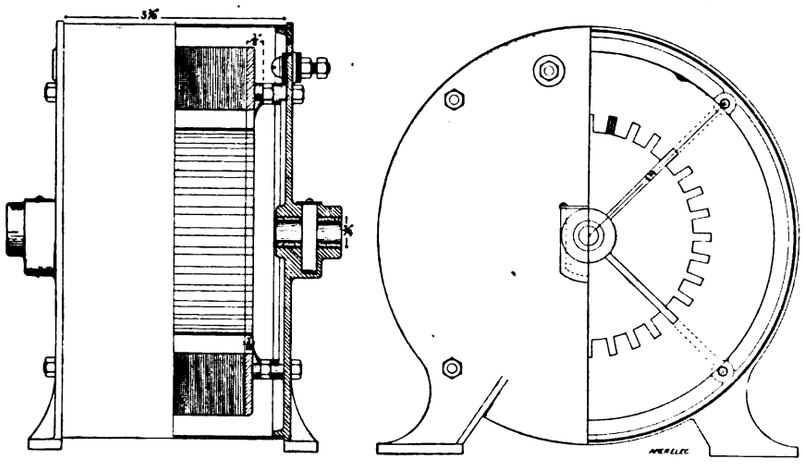
The output of our motor is 186 watts, and the allowance for friction 30 watts. The total energy transformed from the electrical to the mechanical state is, therefore, 216 watts. The $C^2R$ loss in the secondary is 15 watts. It is a well-known fact that the ratio of the motor speed to the speed of synchronism is the same as the ratio between the energy transformed in the secondary to the energy absorbed by it. The speed of our motor at load will, therefore, $\frac{2161}{23}$. 1800 = 1680 r.p.m. When a rotor be of 5 ins. diameter, running at 1680 r.p.m., develops mechanical energy at the rate of 216 watts, the tangential force on its circumference is 4.34 lbs. Now a conductor a inches in length, carrying an alternating current whose $\sqrt{}$ mean square value is I in a sinusoidal field of mean intensity, B has



Digitized by Google

a mean force of $\frac{I\,a\,B}{10180000}$ lbs. exerted on it. If there be C conductors, the force is $\frac{C\,I\,a\,B}{10180000}$ lbs. We may substitute the values of a and B and equate this expression to our circumferential force,

$$\frac{C\,I \cdot 3.5.16600}{10180000} = 4.34$$

$$C\,I = 760$$

The number of secondary conductors, multiplied by the amperes per conductor is, therefore, 760. We will put 15 conductors on the secondary, which will give a current of a little over 50 amps. per conductor. The loss in each conductor is one watt, and the resistance per conductor, therefore, $\frac{1}{2500}$ ohm. This includes, of course, the resistance of the soldered joints and the return on the ends, which cannot be exactly calculated, but which may be taken at one-half of the total, so that the actual resistance of the conductor is only $\frac{1}{5000}$ ohm. The size of wire of which a length of 3½ ins. has a resistance of $\frac{1}{5000}$ ohm is No. 8 B. & S., which we will use for the cage winding of the motor. The maximum density of our equivalent rotating field of constant strength was 25,000 lines per square inch. We have to make a small allowance for the insulation of the discs, and also take into account the fact that our actual rotating field is fluctuating, which subjects parts of the core to a considerably higher magnetic density. At 35,000 lines per square inch the hysteresis loss per cubic foot at 60 cycles is 360 watts. There are 129 cubic in. of iron in the stator core below the teeth, and the hysteresis loss would, therefore, be 28 watts. In the teeth the magnetic density will reach 60,000 lines per square inch. The hysteresis loss at this density and frequency is 840 watts per cu. ft. There are 17 cu. ins. of iron in the teeth, and the hysteresis loss is, therefore, 8.5 watts. In the rotor the hysteresis loss is practically nil, as the frequency of the reversal of magnetism is proportional to the slip of the rotor, which at full load is only one-fifteenth the frequency of reversal of the magnetism in the stator core. Our total hysteresis loss is, therefore, 36.5 watts, which is well within the limit of our allowance for it.

FIGS. 3 AND 4.—END AND SIDE ELEVATION, HALF IN SECTION.

### CONSTRUCTION OF MOTOR.

The construction of the motor will now be explained, reference being had to the accompanying drawings. As the motor is symmetrical in both vertical planes, the drawings of the stator show it part in full view and part in section.

The stator is built up of discs stamped from No. 27 transformer iron. These discs have an internal diameter of 5 ins. and an external diameter of 9 ins. They should be varnished on one side with an insulating varnish, thinned down so as to form a thin, uniform coating on the surface of the discs. The discs must be dried before being assembled. Two disc-shaped brass castings of the same internal and external diameter as the discs and a thickness of 3/16 ins. serve as end plates. These castings have four lugs on the outer edge, strengthened by ribs. Through these lugs the clamping rods pass.

A round piece of sheet iron, 10 ins. in diameter, should be procured, from which to make a templet. Find the center of the sheet iron and lay out a circle of 4 5/8 ins. radius. Divide the circumference into four equal parts and centermark the division points. Drill the center and the division joints on the circle with a small drill. (About No. 40.) This templet is clamped on the brass castings so that the holes on the circle come about over the center of the lugs. With the same small drill used before a hole should now be drilled through the brass casting. These holes are then enlarged with a ¼-in. drill. The clamping rods are ¼-in., either Bessemer or cold-rolled steel rods, cut off to 6¼-ins. With a ¼-in. standard die a thread is cut on each end of the rod to a distance of 1¼ ins.

The disc may now be assembled. The clamping rods are not strong enough to properly compress the discs, and this should be done under a drill press or in a vise while the nuts are tightened up. Enough discs must be put on to make the length 3½ ins. when tightened up. After the core has been put together it should be chucked in a lathe and a light cut taken out of it to make the inner diameter 5 1/64 ins. Care must be taken not to make the bore too large, as this would much reduce the efficiency and capacity of the motor.

The rotor is built up of discs of the same material as the stator, ⅝ in. internal diameter and 5 ins. external diameter. Two disc-shaped brass castings serve as end plates. The hole in the center of these castings should be finished to ⅝ ins.

The shaft is turned up from a piece of cold-rolled steel of ¾-in. diameter. The middle part of the shaft is turned to such a diameter that the discs fit over it and the ends so as to be a running fit in a ½-in. hole. A ⅝-in. thread is cut on each end of the middle part of the shaft.

The discs for the rotor need not be insulated but can be built right up on the shaft and clamped by the two hexagon nuts shown in the drawing. A hole is drilled into the shaft through the end plates, as shown, and a steel rod or round spike is driven into the hole and sawed off. The rotor is now put into a milling machine,

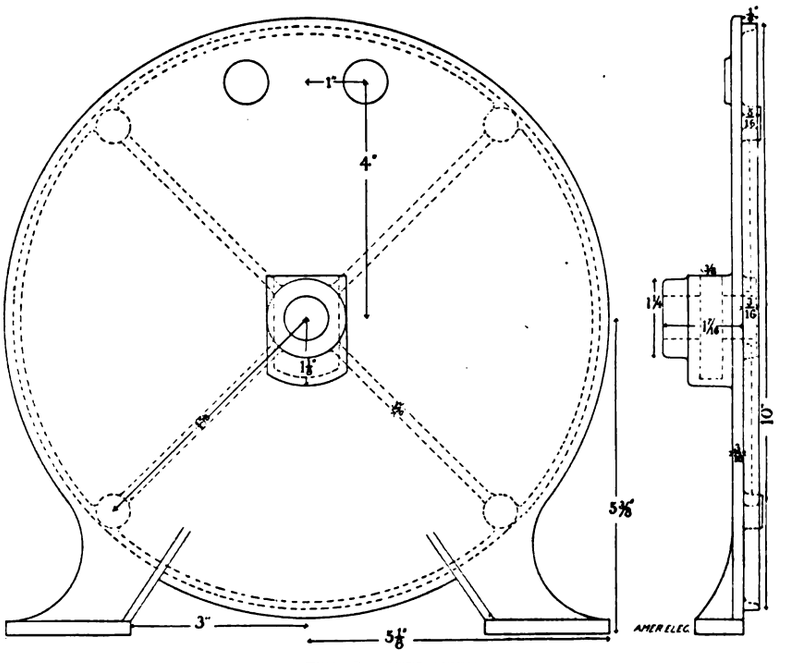


FIG. 5.—END DISC.

Digitized by Google

and, with a ⅛-in. milling cutter, 15 slots are cut 3/16 in. deep. The No. 8 copper wires have to be driven into these slots. They are soldered at the ends to the brass end plates, the solder being applied liberally and made to fill up all around the wire. The rotor should now be put in a lathe and turned down to a diameter of 4 63/64 ins. Care must also be exercised here to avoid taking too large a cut. While the rotor is in the lathe, the nuts on the shaft are turned to ⅜ in. in length.

We now take the bearing supports, and by means of our templet drill the holes for the clamping rods. In fastening the templet to the castings the centers should be made to coincide. In one of the castings two ⅜-in. holes for the binding screws are drilled through the center of the bosses provided for this purpose. A piece of soft wood is cut that will fit into the oil chamber. A ½-in. hole is drilled through this piece of wood, through which the shaft may pass.

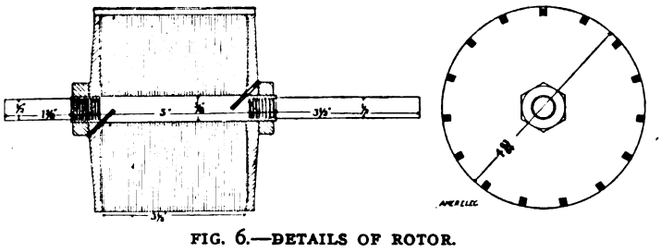

FIG. 6.—DETAILS OF ROTOR.

The rotor is now wrapped with paper until it fits tightly in the stator. It is put in place and the bearing supports are slipped on with the wood in place in the oil chambers. The bearing supports are fastened down by means of nuts on the clamping rods. Some babbitt metal should now be melted in a ladle, the motor set on end and the outer parts of the bearings filled with babbitt. The bearing supports should now be marked so that they can be put on the same way again after they have been taken off. Take off the bearing supports, reverse the shaft through them and fill up the remaining end with babbitt. The ends of the babbitt lining should now be trimmed up, the bearings put back on the core and a ½-in. reamer run through them.

We now take the stator core and put it in a shaper to cut the slots. The slots are 182 mils wide and 426 mils deep, and there are 32 of them equally spaced around the inner circumference of the stator core. After the slots have been cut, all the sharp edges are rounded off with a file and the core is cleaned of all iron dust and grease. The insulation is next put on. Shellac dissolved in alcohol is the best insulating substance to stick the insulating material to the core. Two thicknesses of pressboard, 15 mils thick should be used in the slots, the troughs being made about ⅛ in. longer than the core. The ends and outside of the core are insulated in the same manner as ordinary direct-current armatures, and it will not be necessary to describe this specially. Any one not familiar with the method of insulating armature cores may refer to the descriptions of small motors that have appeared in recent issues of the AMERICAN ELECTRICIAN.

The wire is wound in the slots two wide and six deep, while on the outside of the core it is wound only two deep. The coils are connected as shown in the diagram. In the first eight coils the ending of one coil is connected to the beginning of the next. The ending of the eighth coil is connected to the ending of the ninth, the beginning of the ninth to the end of the tenth and so on until the sixteenth. The beginning of the sixteenth is connected to the beginning of the seventeenth, the end of the seventeenth to the beginning of the eighteenth, and so on to the twenty-fourth, where the connections are changed again. The beginning and ending of the whole winding are brought out to the binding posts. These consist of ¼-in. round-head machine screws, 1¼ inches long, passing through the bearing support, being insulated from it by fiber washers and bushings. A tube of sheet iron is made, 10 ins. diameter and 5 ins. long, which will just fit over the circular offset on the bearing supports and serve to protect the windings of the stator. This completes every part of our motor, and it may now be assembled.

The motor is not self-starting, and has to be brought up to speed by some external means. If the bearings are well aligned, as they should be, a vigorous start by hand on the pulley will be sufficient to make the motor pick up. The motor should be started immediately the current is turned on, and for this reason a switch should be placed convenient to the motor.

## AMERICAN TELEPHONE PRACTICE.

### THE COMMON RETURN SYSTEM.

BY KEMPSTER B. MILLER.

Where a number of lines radiate from a central point to a number of subscribers' stations, the cheapest way of arranging the circuits, if expense alone is to be considered, is to make each a grounded circuit. This is done by grounding each line at the subscribers' station after it has passed through the telephone there, and also at the central office after it has passed through the coil of the annunciator or signalling device. Such an arrangement is shown in Fig. 1, and it may be assumed that the lines there shown run in the same direction —on the same poles or in the same cable— to the various subscribers which they serve. In each case D is the line drop at the central office, and R represents the entire telephone set at the several subscribers' stations.

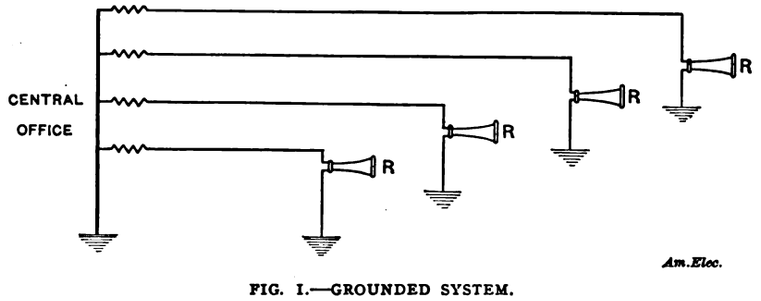

FIG. 1.—GROUNDED SYSTEM.

It is evident that with such an arrangement, disturbances in the receivers may be produced by any one or all of the causes already considered. An electric light or power wire, carrying a heavy current may cause trouble by electrostatic or electromagnetic induction, or by leakage; and moreover, each telephone wire, when in use, may be a disturbing wire to all of the others.

As has been pointed out, the proper remedy for these disturbances is to make each line a separate metallic circuit, and to properly transpose the two sides of each circuit at frequent intervals where the lines are long. This course is followed in most large telephone exchanges, and many small ones; but it frequently happens that commercial considerations will not allow it in smaller installations. Where this is the case a system called the common return or McCluer system is frequently used, with excellent results. The layout is the same as that of the grounded system, with the exception that the return of every circuit is made through a heavy wire common to all of the circuits. A clear conception of the common return system may be had by considering a heavy wire, Fig. 2, to take the place of the earth in a grounded system; each line wire being connected to it at or near the subscribers' station after passing through the telephone instrument R, and at the exchange after passing through the switchboard drop D.

It is quite evident that the common return system will, if properly installed, remove all trouble due to leakage or earth currents; for the entire system of wiring may be kept highly insulated from the ground and from other conductors. Practice, however, differs to a large extent in this respect, as some companies ground the common return wire at the exchange, and also at several other points along its length, others at the exchange only, while others keep it entirely insulated from earth. Probably the reason for placing several grounds on the return wire is to effect a reduction in the resistance of the return path, but this, if needed, should be brought about in another way. Probably the

Digitized by Google

best practice in most cases is to keep entirely free from grounds, although there are many who claim to have effected a marked improvement by heavily grounding the common return at the central office. At any rate, this is an easy experiment to try. The location of the common return wire with respect to the other wires on the poles, is a question concerning which there is much difference of opinion. Undoubtedly the best way of disposing it, so far as the purely electrical considerations are concerned, is to place it on brackets between the two middle cross arms on the poles, for then it bears a more symmetrical position with respect to all of the line wires and is, therefore, better adapted to neutralize induction from outside sources. It is, however, often put on other parts of the pole, sometimes above all the wires, sometimes on a bracket just below the top cross arm, and frequently below the lowest cross arm. The latter is probably the most convenient place, as wires led off to buildings will usually stand clear of the other wires on the pole.

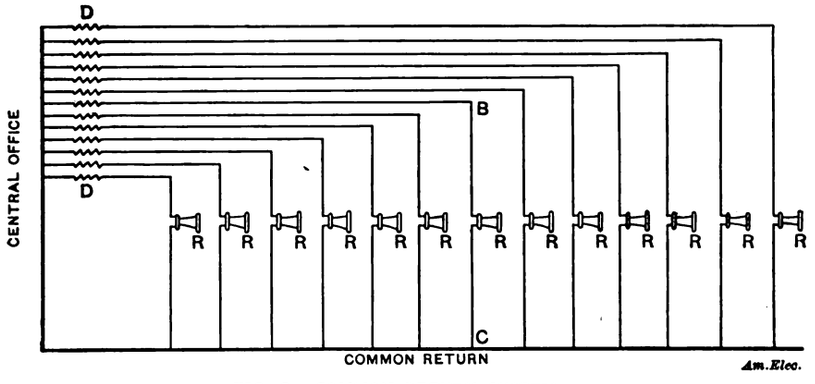

FIG. 2.—COMMON RETURN SYSTEM.

There is even more difference of opinion as to the proper size of the common return wire, than its location. An analysis of the inductive action from neighboring wires may perhaps throw some light upon the subject. If we assume that the entire system is insulated from the ground and from other conductors, it will be safe to say that all disturbances in the telephones due to leakage or earth currents will be eliminated. The only way, therefore, by which neighboring wires can affect the telephone wires is by induction, and this may be either electromagnetic or electrostatic, or both. The ideal arrangement of the common return wire with respect to the line wires would be that in which all were at an equal distance from the disturbing wire. This condition can only be roughly approximated in practice, but in Fig. 3 it will be assumed that the disturbing wire, which may be a trolley or electric light line, is at approximately the same distance from the line wires 1 and 2 and from the return wire CR. The lines 1 and 2 are connected together at central by the cord circuit C, a clearing-out drop being bridged between the cord and the common return, and the line drops DD cut out as in ordinary practice.

It is evident that if no sounds are to be produced in the receiver of line 1, the points A and B must be of equal potential. Similarly the points a and b must be of equal potential for no disturbance to be produced in the receiver of line 2, and the points C and C¹ for no current to flow through the clearing-out drop. It matters not if C, a and A are all of different potentials, the one requisite for silence in the receivers being that the two points at the terminals of each shall be of the same potential. The question, therefore, becomes, what size of wire shall be used for the common return in order to bring about these conditions?

Considering the induction from the disturbing wire to be electromagnetic, it is evident that the electromotive force set up in the several wires will be proportional only to their lengths, as their distances from the disturbing wire is assumed to be the same in each case. The sizes of the wire will have nothing to do with the pressure developed, any more than the size of the wire *per se* affects the electromotive force developed in the armature winding of a dynamo. In the case of the wire 1 the e.m.f. generated in the length CA will equal that generated in the length C¹B of the common return wire. This means that the points A and B have the same potential as have also C and C¹, and no current will flow through the receiver of that line or the clearing-out drop. By the same reasoning the pressure developed in length Ca of line 2 will equal that in the length C¹b of the common return, and no current will flow through the receiver of line 2. So far as electromagnetic induction is concerned, therefore, the size of the common return wire is immaterial.

Considering the question from the standpoint of electrostatic induction, it will be seen that for a given charge on the disturbing wire charges of the same potential will be induced on each of the line wires and on the common return wire. There will, perhaps, be a slight tendency for the small wires to assume charges of slightly higher potential than the larger wire, on account of their smaller radius of curvature, but this would be so slight as to be negligible under the conditions assumed, and would be eliminated were the common return wire made of the same size as the line wires.

So far as inductive disturbances from outside sources are concerned, it seems that the size of the common return wire is practically immaterial, with perhaps a slight theoretical advantage to be gained by making it of the same size as the line wires. In as much as this view is at direct variance with all written statements I have seen on the subject, it is put forward with hesitation.

The same reasoning will show that when any one of the telephone lines is considered as the disturbing wire, the same conclusions are reached.

So far no valid reason has been shown for making the common return larger than the line wires. There is, however, a good reason why this should be done, and this is the fact that the return circuit of any one wire, is made not only through the common return wire, but also through all of the other line wires in multiple. Referring to Fig. 2, it is evident that currents generated in line ABC may find a return path through the common return wire, and through all of the other wires in multiple. In fact all of these return paths will be chosen, the current dividing among the other line wires and common return, inversely as to their respective impedances.

The current flowing through these other lines would produce cross talk were they of sufficient magnitude to do so, and the only way of preventing this is to make the common return wire of such low resistance that practically all of the current will pass through it. The fact that the common return wire may be made to possess practically no self induction, and, therefore, only the impedance due to its ohmic resistance; while the line wires all include in their circuits either the receiver and induction coils or the bell and drop coils, serves to divert nearly all of the current through the common return wire, where it belongs. On account of the marvelous sensitiveness of even poor receivers, a comparatively small resistance in the common return will shunt enough current through the various instruments to cause cross talk to a considerable extent.

There is undoubtedly a large amount of copper wasted in common return wires, and it is probable that a No. 8 B. & S. gage

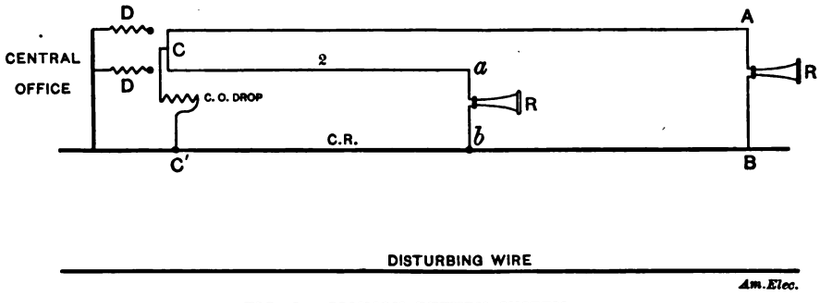

FIG. 3.—COMMON RETURN SYSTEM.

Digitized by Google

copper will in most cases answer the purpose. It too frequently happens that larger common return wires are used in the hope of remedying a difficulty which is due to another cause entirely. Cross talk in switchboards and office cables is often attributed to the smallness of the return wire, which in this case might be increased indefinitely without improving the service.

Of course, the ideal conditions assumed for the disposition of the wires cannot be attained, and in so far as they are not attained, induction is likely to occur.

## INTERIOR WIRING.

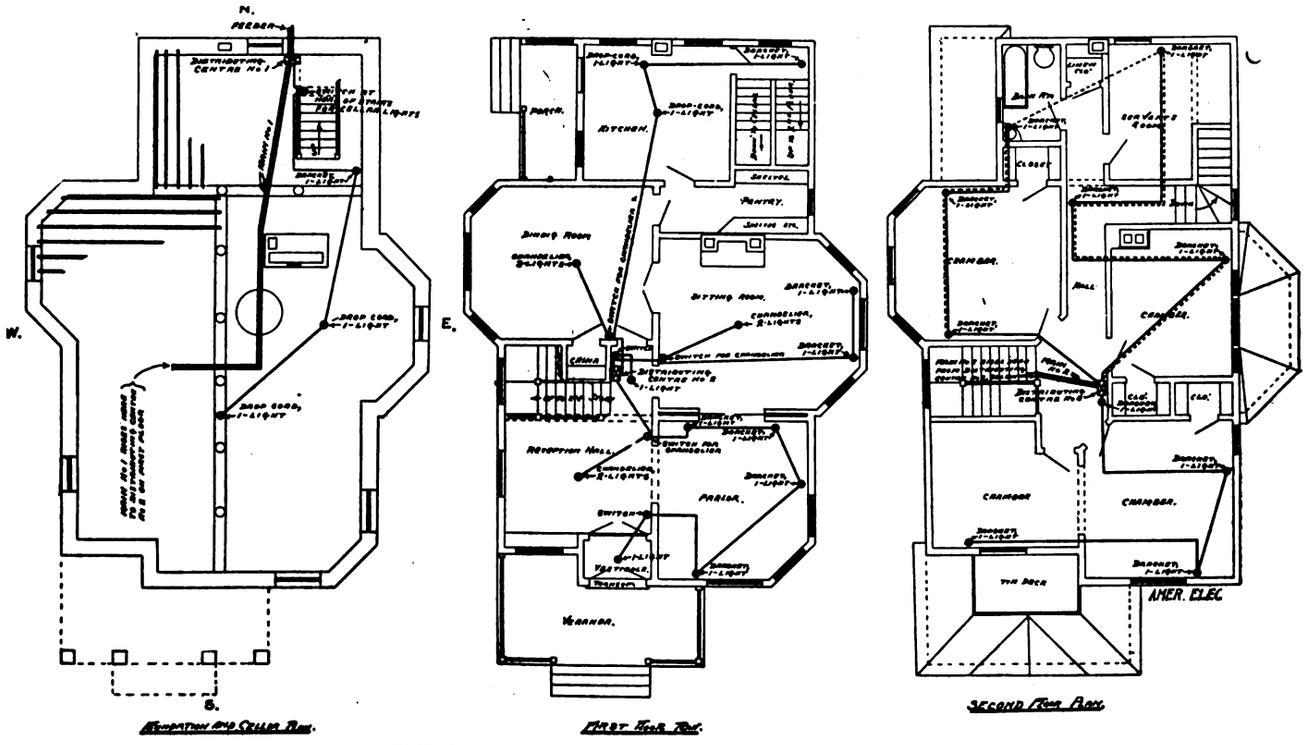
### BRANCH CIRCUITS AND CALCULATION OF CONDUCTORS.

BY CHAS. E. KNOX.

The lights having been satisfactorily located in the preceding article in the building selected, the next thing for consideration is to arrange the branch circuit work. It is presumed that the lights have been located in conference with the architect. If this be the case, the next thing to settle with him would be the location of the distributing centers, the point where the mains may rise and to determine what space is available for the branch circuit conduits.

Taking up the first of these points, we have assumed that the current will enter the rear of the house. We will therefore place the main distributing center on the rear wall of the cellar. Here the service switch and meter may be placed without taking any space that is likely to be useful for other purposes. It can readily be seen by inspection, that one center of distribution will be ample for each of the upper floors. A good central for these groups of cut-outs is shown in Figs. 2 and 3. (See February number.) Being placed in the stair hall, they have the advantage of being accessible at all times without being obtrusive.

In regard to the rising point for the mains, no trouble will be found in a frame building of this kind, as space between the "studs" forming the frame-work for the partitions, can be utilized.



As to the available space for the branch circuits, no trouble will be found in placing these conduits if the beams are "furred" for lathing, as the conduits can run between the furring strips in one direction and between the beams and above the furring strips when they run in a direction perpendicular to the furring strips. If no furring strips are used, the beams will have to be notched for the conduits.

As to the exact course of the branch circuits from the distributing center to the various outlets, we will indicate the number of branch circuits, the grouping of the outlets on these circuits, but will not attempt to show the exact course or the location of the branch circuit conduits. Some years ago, a leading electrical engineer in New York City devised a very clever scheme where, by using characteristic lines and various symbols, not only the intended course, but the exact location of every conduit could be designated. There were also symbols representing the various kinds of outlets and even suggesting the kind of fixtures intended to be used. Notwithstanding the comprehensiveness of the scheme, it was so exceedingly simple, that any wireman could grasp it in a remarkably short time, by means of a schedule of symbols furnished with the plans. We will not attempt to do this here, because in the first place, it is beyond the scope of this article, and in the second place, the symbols and lines used for that particular purpose are copyrighted.

Coming back to the branch circuit work, let us commence with the cellar. Run one branch circuit from the cellar distributing center to the switch at the head of the cellar stairs and thence to the three outlets in the cellar, (see Figs. 1 and 2). This length of circuit would, of course, be shorter than it would be if the circuit originated at the first floor distributing center.

On the first floor we find there are fourteen outlets and eighteen lights. If we allow three circuits for these outlets, we will have an average of six lights to the circuit. We might get along with two circuits, but this would allow very little margin for increasing the number of lights. A fair grouping of the lights on three circuits is shown in Fig. 2. Where branches are shown here at switches (as in the dining room), it is intended that one portion of the circuit is controlled by the switch (in this case, the chandelier), the other portion being connected back of the switch and therefore not controlled by the switch. (See diagram in a previous article.)

On the second floor we have ten outlets, supplying a total of ten lights. Two circuits would be ample, so far as the number of lights is concerned. It is questionable, however, whether there would be any saving in having the lights arranged here in two circuits over their arrangement on three circuits. Figure 3 shows both arrangements; the grouping of the lights in the rear portion on two circuits being shown in full lines, and on one circuit in dotted lines. Of course, the circuit work could be shortened by "branching" at a light outlet, but for the reasons given in a preceding article, the objections to this offset the slight saving in cost.

FIGS. 1, 2 AND 3.—LOCATION OF LIGHTS AND CIRCUITS.

Digitized by Google

The branch circuit work having been laid out, the next step is to arrange the feeder and main circuit work. In order to do this, a sectional elevation of the building should be obtained from the architect, showing the number and heights of stories. A section of the building under discussion is shown in Fig. 4. On this section indicate the distributing centers (diagrammatically) on each floor. Determine the number of lights fed directly through each distributing center. In this particular case there are three lights fed from the cellar (main) distributing center, eighteen from

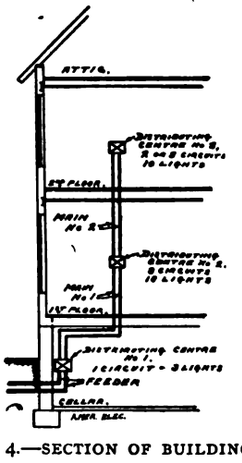


FIG. 4.—SECTION OF BUILDING.

the first floor and ten from the second floor distributing center. By inspection in this case it is readily apparent that one feeder with prolongations (mains) will be sufficient. As there are so few hall lights, of course no special provision need be made for them. Show the feeder and mains on the sectional elevation connecting the three centers (see Fig. 4). Then indicate them on the floor plans, following as closely as possible their definite proposed location (as their approximate length is necessary to determine their size). Then get the length of the mains from the plans and the elevation, allowing a certain percentage in addition to the calculated length for deviations, etc.

In this case we will assume that the length of the feeder from the transformer to the main distributing center is 150 ft. It will also be taken for granted that this feeder is to be supplied by the wiring contractor and not by the local lighting company. The lighting company will, of course, supply the transformer and the meter.

The remaining question to be settled is the amount of loss to be allowed from the transformer to the most distant lamp. Assume that this total loss is to be three volts. About one volt of this should be allowed for the branch circuits. If this be done, two volts remain to be divided between the feeder and mains. Suppose that of this amount, one volt be allowed for the feeder, six-tenths for main No. 1, and four-tenths for main No. 2.

With these assumptions, let us make a preliminary calculation of the sizes of wire required. If the results obtained from this allotment of the losses is not such as to give the best results at the least cost, a new apportionment of the losses and a second calculation should be made. Now summarize the data for the feeder and mains as follows:

Feeder, length, 150 ft.; load, 31 lights; loss allowed, one volt; main No. 1, length, 55 ft.; load, 28 lights; loss allowed, 6-10, (six-tenths); main No. 2, length 29 ft.; load, 10 lights; loss, 4-10, (four-tenths).

Using the formula, size in circular mills,

$$= \frac{\text{No. of lamps} \times \text{length in ft.} \times 11.42^{*}}{\text{drop in volts}}$$

we find the following sizes of wires: Feeder No. 4, B. & S. wire; main No. 1 = No. 6 B. & S. wire; main No. 2 = No. 12 B. & S. wire. As these sizes and losses make a good arrangement, we will adopt them.

This practically completes our task so far as the plans of this particular building are concerned, with the exception of the schedules.

Schedules present a very useful method for collecting all the data relating to the circuit work, and putting them in a concise form. It is well to have a schedule for the outlets and lights, giving the number of each kind of outlet on each floor with a summary of the total number of each kind on all the floors. A schedule of the feeders and mains, giving size of wire, length and loss in volts of the feeders and mains is almost essential. It is also well to make a schedule of branch circuits showing the number of outlets and lights supplied by each circuit, also a schedule of switches giving the outlets or circuits which they control.

## INDUCTIVE LOADS ON ALTERNATING CURRENT TRANSFORMERS.

At the recent Milwaukee meeting of the Northwestern Electrical Association, Prof. D. C. Jackson read a paper on the effect of inductive loads, such as arc lamps, on the regulation of secondary alternating current circuits, in which the importance of the question was illustrated by examples taken from practice.

As an illustration, three 5000-watt transformers for frequency of sixty were taken. Each had 2 per cent resistance drop at full load and the reactive drops were 3 per cent, 5 per cent and 7 per cent, respectively. A primary pressure of 1120 volts was assumed and a secondary pressure of 112 volts.

In the case of the first transformer, at full load the voltage at the secondary terminals would be reduced by reactive and ohmic drops to 109 volts. With a load of arc lamps having a power factor of .7, the secondary pressure would become 108 volts, thus giving a drop of four volts. In the case of the second transformer, the drop in the transformer would reduce the voltage to 109.6 volts, while with a load of arc lamps having a power factor of 7 per cent, the voltage would be reduced to 106.4 volts.

In the case of the third transformer, the secondary voltage would be 109.5 volts with a non-inductive load such as incandescent lamps. With a power factor of 50 per cent, which is sometimes met with in practice, the secondary voltage would be 104.1.

The above illustrations show clearly that it is necessary to use transformers with little reactive drop in case inductive loads are operated from the same transformers as incandescent lamps. Transformers with a frequency of 60 should be purchased with a guaranteed reactive drop not exceeding 5 per cent at full load in any size, and not exceeding 3 per cent at full load in the larger sizes. Many of the older transformers, Prof. Jackson stated, show a reactive drop with 60 frequency which exceeds 10 per cent at full load and some even approach 20 per cent. In the latter case, with a resistance drop at full load of 2 per cent, the secondary voltage with a full load of incandescent lamps would only be 105.5, or a drop of 4.5 per cent; while with a secondary load of arc lamps having a power factor of 70, the voltage would fall to 93.5. High frequencies cause the reactive drop to be increased, and Prof. Jackson believes it hardly possible to operate together arc lamps and incandescent lamps at a frequency of 133.

A determination of the reactive drop in a transformer may be made as follows:

Short circuit the secondary coil through an ammeter and connect the primary coil to a lighting circuit through a variable resistance. Adjust this resistance until a normal full load current is indicated by the ammeter. Then the reading of a voltmeter across the terminals of the primary coil gives the total drop of pressure. The resistance drop is found directly by dividing the copper loss of the transformer by the ammeter reading and the reactive drop then obtained by squaring the drop measured, subtracting from it the square of the resistance drop and taking the square root of the remainder.

Prof. Jackson stated that some arc lamps he has tested had a power factor as low as 50 per cent, which means that the transformer capacity required for such lamps is just twice as great as that required for incandescent lamps aggregating the same watts. The capacity of a transformer is measured by the current which passes through it and with the power factor of 50 per cent, half of this current is idle current. Lamps that are purchased should be tested by central station men for watts absorbed in the arc, watts absorbed by the lamp, as a whole, and volt-amperes absorbed by the lamp. This, he states, is a matter of a few minutes' work, providing the necessary instruments are available.

## SAVING BY THE THREE WIRE SYSTEM.

ALTON D. ADAMS.

A well-known rule of electric circuits is that the weight of copper required to transmit a given amount of energy at a certain percent of loss varies as the square of the pressure at which the transmission takes place for any given distance.

Recently a writer, evidently not in accord with this rule, has stated that "the actual

*The constant for 104-volt 16-c.p. lamps.

Digitized by Google

saving in wire by the use of the three-wire system is one-fourth when the neutral wire is made the same size as the outside wires, and when an equal drop is considered," and again, "these two reductions then constitute a total reduction of area to one-fourth the original size, but the loss in the two systems will not be the same if this process is carried out."

Now the purpose and use of the three-wire system is to double the pressure or volts at which electric energy is distributed to incandescent lamps so that for the common cases with the 110-volt lamp and 10 per cent loss of energy on the two and three-wire systems, the two-wire pressure would be $110 \div .9 = 122.22$ volts, and the three-wire pressure, $2\ (110) \div .9 = 244.44$ volts at the dynamo.

According to the law above stated the weight of copper required for the three-wire system is three eighths of that for the two-wire for the same number of lamps and loss of energy in each system, allowing the neutral wire to be of the same size as each of the outside wires.

To make clear the several factors involved in each case, Figs. 1 and 2 are used to show the arrangement of each system for the same number of lamps. When all lamps are burning on the three-wire system the neutral wire does not convey energy either to or from the lamps, and it

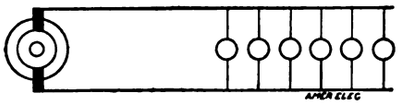

FIG. 1.—TWO-WIRE SYSTEM.

might be disconnected at the dynamo without changing conditions in the system.

If, however, at any time more lamps are connected to one outside wire and the neutral than to the other outside and the neutral, the neutral comes into use as will be shown hereafter.

The size of the neutral wire for any three-wire system is usually made the same as that of the outside wires, but this is simply a good guess as to the amount of work the neutral wire may be called on to do; again, the neutral is frequently made equal in size to the sum of the outside wires, especially in buildings, so that a change can be made to the two-wire system if desired by connecting the two outside wires as one and the double size neutral as the other.

The subject of direct calculation in the three-wire as in the two-wire system is the size of the two outside wires, and the size can be shown to be but one-fourth as great for the three as the two-wire system for the same energy loss.

Consider the case of 100 110-volt, 0.5 amp. lamps connected on the two-wire, also on the three-wire system under conditions of 10 per cent loss above stated.

The amperes flowing in the two-wire system are $100 \times .5 = 50$, and as the dynamo pressure 122.2 minus the lamp pressure 110 is lost in wiring, the watts consumed in wiring are $12.2 \times 50 = 610.0$. As in the three-wire system current passes from one-half of the lamps to the other half, the required current is but one-half as great as that for the two-wire system, so that for the present case the current in three-wire system is $50 \times .5 = 25$. amps., while the volts lost are $244.4 - 220 = 24.4$, making the watts consumed $24.4 \times 25 = 610.0$, the same as in the two-wire system, for the same percent of loss.

It should be noted that, though the total variation in pressure for the same percent of loss is twice as great in the three as in the two-wire system, yet the variation of pressure at each lamp, or between either

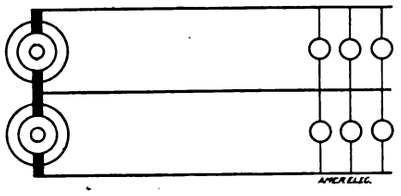

FIG. 2.—THREE-WIRE SYSTEM.

outside wire and the neutral is the same as that of the two-wire system; thus the pressure between the neutral and either of the dynamo terminals in above case is $244.4 \div 2 = 122.2$ volts, or just that of the two-wire system, and of this 122.2 volts, 12.2 volts are lost in the outside wire from either half of the lamps to the dynamo, this being the same loss as in the two-wire system.

Having proved above, that, for a given number of lamps, equal energy is lost in each system when the total drop in pressure in the three-wire is twice that in the two-wire system, the next step is to show the relative area and weight of two conductors, one of which is designed to conduct one-half the amperes with double the applied volts of the other, each having the same length.

Taking first the two-wire mains with current in them of 50 amps. and pressure loss of 12.2 volts, by the formula amperes = volts ÷ ohms., $50 = 12.2 \div$ ohms., so that, ohms. $= 12.2 \div 50 = 0.244$; that is, the two-wire mains must have a resistance of

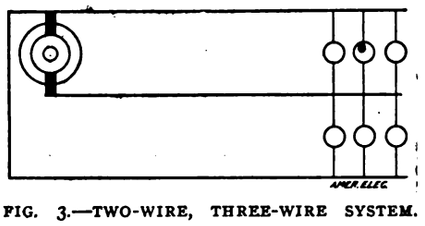

FIG. 3.—TWO-WIRE, THREE-WIRE SYSTEM.

0.244 ohms. The three-wire mains have in them current of 25 amps. at 24.4 volts, so that $25 = 24.4 \div$ ohms., or ohms. $= 24.4 \div 25 = 0.976$, from which the relative resistance of the three-wire to the two-wire mains is $.976 \div .244 = 4$ to 1, or the resistance of the three-wire mains is four times that of the two-wire mains for the same number of lamps, distance and loss of power. Taking 11 ohms as the resistance of a copper wire 1 ft. long and 1 mill diameter, the size of wire in circular mills for the two-wire mains is found from $0.244 = 11\ L \div$ c.m. or c.m. $= 11\ L \div .244$, from which c.m. $= 45.08\ L$, in which L is the total length of wire in mains.

The three-wire mains having a resistance of 0.976 ohms require a section of c.m. $= 11\ L \div .976 = 11.27\ L$.

Now the relative area of conductors for the three-wire and the two-wire system is, from the above, $11.27\ L \div 45.08\ L = \frac{1}{4}$, and as for the same length weight varies directly with area, the weight of conductors is only one-quarter as great for the three-wire as for the two-wire system, length, lamp load and loss of power being the same in each case, and provided no third wire is required. If the third or neutral wire is made the same size as either of the outside wires, it must have one-half their combined weight, which is $.25 \div 2 = .125$ of the weight of the two-wire system, so that all three wires of the three-wire system weigh $.25 + .125 = .375$, or three-eighths the weight of the two-wire system. If the neutral wire is made twice the size of each outside wire the weight of copper for the system will be $0.25 + 0.25 = .5$ of the weight for the two-wire system. Should a three-wire system, having the neutral twice either outside wire in size, be connected as shown in Fig. 3, with the neutral wire to one dynamo terminal and the two outside wires at the other, the loss of pressure or volts and of watts in the mains will be twice as great as when the system is connected up

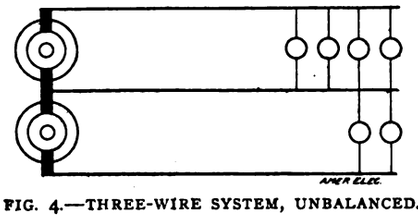

FIG. 4.—THREE-WIRE SYSTEM, UNBALANCED.

on the three-wire plan. This will be evident when it is considered that the amperes, volts, and therefore watts lost in the two outside wires remains the same in the two as in the three-wire connection, and in the two-wire there is an additional and equal loss in the neutral wire, since it then carries as many amperes as the other two.

In Fig. 4 is shown a case where the neutral of the three-wire system comes into use, as there are only one-half as many lamps between the positive and neutral wire as between the negative and neutral; in this case the positive and neutral wires each take about the same number of amperes to the lamps, and the sum of the amperes in these two wires flows toward the dynamos through the negative wire, this results in poor regulation at the lamps.

Were there no loss in the mains and feeders of the three-wire system, the pressure at lamps would be constant no matter how great the difference in the number of lamps between each outside wire and the neutral, but as there is loss in any practical system of wiring, perfect regulation cannot be had, the volts being too high between the outside and neutral wire where the less number of lamps are connected and low between the outside and neutral wire, where the greater number of lamps are connected. This lack of regulation forms one of the greatest objections to the use of the three-wire system, and central stations take precautions to have the loads on both sides the neutral as nearly equal as possible.

## STEAM AND WATER STOP VALVES.

### GLOBE VALVES.

Probably this is the most widely known form of valve that is used in present engineering practice. It is a good form of valve as far as simplicity and cost are concerned. Its one great defect is the deflection of current through it, not only once, but twice. When the stream of water strikes the valve diaphragm, it is not only turned from the direction it was following when it entered the pipe, but the stream or current, or some parts of it, are actually reversed so that they must flow in exactly the opposite direction from which they first entered the valve. And in leaving the valve, some of the fluid or gas is actually reversed in direction again. The loss of pressure caused by the above actions is considerable and goes far to offset the advantages of simplicity and cheapness mentioned above. Indeed, the tendency of engineering is toward the use of gate instead of globe valves for all purposes. But this is a mistake. There is certain work for which the globe valve is best suited, and the gate valve will not hold such work for any length of time. There are fields for both valves and they will surely find their proper fields—and hold them.

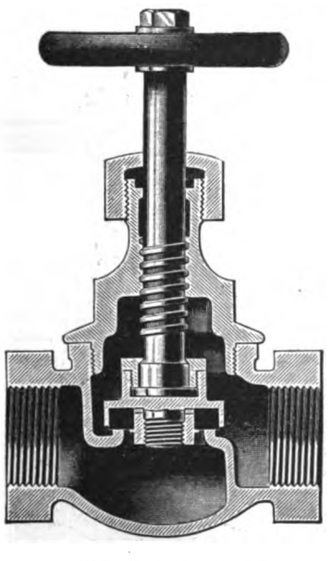

FIG. 1.—THE JENKINS GLOBE VALVE.

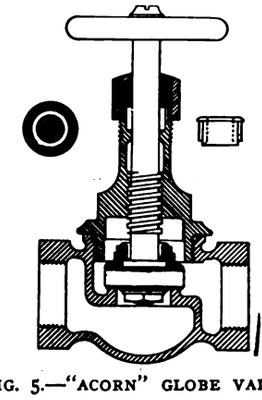

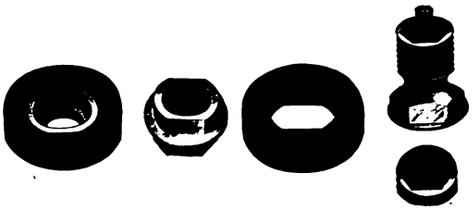

FIG. 5.—"ACORN" GLOBE VALVE.

A well-known form of globe valve is shown in the engraving presented in Fig. 1. It shows a sectional view of the Jenkins Bros. valve, in which the following distinctive peculiarities may be noted: The opening of the valve is considerable. The stem has a long travel, thus bringing the disc a considerable distance from the seat when the valve is fully open. This construction in a valve allows the passing matter to flow straight through the opening in the seat without having to make a quick turn under the disc, which acts as a baffle-plate to deflect the flow across the seat, thereby subjecting that portion of the valve to much more wear and cutting action than in a valve like that shown in the engraving, having a good deal of lift. In fact, a valve with a low lift of disc is—or its cutting action is—like a valve that is only partially open. We all know how a globe valve works which is used constantly for throttling purposes—it doesn't last long. The high lift of this valve tends to lengthen the life of the seat—and the disc as well.

The disc used with these valves is also well known, but there is one or two peculiarities that all engineers may not be aware of. Fig. 2 shows this disc, also the manner in which it is held in place by a nut which not only allows the packing to be easily removed, but actually removes it when the nut is taken off. Another peculiarity is in the packing ring. It was designed for a packing which would not be spoiled the first time sand or other dirt was caught between the disc and seat, but would yield and let the foreign matter press into the disc without doing much damage. Another thing about the packing which is there, but was not searched for, is that the packing material has a very great ratio of expansion as compared with brass. It is owing to this, that if a Jenkins valve be closed when very hot, it will leak a very little as soon as it gets cold. The packing contracts more than the body of the valve. It is for this reason that engineers, after closing a valve, always return to it after a short time and give the hand wheel another slight movement. The inexperienced engineer would at once screw the valve down tight when he closed it, thereby spoiling the disc the very first time it was used. This or any other valve should, on being closed, have the disc and seat barely touched together, and never forced together with great pressure by bull strength and stupidity on the hand wheel.

Another characteristic of this valve is the method of arranging the packing and gland nut so that the latter cannot be turned by

FIGS. 2 AND 3.—JENKINS DISC AND LOCK-NUT, AND KEYED STUFFING BOX.

FIG. 7.—DETACHABLE DISC.

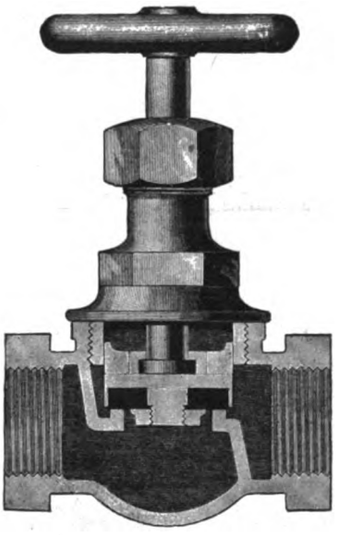

FIG. 6.—RENEWABLE DISC VALVE.

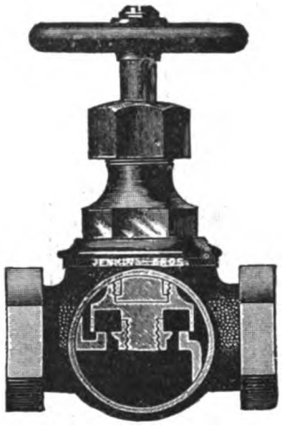

FIG. 4.—SCOTT-JENKINS GLOBE VALVE.

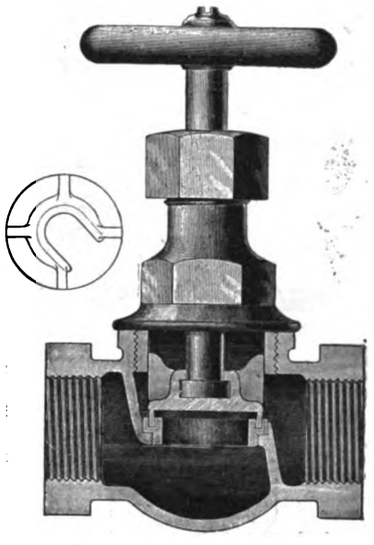

FIG. 8.—RENEWABLE SEAT VALVE.

Digitized by Google

the stem imparting motion to the packing and thence to the nut. Fig. 3 shows the "keyed stuffing box," which is made by shaping the packing box into a hexagonal form instead of leaving it round as is the usual manner. As there can be no communication of motion between the stem and the nut through the packing, there is little chance of the nut being turned off when opening the valve—a great nuisance with some of the older forms of valves.

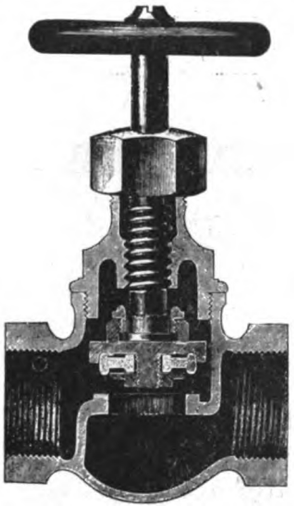

FIG. 9.—COPPER DISC VALVE.

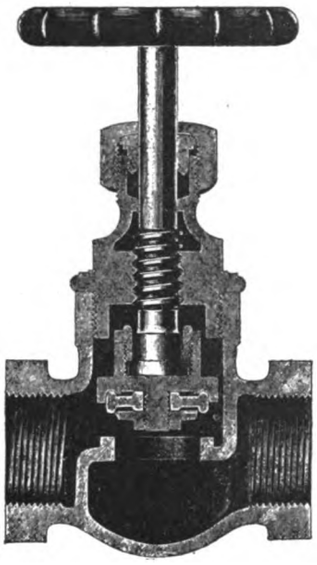

FIG. 10.—HEAVY COPPER DISC VALVE.

A valve made upon the same lines as the one described above is represented by Fig. 4. This—the Scott-Jenkins globe valve—is made by the Roe Stephens Manufacturing Company, and is a Jenkins valve to all intents and purposes, using the same packing and built in pretty much the same manner.

The valve illustrated by Fig. 5 is known as the "Oakes' acorn" globe valve, and is

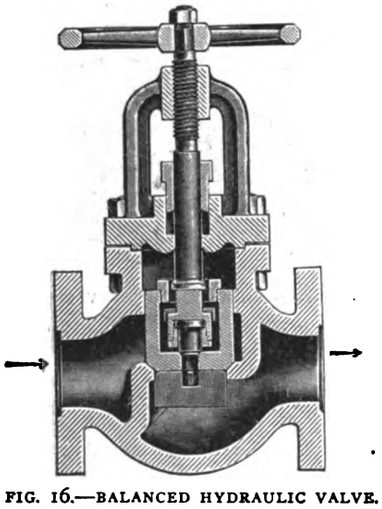

FIG. 16.—BALANCED HYDRAULIC VALVE.

manufactured by Thomas G. Oakes. The principal feature of this valve is the locked gland in the bonnet, as shown by the detail engravings. The packing does not bear directly against the nut, but is forced down by a gland which carries two lugs, which in turn engage corresponding shallow slots in the body of the valve casting. All valves above and including three-quarters inch are made with the gland above described.

When the brass to brass seat and disc valve is not used, some provision must be made for the renewal of the discs, for they are not expected to last any great length of time if there is a passage of dirt or of any other foreign substance in the water or steam. In the valve already described it may be noted that the discs are renewed by taking out a packing washer and replacing it with a new one. In the valve shown by Fig. 6 the entire disc is removed and replaced by a new one, and the packing washer in the disc may then be renewed at pleasure. By removing the bonnet of the valve the disc can be taken out without the further use of tools. There are guides attached to the disc which slide on the inside surface of the bonnet of the valve, forming a positive guide for the disc so that it strikes squarely upon the seat.

A view of the disc detached is given by Fig. 7, and the manner of its connection with the valve stem is plainly shown. These valves are represented as remaining perfectly tight under all moderate pressures of steam, oil or gas, but for very high pressures, the manufacturer, the Kennedy Valve

FIGS. 11, 12 AND 13.—SWIVEL GLAND, STUFFING BOX AND COPPER DISC.

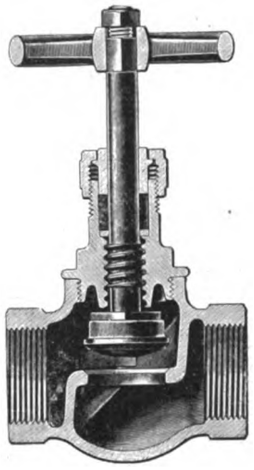

FIG. 14.—SOLID SEAT AND DISC VALVE.

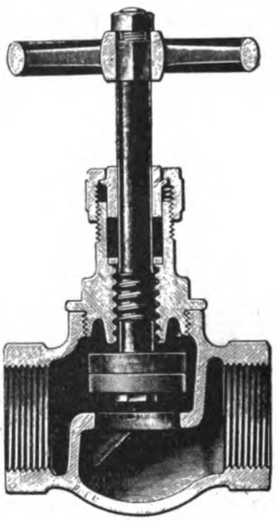

FIG. 15.—LEATHER DISC VALVE.

Manufacturing Company, claims its novel feature to be in the renewable seat, instead of in a renewable disc. As shown by Fig. 8, the seat consists of a ring made of annealed copper, slightly wedge shaped and held firmly in position by the screw nipple into which the ring is inserted. The change is made by unscrewing the bushing above mentioned and inserting a new one. All this can be done by simply removing the bonnet of the valve.

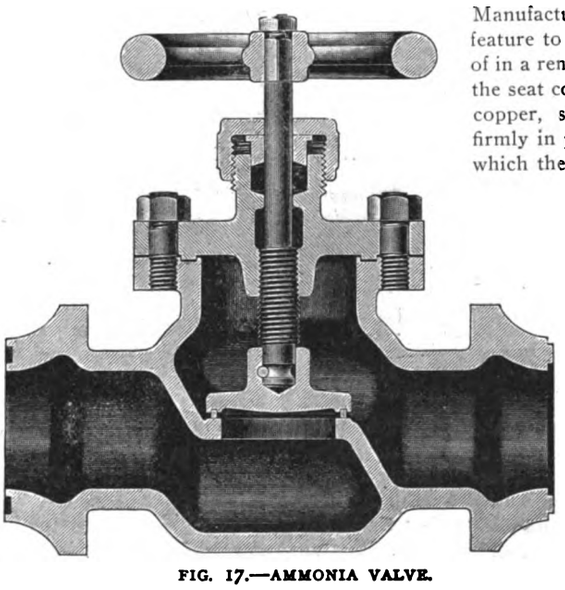

FIG. 17.—AMMONIA VALVE.

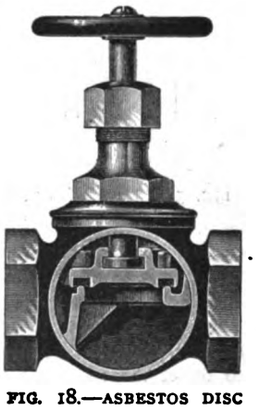

FIG. 18.—ASBESTOS DISC VALVE.

Copper seems to be a favorite substance for use in making tight valves, and in the form illustrated by Fig. 9 the disc is made of that metal. The disc is also reversible,

Digitized by Google

and when one side becomes worn or damaged it may be turned over and used again in that position. This valve is made by the Crane company, who also make the heavy form of valve shown by Fig. 10. This also has the reversible copper disc which is attached as shown. It will also be seen that there is a rounded backing which engages the under side of the bonnet when the stem is screwed out to its fullest extent for the purpose of renewing the packing. Fig. 10 also shows the manner in which the stuffing box is constructed.

The Crane valves, or at least when so ordered, are fitted with a peculiar swivel gland stuffing box as illustrated by Fig. 11. By this form of gland the pressure is always square against the packing, and there is none of that sidewise twisting business which must take place to a certain extent whenever the nut bears directly against the packing. Figs. 12 and 13 show details of the copper disc, also of the nut which holds the disc, and its manner of application to the disc and to the stem.

Figs. 14, 15 and 16 illustrate three valves made by the Eynon-Evans Manufacturing Company. These valves are the ordinary globe, the leather disc, with bronze body for acid waters—in the coal districts—and the balanced hydraulic globe valve, made for pressures of 250, 750 and 2,500 lbs. per sq. in. This valve, it is claimed, is made heavy enough to stand the pressure, and cheapness is made a secondary consideration. The lift of disc is quite short, but the area of opening between seat and disc is about 1¼ times the area of the pipe to which the valve will be attached.

The construction of the leather disc valve is so plainly shown by the engraving that little further description is necessary. All these valves may be packed around the stem while under pressure, without leakage, as the engravings plainly show.

The balanced hydraulic valve, Fig. 16, has its disc relieved of pressure by a close fit between the elongated disc and the walls of the cavity in the bonnet. Then the cavity, thus shut off by the disc, is connected with the discharge side of the valve by means of a suitable passage vertically

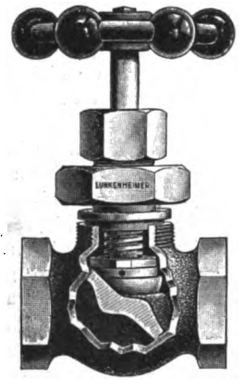

FIG. 19.—LUNKENHEIMER REGRINDING VALVE.

through the disc of the valve. No matter then, how high the pressure runs in either inlet or outlet sides of the valve, the disc—or plunger, as it may appropriately be called—must always move as easily as if there was no pressure at all against the valve.

Another form of high pressure valve is shown by Fig. 17, in which the type well known as an "ammonia valve" is illustrated. The bonnet is bolted on, instead of being screwed, and the stem is fitted with a very heavy gland and a follower, both being so beveled that the stem packing is forced against the stem, rather than squarely downward.

The valve shown by Fig. 18 is made by the Fairbanks Company, and is fitted with a disc, the wearing surface of which is vulcanized asbestos. It is claimed that the asbestos as used in these valves will not crack or flake off, thereby making a very durable packing. The discs, as shown by the detail engravings, are not screwed to the stem, but by removing the bonnet, the old disc may be removed and a new one put on in a very few seconds.

Several types of regrinding globe valves are on the market, and the following engravings show representative types of them. Fig. 19 is the Lunkenheimer, made by the

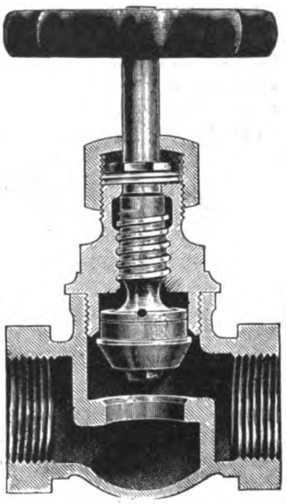

FIG. 20.—"EXCELSIOR" REGRINDING VALVE.

Lunkenheimer Company. Unlike most valves, the hub is not threaded and screwed directly into the valve shell. Instead, there is a union nut which screws over the body and clamps the bonnet to the body by means of a flat ring on the former, which lies on top of the body. By loosening the union nut, the stem may be rotated without working the thread, and if a bit of wire be put through the small hole in the disc, that will be held rigid with the stem, and the valve may be reground with a little soap and powdered sand on the disc. After this mixture is put on, replace the trimming, but leave the union nut loose. The hub will rotate and guide the stem while regrinding the seat bearing.

Fig. 20 shows another regrinding valve—the "Excelsior" made by the Kelly & Jones Company. The disc is made of a special hard alloy. By removing the bonnet and inserting a pin in hole shown in engraving, the disc is locked to the stem. The bonnet thread is then re-entered about one thread in neck of valve, when the stem may be run down until the thread is disengaged from bonnet. The valve can then be reground without further manipulation.

Still another regrinding valve, the "Star" valve, made by the William Powell Com-

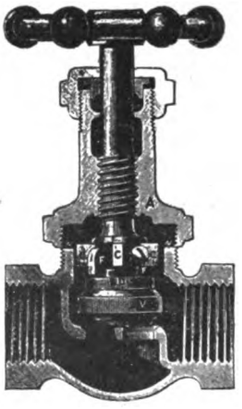

FIG. 21.—"STAR" REGRINDING VALVE.

pany, is the subject of engraving No. 21. It is claimed that this is the original of all lockable loose disc valves, and it certainly requires no pieces of wire to be inserted in order to lock the disc for regrinding. A lock-bar is contained complete in each valve, and to use it it is only necessary to release the bonnet and the stem can be taken out for inspection. A half turn of the set-screw will release the lock-bar, which will then drop into the slot in the disc and may be fastened there by the same screw.

After regrinding, return the lock-bar to its original position and fasten it there with the set-screw. Wings are provided which guide the disc and prevent all side motion to cause undue wear to the seat. This company also makes another form of globe valve—not regrinding—which carries the regular Jenkins disc packing.

## ECONOMY OF STEAM PRODUCTION.

BY A. L. HARRISON.

Continuing on the line of the latter part of the article in the February issue, I wish to call attention to a quite prevalent error as to the economy of labor due to "mechanical stokers." If the coal must be shoveled into the hopper, it will require quite as much labor per given number of boilers operated as when hand-fired furnaces are used. If coal-handling machinery be properly placed in connection, there is some labor saved, but not to the extent usually claimed by interested parties. The attempt to save labor in this connection is sometimes carried to such an extent as to preclude the possibility of proper attention being given to the fires, and in such cases the waste of fuel and extra repairs more than offset the economy in labor.

It cannot be too strongly impressed on all interested that no mechanical furnace will run itself, but must have more or less intelligent attention and supervision to keep the fires from becoming too thick, or so thin as to burn holes in the fire through which excess air rushes, destroying econ

Digitized by Google

omy. Then there is attention required to feed water, by the damper and other details too often neglected with consequent reduction of economy.

I have called attention to the labor item that I may take it plain that whatever economy may be secured by saving of labor in handling either coal or ashes mechanically, is due to and properly credited up to use of conveyers, bins, chutes, etc., and not to the "stoker," only so far as the stoker may help to make handling machinery practical.

The type of mechanical stoker known as the "automatic furnace" differs from each of the other types in almost every important practical feature. The specially unique feature of this form, however, consists in its being self-cleaning as well as self-stoking, thereby making it not only a different type of "stoker," but also a distinct class; or, in other words, an "automatic furnace," rather than a "mechanical stoker;" but, like the other "stokers," this furnace will not run itself without intelligent supervision, and while the work is less laborious, because there is little or no cleaning, there can be no reduction in the number of attendants in small plants, and not to exceed one in four in large plants without loss in efficiency, unless handling machinery is attached. The economy, therefore, to justify the extra cost for any mechanical furnace must be found in the fuel economy that can be realized after deducting the cost in fuel represented by the steam used to operate the mechanism, which, in some cases where live steam jets are used to "kill the smoke," amounts to fully 15 per cent of the steam produced.

No reader should wrongly construe the above as intended to discourage the use of mechanical furnaces. On the contrary, it is intended to encourage intelligent selection and thereby promote the use of such as can show real every day economy of fuel sufficient to justify the extra cost of installation as compared with the ordinary or hand-fired forms. The labor saving and other utility features then become additional inducements, and the economy should promote a quite general use of the best in both small and large plants.

Mechanical furnaces, in common with all new or improved forms of mechanisms, suffer from the representations made by those who think only of securing a present sale, and who, to secure it, lead their customer to expect what can by no means be realized, and the result is disappointment.

A dissatisfied user seldom appreciates the actual benefits, and in cases where a crude or ill-devised form has been "worked off" on a user, he becomes soured and condemns indiscriminately all mechanical furnaces. This accounts for so many intelligent owners of steam plants holding strenuously to such ideas as is indicated by the following quoted declarations: "No furnace can beat hand-firing." "No stoker can be crowded." "All of them will smoke if you try to crowd." Such statements come principally from three distinct classes of persons, the class whose knowledge is second-hand and unreliable; those who have become soured by having been "taken in" by a good talker, or who failed to get proper results by reason of lack of intelligent methods; and, last, but not least, those who from self-interest in an inferior form are trying to hold up their own by lowering the plane of merit due other and more meritorious forms.

As it is natural for all persons of "shady" moral practices to decry the existence of real excellence, so those who are interested in a second or third-grade mechanism naturally decry the existence of a mechanism of like designed purpose which is possessed of unusual merit. Much of the prejudice existing against use of the mechanical furnaces is due to the chatter of those who profess to have a new and improved form which, in fact, is only a modification of old or discarded forms, and which modification is in no practical sense an improvement.

It certainly is no credit to a mechanical engineer to be spending either his time or his employer's money experimenting with forms which knowledge of "the state of the art" would condemn on sight. How is the average man to know how to get at it so as to make an intelligent selection? Just as the average business man gets at intelligent selection of any other important system or mechanism for the promotion of his business interests.

One reason why so many fatal mistakes have been made in this particular line is the fact that so many business men consult those who are supposed to know, and ought to know, but who actually do not know enough about the actual "state of the art" to know what the experience has been, and know so little about the vital requirements necessary to constitute possible practical success that they are more frequently led into indorsing a failure, or only partial success, than they are instrumental in promoting the use of a furnace which will reflect credit on their professional knowledge, and be a continued satisfaction to their client.

The following quotation: "It will burn more coal per square foot of grate and give more steam per pound of coal, more steam per square foot of heating surface, raise steam more readily and maintain any given gage pressure more steadily, whether the load be regular or irregular, than any other form of furnace," is taken from the circular issued and distributed by one of the established concerns which manufactures a mechanical furnace, and is either intentionally misleading, or it is an important fact which every consulting engineer worthy the name should know.

How many consulting engineers know—remember, I say *know*—whether this declaration is in any sense substantially true or not?

I do not say this to discredit the profession, but to emphasize the lamented fact that no proper attention is given, even by those whose profession requires it, to the proper construction and arrangement of a boiler furnace.

In proof of this assertion I might cite the fact that as yet no engineer or other authority on mechanical subjects has ever attempted to publicly discuss the merits of "stokers" or mechanical furnaces in anything like a thorough manner, or so as to impart definite information as to the exact "state of the art," or the special difficulties experienced or possible benefits to be realized. There has been no discussion along this line in the American Society of Mechanical Engineers' meetings beyond the occasional reading of a paper usually dealing in generalities or based upon exact knowledge of but a single type.

Only about a year since a considerable portion of the time of no less than three sessions of the Franklin Institute was gravely occupied listening to papers read by representatives of "smoke preventing appliances," most of which would not bear intelligent discussion; and there was no discussion of either the meritorious or unmeritorious, presumably because the members had not sufficient knowledge of the subject to venture to discuss it.

It is for the purpose of stirring up the profession to a proper appreciation of the importance of this question of the possible economics to be realized by a more intelligent use of scientific knowledge relating to combustion, and of the facts of experience in the burning of "steam" coal, that I have thus called attention to these facts which are prima facie evidence of a lack of knowledge, and of a lack of a proper disposition and energy to acquire the knowledge, necessary to wisely promote improvement along this line.

## ELECTRIC RAILWAY PRACTICE.

### COMMUTATORS—THEIR CARE AND REPAIR.

BY JOS. H. SMITH.

In the early days of the electric motor commutators were not considered a very important factor in their construction. The segments were thin and small and very poorly insulated, mostly with paper, and when one gave out it was thrown in the scrap and a new one substituted.

Now everything is changed. When the inspector examines a motor for trouble, he first looks at the commutator, and in most cases by its condition can tell where the fault lies. To-day, then, the commutator receives that respect from the designer and repair men which is its due, with the consequence that most of them last about three years.

In this article some hints will be given on the care and repair of commutators, but it should be borne in mind that strict attention to the former will prevent a too frequent application of the latter.

No rule can be given to govern all circumstances, or how often a commutator should be turned or sandpapered, so this will be left to the inspector's judgment. For sandpapering a commutator in a motor a block of wood should be cut the width of the commutator and as long as the distance between the brush holders will permit. A semicircle should be cut in this of the same arc as the commutator, and a handle fastened to the back of the block. No. 2½ is the proper sandpaper to use, cut into strips the right width and

Digitized by Google

tacked on the ends, allowing slack enough to set well in the circle. The car should be run at a very high speed, as this will give a smooth surface and clean the commutator quickly.

Wipe the commutator free from the flint and copper dust and apply a cloth with a very little vaseline, which should be wiped off with a clean cloth. Be sure and remove the brushes before sandpapering. The brushes should not be allowed to wear down excessively, as the tension then becomes weaker, and they will spark. Brush holders should set about one-quarter of an inch from the commutator. Springs should not be so tight as to wear a brush out in a couple of days, as this wears the commutator unnecessarily.

When all the segments turn black it should be seen that the springs are not too weak, or that the commutator is not worn out. If only a few of them are black, clean the mica cone and band rings with sandpaper and look for loose joints. A round-nose tool should be used in turning down a commutator, and run with a slow feed. Avoid square corners on commutators which have no bead ring, as a square corner leaves a jumping point for the current. Bead rings should be cleaned and painted with insulating japan very often; shellac should not be used. When string is used it should be treated in a like manner.

To clean a commutator remove it from the shaft and place it on an arbor setting horizontally in a vice. Clean the face of the segments with sandpaper, and place a band of paper around them, over which place a thin steel band two inches wide and about one inch shorter in length than the circumference of the commutator. The ends should be turned up at right angles to the ring and reinforced with a piece about one-quarter of an inch thick, riveted to them, drilled and threaded to receive a long screw to draw the ends together.

When the segments are held together tightly with the band, the bolts or clamping ring should be taken off and the ring of segments removed. These should be cleaned inside and on the ends, and then tested with the terminals of a four-light circuit, going over every segment; if the current runs across from one segment to another, clean that spot until it is clear. After putting the commutator together, set up the bolts and test again.

If the old mica cone or band rings are used they must be cleaned on the surface with fine sandpaper. Test for a ground with a wire direct from the trolley with a fuse in circuit. A commutator cleaned in this manner is as good as new.

When soldering with a blow lamp or torch, use great care and try and heat all the segments as near alike as possible, as an uneven heat changes the temper of some of the segments and makes them wear faster than others.

A very good method of soldering is to cut the solder into blocks about quarter of an inch square, place them over the leads, and just heat enough applied to melt them. The surplus solder is rubbed off with a cloth. A very good flux is made from powdered rosin dissolved in turpentine or alcohol; acid should never be used. The mica should be cleaned with a hack saw blade after soldering.

In replacing either a copper or mica segment, tie a rope around the commutator and remove the clamping ring; then loosen the rope enough to remove the defective segment, and also a good one for a pattern. If it is a mica segment take a square piece of mica as large as the segment and of the right thickness, and place this with a copper segment in a vise, with the mica in front; file toward the copper, which acts as a backing and prevents the mica from splitting or tearing. Clamp the two together with a hand vise when changing the position in the vise.

If a cut in the mica is not very bad, or time is precious, mix a paste of soapstone or slate grated on a file with shellac and apply heat and smoothe with a file.

When changing or repairing a mica band ring, and it cannot be put on whole, cut it once and split into three layers on each side of the cut for about 3 ins.; then cut the layer off the first one 3 ins. from the end, the second one 2 ins., and the third 1 in.; cut the other side in like manner, only reversing the order of cutting, so that they will lap over each other and be of the same thickness in the joint.

Do not cut the mica off square and bring the ends together, for if it does not fit well, or is too small, there will be an air space; and if too large it will wrinkle.

In fitting new brushes to an old commutator see that the face of the brush has a good contact. Place a lighted match behind the brush, and the light will show where the brush does not touch; then file to fit.

## *Lessons in Practical Electricity*

CALCULATION OF ALTERNATING CURRENTS.

In this and a succeeding article will be illustrated the manner in which the apparently involved methods for the calculation of alternating current phenomena arise; that is, the origin of the terms angle of lag, phase difference, vector addition, etc. In order to fix more clearly the ideas involved, a numerical case will be taken.

Suppose we have an inductance in an alternating current circuit. This inductance we will assume to be a choke coil having a resistance of .5-ohm and a coefficient and self-inductance of 1 millihenry. We will also assume that the alternating current has a frequency of 125 periods per second; that is, there are 15,000 alternations per minute. Suppose, further, that 10 amps. as measured by an ammeter pass through the coil, and that it is desired to know the e.m.f. between its terminals when this amount of current is flowing.

Having once assumed a sine variation of e.m.f. and current, but a single point is needed in order to construct the curve representing this variation. Thus, referring to Fig. 1, if we know the maximum voltage or current, O D, the sine curve can be laid down as follows:

Having assumed the current to be 10 amps., the maximum value of the current will be 1.7 times this, or 17 amps. To any scale lay down the circle O M, drawn with a radius 17; then divide the semi-circumference into a number of equal parts, A, B, C, etc.; and from these points let fall the perpendiculars, Aa, Bb, Cc, etc. Next, divide a horizontal line, M N, whose length is equal to the length of the semi-circumference of the circle, into as many equal divisions as the circumference has been divided, and transfer the lengths of the perpendiculars to corresponding divisions on this line, which will give us the lines Aa, Bb, etc. Through these points, draw the curve M B D F N, which will be the sine curve for a half-period. This can then be duplicated below the line to the right for the remaining half-period, as shown.

Referring to Fig. 2, suppose that we have in this manner laid down to scale the current curve, C. We wish now to obtain the curves showing the drop in the coil due to resistance, and the curve showing the drop in the coil due to inductance; the resultant of these two curves will then be the impressed e.m.f., which is the quantity desired.

To determine the first curve, since the maximum current flowing is 17 amps., and the resistance of the coil is .5-ohm, the maximum ordinate will be C R = 8.5 volts. Moreover, since the resistance drop will be greatest when the value of the current is greatest and zero when the current is at zero, the corresponding curve will follow the variations of the current curve; in other words, will be a sine curve and in phase with the current curve. Laying down, therefore, the ordinate L R equal to 8.5, we have the maximum ordinate of the sine curve and the remaining portion may be obtained by means of the circle construction, as given in Fig. 1.

To obtain the inductance curve, it must be borne in mind that the inductive e.m.f. is caused by the cutting in and out of the coil of lines of force due to changes in the current flowing, and that the more rapid the rate of this cutting, the higher will be the inductive e.m.f. At any instant the number of lines of force within the coil depends upon the value of the current flowing therein. It will be seen by reference to the current curve, that the current, and therefore lines of force change in value least rapidly at the peak and most rapidly when passing through zero. In fact at the instant of passing through the peak, the rate change of current and therefore of cutting of lines becomes zero, and, consequently, at this instant the inductive e.m.f. will be zero. On the other hand, when the current curve passes through zero, its rate of change, and, consequently, the rate of change of the lines of force in the coil due to the current, is greatest and at this point the inductive e.m.f. will be greatest. That is to say, the zero of the inductive e.m.f. will be on the same perpendicular as the maximum of the current, and the former

Digitized by Google

will be on the same line with the zero of the current curve.

Knowing the frequency, self-inductance and current, we can calculate the e.m.f. from the formula, $E = \frac{2\pi n L C}{1000}$ substituting $L = 1$, $n = 125$ and $C = 17$, we have for the inductive e.m.f. 13 volts, which is the maximum ordinate since we have used the maximum value of current. The curve of inductive e.m.f. can now be laid down in the same manner as that of the resistance e.m.f.

The impressed e.m.f. is the e.m.f. required to overcome the sum of the resistance and inductive e.m.fs. At the point N, for example, the resistance e.m.f. is N R', while the inductive e.m.f. is N L'. Since, however, one of these is below the line and the other is above the line, their algebraic sum or the impressed e.m.f. required to overcome the two, is the arithmetical difference between the two, which is N E'. At the point L, since the inductive e.m.f. is zero, the impressed e.m.f. is equal to the value of the resistance e.m.f. at that point, or equal to L R. In this manner we can proceed and obtain the algebraic sum at each point of the resistance and inductive e.m.fs., which sum will be the value of the impressed e.m.f. at that point. By this means we can get the curve E, having a maximum value of 15, which is the curve of impressed e.m.f., and this maximum value divided by 1.7 will be the e.m.f. that would be measured at the binding-posts of the coil by a voltmeter, or 8.8 volts. The scale of Fig. 2 does not altogether conform to the above data, but the diagram nevertheless serves to fix the ideas; the actual value of the impressed e.m.f. was found by calculation, as will be explained in the next lesson, but by a correct geometrical construction could have been measured from the diagram.

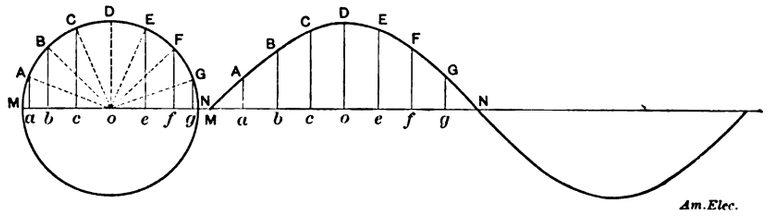

FIG. 1.—CONSTRUCTION OF SINE CURVE.

Referring to Fig. 2, it will be seen that at S and Q the resistance e.m.f. and current curves cut the horizontal line at the same point, and they are, therefore, said to be in phase. Considering that the earlier it is in time the earlier a curve cuts the horizontal line to the left, it will be seen that both the inductive and impressed e.m.fs. cut this line ahead of the current curve; or, in other words, the current lags behind both the inductive and impressed e.m.fs. In the case of the inductive e.m.f., this lag will be seen to always amount to one-half a semi-period, while the lag of the current behind the impressed e.m.f. is about one-half of this.

The exact amount of the latter may be determined by measuring the lengths of the distance K S, and of the distance S P, representing an entire period. Then the ratio of the former to the latter will be the lag in fraction of an entire period. Or, if the length S P is named 360 deg., then the lag K S expressed in degrees will be 360 multiplied by the ratio above found. In the present case, the current lags behind the impressed e.m.f. by about one-eleventh of a period, or 33 degs. As Fig. 2 shows, however, there is really no angle involved, the condition actually existing being merely that the current and impressed e.m.f. do not reach their maximum or minimum values at the same time, being thrown out of phase a definite amount by the inductive e.m.f.

It will be noticed, that since the inductive e.m.f. is at zero when the current is at a maximum, and vice versa, the corresponding curves must differ in phase by a quarter-period; or, if we call an entire period 360 degs., the phase difference is 90 degs.; or, in still more mathematical language, the current and inductive e.m.f. are in quadrature; or, in still other terms, they are quarter-phased, and so on—the duplication of nomenclature arising to a great extent from the anxiety of a certain class of writers to appear original.

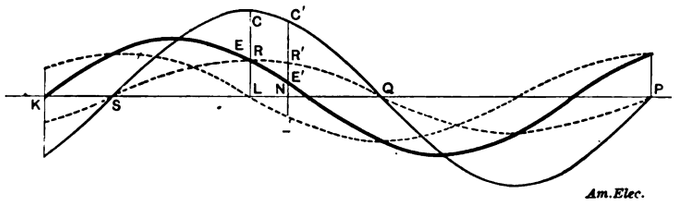

FIG. 2.—DETERMINATION OF IMPRESSED E.M.F.

From the above we see that when we consider alternating currents in a direct manner, we may add and subtract alternating voltages and currents precisely as in the case of direct-currents. It would, however, be entirely impracticable in each case to make such a construction as that shown, and therefore, the artifice is adopted which brings in angles, vector addition and the other artificialities which make alternating currents so puzzling to the beginner. If one at the beginning accepts the language and methods referred to as due to artificial conditions adopted in order to facilitate calculations, he should have no difficulty in a clear understanding of the phenomena which otherwise would naturally be a mystery to him. In the next article will be considered the application of the mathematical properties of the sine curve, by means of which alternating current calculations are enormously simplified.

## TWO-RATE CHARGING FROM THE CONSUMER'S STANDPOINT.

BY LYMAN C. REED.

Two-rate charging for current is quite a recent development in electric practice, and arises from the conditions presented by the load line of the central stations which supply current for light and power purposes. In central stations, as a rule, there is an abnormal amount of current to be supplied from about 4 P. M. until 9 P. M., and at some time between these hours the "peak" of the load line reaches its highest point. The plant has to have sufficient capacity in boilers and engines to meet the demand, notwithstanding the fact that the mean load line seldom averages over one-third of the maximum demand.

In order to try to even up the load line —that is, to make the demand on the plant as nearly uniform as possible each hour of the twenty-four—two rates have been much in favor in some localities, the purpose being to encourage the use of current when the demand on the plant is light and to discourage the use of current when the peak of the load is on. An even load line would reduce the cost of production, not only by the increased efficiency of the machinery used, but also by lessening the fixed charges. However excellent the method of two-rate charging may be, nevertheless the important factor in the whole plan is the consumer.

Looking at the question entirely from the consumer's standpoint, which, after all, must be the final outlook, it is found that the system of charging at different rates for current is a very unsatisfactory way of selling it for many reasons, among the most prominent being the fact that it is entirely unfeasible to educate the average consumer up to the theory of two-rate charging. In a city with a mixed populatoin of all nations it is impossible to explain two-rate charging to the ignorant classes.

The selling of current may be compared to the selling of any other commodity, in that nearly every business has what we might call a load curve and hours of most profitable selling. The adjustment is not made, however, in commercial circles by selling goods at one price during certain hours and at a cheaper rate during others. The manifest absurdity of such a course appears evident in the case of a dry goods store, or similar house, and why is it not equally absurd in the selling of current? We find in all commercial business the price regulated by the amount bought. If goods are purchased in large quantities certain discounts are secured; if purchased in small amounts the buyer has to pay

Digitized by Google

more. This, then, being the usual method throughout the world, why should electricity be made a singular exception to the universal law of demand and price? A business house operated upon the system of two-rate charging would be laughed at, yet it costs more for them to sell goods with an empty store than with a crowded one, because the quota of clerks necessary to wait upon the people during the busy hours has to be maintained during the hours of small business. The analogy between the central station and the usual business house is clearly a suitable one, in that the fixed charges, load curve and demand in each case show a great similarity.

What the consumer wants is current at the lowest price obtainable, and John Smith is not satisfied unless he gets it at the same price that Paul Jones does. The hours during which he uses the current he considers, and rightly too, a matter entirely regulated by his own wishes, and does not understand why he should help pay for the current which Paul Jones uses because the business of the latter necessitates the use of current at a different time of the day.

This attitude of the consumer makes difficult any system of two-rate charging. A sliding scale of discounts is readily accepted, as the consumer is entirely familiar with this method of buying, and can understand it perfectly. A fixed price per kilowatt and a fixed discount according to the amount consumed seems eventually the system which must be adopted as being the simplest and most satisfactory.

The income from a certain amount of current produced can be made the same, whether charged for according to the demand or at a fixed rate, and certainly the rate which satisfies the consumer is the one that should be adopted. It is advocated that the central station should discourage the use of current at the time of the peak and try to cut it down. As a well-known fact, the consumer will not burn light in the daytime unless he needs it, no matter what the rate may be. His need at the time of the peak is just as great as if he had not used light all day, and in that case, if the rate is high at this time of day, he will use some other method of lighting. If the central station discourages the use of light at the time of the peak by charging at a higher rate, they simply lose a profitable portion of their load.

It is our opinion that every known means should be employed to encourage the use of light at all periods of the twenty-four hours and adjust the matter of the peak in the plant itself, or by means of sub-station storage batteries. If John Smith wishes to burn his lights only for two hours in the evening, by all means encourage him to do so, as otherwise he might not use light at all, and thus the central station would lose that amount of custom. It sifts itself down to the simple question of whether a peak load pays, and under what conditions it pays best.

The question seems to be readily solved by the use of accumulators. The peak is being stored during the period of light load—true at a loss in efficiency of transformation, but at a time when it would load up a unit which might otherwise be working at half load, and therefore at low efficiency. It is therefore evident that the question of an even load line must eventually, from the very nature of the case, be answered by some means in the plant itself, and not by a system of two-rate charging.

A plant operated so that the engine output is always a straight line would have no difficulty in quickly ascertaining the lowest figure at which it could sell current with a fair profit. It would then be a matter of indifference at what hour the peak of the load obtained. The consumer could be approached and told that current costs so much, and that a sliding scale of discounts is given, according to the amount he consumes. The matter then becomes very simple. The consumer is satisfied, because all parties are getting current at the same price, and hence no jealousy is felt. Where different rates have been fixed it eventually leaks around that so and so gets current cheaper than some one else, and then a vigorous complaint is made. The company, in order to retain the consumer, has to concede the lower rate to him. These complications and an unnecessary amount of clerical labor can be avoided by having a fixed price.

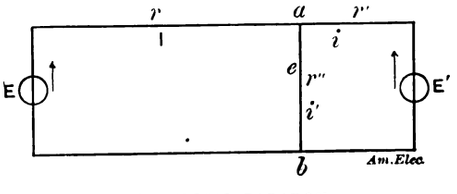
The load line of the consumer, as a general rule, usually corresponds in a measure with the load line of the plant, and it is perfectly equitable from the standpoint of the central station to encourage by cheap rates day and all-night burning. The method in itself is just, and if it could be carried out in minutest detail, with all the consumers working in harmony, no better way could be found of selling current. But the consumers will not work in harmony. One man will not consent to be charged at a higher rate than his neighbor if he can possibly help himself, and so the whole problem is thrown off the consumer's shoulders and left for the central station to solve.

Everything points to a solution by accumulation for doing away with the excessive engine peak at certain hours.

In conclusion, I would add, from the standpoint of the consumer, a fixed price per kilowatt, with a sliding scale of discounts, is what is wanted as being the most equitable basis of charging. The central station can receive the same income from the same quantity of current sold without prejudice or favor, and be at all times on a harmonious footing with its consumers.

[The above article was received too late for insertion in its proper position, ahead of the editorial pages.—Ed.]

## Artificial Graphite



It is proposed to manufacture graphite by electrical means, and a factory will be erected for this purpose at Niagara Falls in the spring. Mr. Edward G. Acheson is the inventor of the process, which will also be applied in the manufacture of electric light carbons, converting the ordinary carbon partly into graphite, thereby improving the conductivity and hardness.

## An Electrical Paradox.

Owing to an unexpected rush at the time of going to press with our last issue, Fig. 1, which we publish herewith, of Mr. Baxter's communication, was left out, and the other figures were numbered 1, 2 and 3, whereas they should have been 2, 3 and 4. Several typographical errors were allowed to slip through which are rectified in the following:

In equation (2) the numerator of the second member should be E — r I. In equa-

AN ELECTRICAL PARADOX.

tion (4), the first member is—i. The equation at the end of third paragraph on page 93, should be

$$r\,I = \frac{(2r'' + r')\,E}{2r'' + r'} = E.$$

and the line following it should read:

"Hence, since r I = E, and e = E—r I, we have—e = o."

## Wastefulness of Live Steam Injectors.

*To the Editor of American Electrician:*

Sir—Mr. Hobart, in his letter in your January issue, does not meet my point as to the wastefulness of a live steam injector. The experiment which he describes will, of course, result exactly as he states. In my letter I say, "with the injector and return trap, the heat units in the steam consumed are absorbed by the water, and so returned to the boiler, the water being heated in passing through the apparatus." So far we are at one. My point is, that this rise in temperature prevents the absorption from exhaust steam of just that many heat units per pound of water, and, since these latter would be obtained without expense of fuel, the heat absorbed in the injector from live steam is wasted, although returned to the boiler. In other words, this heat, an expensive product of the boiler, is substituted for heat from exhaust steam, a waste product of the engine.

I think that Mr. Hobart will agree, first, that over and above the work of forcing the water, no part of the heat in the steam used in the injector is really recovered, unless the temperature of the feed entering the boiler is raised; second, that with a proper equipment of exhaust steam feed water heaters, the temperature of the feed entering the boiler will be the same, whether a pump or an injector be used.

The necessary corollary from these two

Digitized by Google

propositions is, that if a plant be properly equipped with exhaust steam heaters, the heat of the live steam used by the injector is recovered only to the amount of the actual work of forcing the water, and the remainder is lost.

JOHN WILSON BROWN, JR.

Philadelphia, Pa.

### A Mild Puzzle.

*To the Editor of American Electrician:*

Sir—Having read with much interest in the February number of the AMERICAN ELECTRICIAN, Mr. J. C. Brown's "Mild Puzzle," I offer what seems to me to be a reasonable explanation.

When the machine is connected as shown in Fig. 2, its field armature and the voltmeter offer parallel paths for current from the 110-volt mains, a, b. The parallel connection enables more current to be taken, and consequently the motor was dragged ahead of its normal speed.

The 115-volts indicated by the voltmeter was caused by the counter e.m.f. of the armature acting as a booster to the current of the mains, increasing the pressure from 110 to 115 volts.

In Fig. 3, as soon as the mains a, b, were cut, the armature sent a current around the field magnets in opposition to the direction of the previous current from the mains, a, b. In reversing the polarity of the magnets, the existing lines of force had first to be destroyed, and other lines of force set up in the opposite direction.

As the e.m.f. in the armature is dependent upon the lines of force through which the coils pass, as soon as the existing lines of force were destroyed preparatory to setting up lines of force in the opposite direction, the cause of the e.m.f. was removed and, of course, the current stopped, as the experiment proved. In other words, the magnets demagnetized themselves. The condition of the machine in Fig. 3 was similar to a new dynamo when it is run for the first time. A few lines of force sent through its magnets would cause it to build up and run as a shunt dynamo.

R. L. JOHNSTON.

Bangor, Maine.

### Obtaining Constant Motor Speed.

*To the Editor of American Electrician:*

Sir—I wish to give your readers the benefit of a little bit of experience that I've had recently, and select this means of doing so. My job was to get a No. 3 Westinghouse motor belted to a wheel grinder so as to give an emery wheel peripheral speed of about 5000 feet per minute. Without entering into a consideration of the counter belting, suffice it to say this emery wheel speed called for an armature speed of 1000 r.p.m. The motor was first connected up as an ordinary street railway series motor, and resistance coils put in circuit till the required armature speed was obtained. Upon trying the speed next day, under apparently similar conditions, it was found to be 200 revolutions too high. The motor was run from a feeder subject to considerable variation in voltage, but not enough to warrant so marked a difference in speed. It was noticed that the motor pulley grew very warm, evidencing slipping of the belt. The day upon which the first test was made was a cold day, the day of the second test a warm one; the belt was new. It was therefore concluded that there was more slipping on the warm day, and a subsequent trial proved this to be so. It was then decided to make the armature speed, in a measure, independent of the very light load which the armature was called upon to carry by separately exciting its field magnets. By means of half a dozen coils taken from an old street-car heater the field current was made 8 amps., at which speed the armature ran at exactly 1100 r.p.m. There was no perceptible difference in the speed whether the belt was on or off, and the speed under similar conditions has been found to be the same every day since, except for minor variations due to variations of voltage, governed by the time of day at which the tests were made.

The solution of the problem finds itself in the fact that on a constant potential circuit a series connected motor is inferior to a shunt connected motor, and also to a separately excited motor, as regards speed regulation. The connections adopted above are those of a shunt motor, and both field and armature are subject to variations of voltage, but the effect on the two are opposite even if not equal; a reduction in line voltage reduces the pressure applied to the armature, thereby reducing its speed, while, on the other hand, the same reduction in voltage weakens the field and tends to increase the speed. How far these tendencies neutralize each other the writer does not know. Armature speeds on shunt and separately excited motors are less influenced by variations in mechanical load, because the field circuits are independent, and as long as the voltage is constant the fields are constant, and therefore do not enter as a factor of variation in the speed. On a series motor, since field and armature are in series, any change which influences one influences the other, thereby multiplying the effect. S. T. DORMAN.

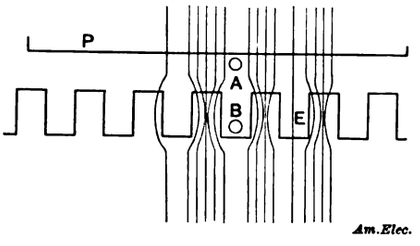
New York.

### An Electrical Paradox.

*To the Editor of American Electrician:*

Sir—In connection with Mr. Laird's second paradox, it is stated that there is no decomposition when an electric current forms a closed circuit within an electrolyte. May there not be decomposition and recomposition simultaneously? When two electrodes are placed in water we know that if a current passes between them, two atoms of hydrogen will appear on one plate for each atom of oxygen at the other. But if the two atoms of hydrogen and one of oxygen should meet before they had taken on the state of independent molecules, and the influence which separated them were reversed, would they not reunite to form water?

Is it necessary that the separated atoms of hydrogen and oxygen be formed into molecules of hydrogen and oxygen before decomposition can be said to have taken place? In other words, will not the electrolyte be decomposed and recomposed according to the Grotthus hypothesis, even though there is no external evidence of such action? AVA R. COLEMAN.



Homer, Ky.

### Why There is no Pull on an Armature Conductor in a Slot.

*To the Editor of American Electrician:*

Sir—The accompanying explanation may assist some of your readers in understanding why there is no pull on an armature conductor in a slot.

In the accompanying diagram, A is a conductor in the air gap, as on a smooth core armature, and B is a conductor in a slot on an iron-clad armature. Now in a given time A and B would cut the same number of lines of force and hence generate

FLUX FROM POLE TO ARMATURE.

the same e.m.f. But while the *rate* of cutting will be the same for A and B, the *velocity* at which B cuts will be much greater than the velocity at which A cuts. That is, we may suppose a line of force to remain in a tooth until the reluctance of its path becomes greater than the reluctance of the path to the bottom of its slot, shown at E, when it will quickly sweep over the slot to the next tooth. If A and B carry the same current, equal work is done in making either cut a line of force, and since they both cut a line in the same interval of time, the rates of work are equal. But since B meets its resistance with a much higher relative velocity than A, the force required to propel it will be much less.

We may look at the matter in another way. The force on a conductor carrying a current depends on the density of the field in which it lies. Obviously A lies in a much denser field than B and will be subjected to a greater force. The force on B will become appreciable only when the magnetization of the teeth is pushed beyond saturation, and some of the lines are forced to remain in the long air gap to the bottoms of the slots. R. K. WRIGHT.

### Reducing Speed of Motors.

*To the Editor of American Electrician:*

Sir—It may interest some of your many readers to hear about what was, to me, a

Digitized by Google

very ingenious method of reducing the speed on a multipolar motor used in driving the shafting of a street railway repair shop. The motor in question was a four-pole, compound-wound Thomson-Houston 100-h.p. street railway generator, ring-wound and provided with four brushes cross-connected by means of two copper half-circles. To reduce the speed two brushes had been removed and the remaining two placed diametrically opposite, just

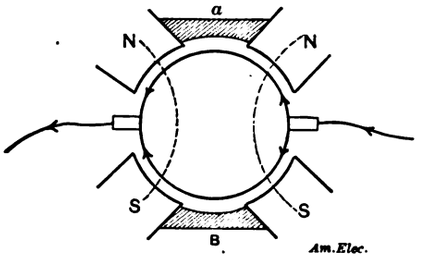

FIG. 1.—SHOWING PATH OF LINES OF FORCE IN DYNAMO FIELD.

as they would be on a regular bipolar machine. This machine had, in fact, been converted into a bipolar machine, and as follows:

The fields were so connected that there were two norths above and two souths below, instead of alternate north and south as is usually the case. The result of this was to have the magnetic lines of force run as shown in Fig. 1, instead of taking the usual path shown in Fig. 2. To improve the effect of the compound poles N N and S S blocks of iron were placed at a b, thereby lessening the leakage from N to S, and more evenly distributing the work among the armature wires. These two norths and two souths virtually amount to the same thing as one big north and one big south, so the machine is in reality a bipolar, with neutral points on the right and left and calling for brushes at c and d.

That the machine ran at much reduced speed is due to the fact that with the bipolar field connection and only two brushes there were more active armature conductors in series. In Fig. 2 we have four brushes, and we see that the circuit splits

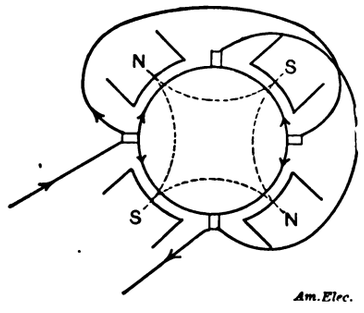

FIG. 2.—SHOWING PATH OF LINES OF FORCE IN DYNAMO FIELD.

twice, and that only the armature wires included between any two brushes are in series. In Fig. 1 the distance between brushes has been doubled, hence also the number of armature wires in series. In other words, the counter e.m.f. has been increased, the machine can take less current at a given voltage, and therefore must run slower for a given mechanical load. The fact must not be overlooked that the effect of dispensing with one set of brushes has been to halve the capacity of the machine; because when we make a two-circuited armature out of a four-circuited one it cuts the current capacity down one-half, and since the voltage remains the same, and since the output is the product of voltage and current, the input is halved.

To restore the machine to its normal capacity it would be necessary to double the impressed voltage, thereby raising the speed to its rated value. I find in this particular case, however, there was no liability to danger, as the machine was far too large for the amount of work assigned to it. It is not, perhaps, out of place to add that the man who devised this scheme does his own cast-welding, builds his own cars and trucks (of late), creosotes his own ties, does his own foundry work, builds home-made air brakes (and they work), and blows snow and bricks off the track with a home-made motor-driven air blast.

## A Simple Apparatus for Converting Battery Current into Polyphase Currents.

*To the Editor of American Electrician:*

Sir—I notice in the "Queries and Answers" column of the January number the question signed A. O. D. N., "How can the rotary field be simply illustrated?"

Having lately constructed a small piece of apparatus for converting battery current into two-phase alternating, for the purpose of illustrating the rotary magnetic field, and, thinking that perhaps "A. O. D. N.," or others of your readers would be interested, I send a rough sketch, showing connections, and a photograph showing the apparatus as completed, and also an experimental form of a two-phase induction motor.

The diagram shows a modified form of apparatus in order to make connections clear. A and $A_1$ represent two brass circles mounted upon an insulating disc. B, B and $B_1$ $B_1$ represent four brass segments, insulated from each other.

One outer segment is connected to the inner circle, and the other segment to outer circle.

The two inner segments are connected likewise, one to inner and one to outer circle.

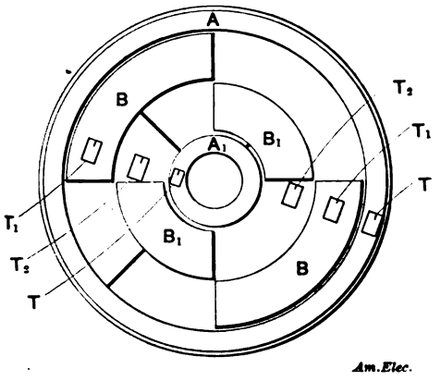

FIG. 1.—DIAGRAM SHOWING CONNECTIONS OF CONVERTING APPARATUS.

By providing brushes, as shown, and connecting battery with TT, and then rotating the discs, currents which will produce a rotary magnetic field in a two-phase winding may be taken from the points $T_1$ $T_1$ and $T_2$ $T_2$.

While this does not produce true alternating currents, which rise and fall gradually, it will, nevertheless, cause the rotar of a toy two-phase induction motor to revolve rapidly. It also has the advantage of using no liquid.

CHAS. C. WAITE.

Newark, N. J.

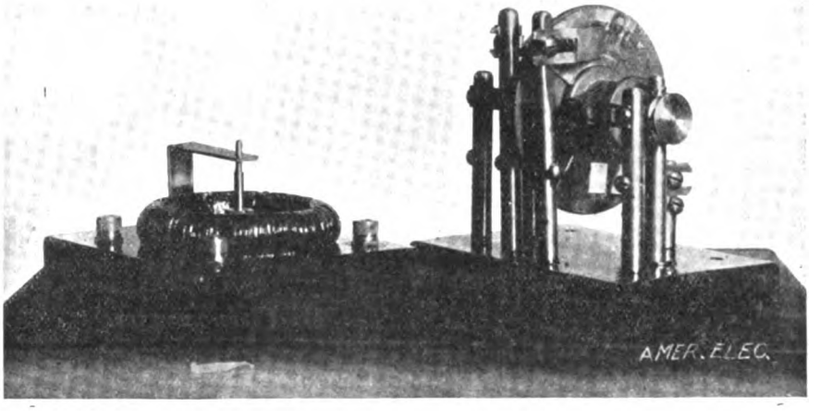

FIG. 2.—APPARATUS FOR CONVERTING BATTERY CURRENT INTO POLYPHASE CURRENTS, AND SHOWING SMALL TWO-PHASE INDUCTION MOTOR.

### To Measure the Current Flowing in a Conductor Which May not be Cut.

*To the Editor of American Electrician:*

Sir—It is sometimes necessary to meas-pension bridge, and the following is a method whereby this may be done:

Let C D be such a conductor, say a cable of a suspension bridge. G is a sensitive galvanometer of low resistance, A is an ammeter, S a storage battery or other source of e.m.f. and r an adjustable resistance. Now, let r be adjusted until the galvanometer G shows no deflection; then the current passing over G D may be read on the ammeter A. (For proof, see letter on "Electrical Paradox" in the January issue.)

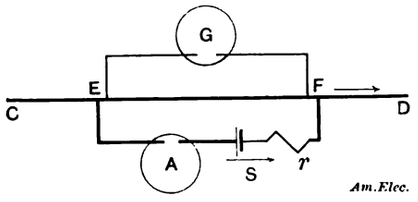

DIAGRAM OF CIRCUITS.

The condition necesary for this measurement is

$$\frac{\text{e.m.f of storage battery}}{\text{resistance of shunt circuit}} = \text{current in C D,}$$

and the current in the circuit, of which C D is a part, is changed by the amount due to the removal of the resistance of the conductor from E to F from the circuit.

St. Louis, Mo. H. L. HOLDEN.

### A Handy Rule for Magnet Windings.

*To the Editor of American Electrician:*

Sir—If we assume a current density of 1000 amps. per sq. in., the carrying capacity of a circular mil is 0.0007855 amps. The resistance of a mil-foot of copper wire at 75 deg. F. is 10.51 ohms. Hence, if E is the voltage of the circuit to which the winding is to be attached

$$0.0007855 = \frac{E}{L \times 10.51} \text{ or } L = 121 \times E$$

where L is the length of the magnet wire in feet. If the estimated length of a mean turn about the magnet core is t, the number of turns will be $\frac{L}{t} = N$; and if the necessary number of amp. turns is M, the current the wire must carry will be $\frac{M}{N}$. The circular mils necessary to carry one amp. at 1000 amps. per sq. in. are 1273; therefore, the cross section of the wire in circular mils is $1273 \frac{M}{N} = 10.5 \frac{Mt}{E}$, and the number of the wire may easily be found in the tables. These formulæ, length of wire = 121 E ft. and size of wire = $10.5 \frac{Mt}{E}$ mils, are much more convenient to apply than the formulæ usually given.

GEO. H. GIBSON.

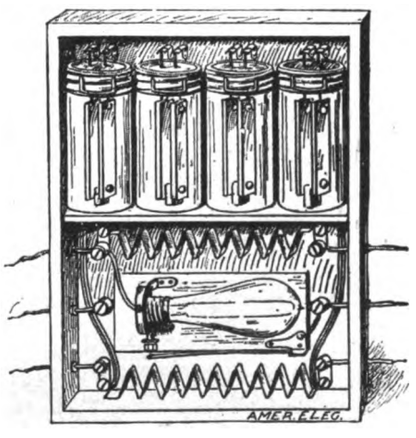
Ann Arbor, Mich.

## Electrical Catechism

*275. Are all electrical measuring instruments based upon the electro-dynamic or the electro-magnetic effects of the current?*

By far the greater number of them are, but other effects have been used, such as the electro-chemical, the heating and the electro-static effects.

*276. What is the electro-chemical effect as used for measuring current?*



When current passes through any liquid conductor (unless it be an elementary substance, such as mercury) the liquid is decomposed, part going to the "anode," the conductor where the current enters the liquid, and part going to the "cathode," where the current leaves the liquid. The anode is dissolved to some extent. When used for measuring, it is customary to have as the liquid a solution of some salt of the same metal that is used for the anode. In the standard form, pure silver is used for the anode, a solution of nitrate of silver for the electrolyte (the liquid) and a platinum bowl for the cathode. A current of 1 amp. deposits 0.001118 gram of silver per second upon the cathode. Such an apparatus is called a voltmeter.

*277. Is the voltameter an accurate instrument?*

It is in the hands of skilled operators. In fact, the voltameter has been adopted by the British and by the United States governments as the standard means for calibrating instruments for measuring currents.

*278. Is the voltameter used as a commercial instrument?*

It has been developed by the Edison Company and was used by them quite extensively for measuring the amount of current used by customers. The meter consists of a German silver "shunt," which carries nearly all of the current and one or two voltameter connected in multiple with it. The resistance of the shunt and of the voltameter are so adjusted that 1/975th part of the current passes through the voltameter, which consists of a bottle containing two zinc plates in a solution of zinc sulphate. The zinc is dissolved at the anode and deposited upon the cathode at the rate of 1224 milligrams for one ampere-hour. The plates are carefully weighed at the beginning and end of each month, the loss in the weight of the anode divided by 1224 and multiplied by 975 shows the number of ampere-hours of current that have passed through the meter. Two voltameters are used, so that one will check the other. For use on three-wire systems the meter is double, there being a shunt and voltameter on each outside wire, none being needed on the neutral wire. In the early meters 1/1000th part of the current passed through the voltameter.

EDISON METER.

*279. Does the chemical meter measure the watt-hours used by a consumer?*

No. It measures the ampere-hours only. But the voltage is supposed to be kept constant, so that the ampere-hours should bear a definite ratio to the watt-hours.

*280. Can the voltameter be used as a voltmeter for measuring pressure?*

Not in its ordinary form. It has been proposed to make one with a very high resistance, in which case the current would be proportional to the pressure. The change of weight of the electrodes might then be taken to determine the average pressure. This has not been very successful.

*281. Can the voltameter be used as an ammeter?*

Not directly. The change of weight during a given time measures the average current during that time, so that it may be considered as an ammeter when the current remains constant. It is not convenient for such purposes and is only used for scientific tests.

*282. Is the voltameter suitable for use as a meter for alternating currents?*

No. Since the alternating current goes first in one direction and then in the other, whatever effect might be produced by one alternation would be reversed by the next, except that in voltameters in which gases are produced, some of the gas might escape between reversals.

*283. How can the heating effect of the current be used for measurement?*

Since every conductor has more or less resistance, it causes a drop in pressure of any current passing, the drop being equal to the product of current by the resistance. This involves the absorption of energy equal to the product of current by drops. The energy thus absorbed appears as heat, which raises the temperature of the conductor. The amount of heat developed in a given time may be measured by an instrument called a calorimeter, from which the current may be calculated if it has been constant. This method was a favorite one when alternating currents first came into use, but it is inconvenient and is rarely used at present.

# Queries and Answers

How may the carbons and the porous cups of sal ammoniac batteries be renewed? D. H.

Boil them in water.

I have built a small dynamo, which will not work. I can see no fault in the construction, only the armature is not exactly round and the field magnets at one place are nearly one-half inch from the armature. Can you tell me what is the matter? L. D. N.

Your question is answered in the second sentence of your query.

How much current from a 110-volt circuit, and what size of wire, are required for a medium electric soldering iron? L. P.

Two amperes of current will be required, and No. 22 iron wire or smaller.

Will there be any harm in substituting a German silver for an iron resistance in a 110-volt direct-current lamp? C. T.

Yes, but the change will not make the slightest electrical difference.

Is the watt consumption of an incandescent lamp proportional to the volts? A. T. B.

Not exactly, as the resistance decreases as the temperature of the filament rises.

How is gun powder exploded by electricity? S. F. A.

By means of a primer containing a fine wire, which is heated to incandescence by the electric current.

Is it good practice to short-circuit a high-resistance gravity line when not in use? J. F. E.

No, though it should not be kept open for long periods without an occasional discharge to keep it in condition.

One of our dynamos is a 700-light shunt machine, which runs well with a steady load, but with less than 50 amps. starts to run away. We have two 125-light compound dynamos of the same type, which run equally well at all loads. What is the matter with the large machine? W. H.

As the speed of the machine is entirely dependent upon the prime mover, the fault lies with the latter.

I have a fan motor rated at 3 amps. at 6 volts. Can I change this into a three-phase rotary converter by providing a triphase wound armature? B. L. G.

By connecting three rings to equidistant commutator bars, you will have a rotary converter that will give three-phase currents.

What solution and batteries should I use for nickel plating small articles? L. P.

A proper answer to this would require a treatise such as can be bought in book form. Besides, nickel plating is an art that requires skill.

What are the electrical properties of selenium? G. M. J.

The electrical resistance of selenium varies with the amount of light to which it is exposed, decreasing in sunlight to about one-half its resistance in the dark.

What would be the cost of a storage battery to run six 16-c.p. lamps for sixteen hours on one charge? Also, the cost of charging the same by battery and from a lighting circuit? L. E. B.

The battery would cost about $400. The cost to charge from a primary battery would be prohibitive. A central station could charge the battery for $1.00 or less.

What determines the charging voltage and amperes of a storage cell? H. C. S.

The charging capacity of a storage cell is about 2.45 volts; the charging current is from 8 to 9 amps. per sq. ft. of positive surface, including both sides of the positive plates.

How may an armature be tested for a ground? W. S.

Take the leads out of opposite commutator bars, when the ground, if single, can be easily located in one of the halves. Then proceed similarly to locate in a quarter, and so on.

I have a home-made seven-plate, four-cell storage battery, which, when charged by a gravity battery, will, when running a 3-amp. fan motor, drop from 8 to 4½ volts after ten minutes. If left idle about fifteen minutes the voltage recovers to 6½ volts. What is the matter? W. H.

The cells are not properly charged. A gravity battery will not satisfactorily charge a storage battery. Not only is the rate of charging small, but a great part of the current is wasted.

A ring armature is wound with No. 18 wire, forty-eight turns in a section, 138 sections. What would be the effect if four of the sections had only twenty-four turns? A. M.

If the four sections were close together, there might be some sparking and heating; if well distributed around the armature the only difference would be a very slight reduction in voltage at the brushes.

How is the current capacity of a machine determined? W. S. W.

Divide by the voltage, the rated capacity of the machine in watts (1000 times the kw. rating). If rated in horse-power, multiply the horse-power by 746, and divide by the voltage.

Kindly advise me what mathematical books I should study in order to thoroughly understand the various works on electrical engineering. I have studied algebra to quadratics, plane geometry and trigonometry. G. E. H.

Review the three studies mentioned, extending algebra, and you will be amply qualified, though a knowledge of elementary calculus would not be amiss. How could you study trigonometry with benefit on such a slight basis of algebra?

I want to build a dynamotor for a 110-volt circuit, to give an output of 16 volts and 1 amp. Kindly give directions. A. P. H. S.

If you already have a motor, try a third brush, making contact at an angular distance from one of the original brushes of about 30 degs. on the commutator. If the motor is not too small the small current taken should cause little or no sparking.

Why will a car go down a grade faster with the power off than with it on? J. B. C.

It will not do so. In practice, the electric power is cut off when the grade is entered, and gravity, acting on the car, may give it a greater speed than the motors possibly could, if the descent is long and steep and the car not braked.

How can I prevent the sulphuric acid from creeping up the terminals of sealed storage cells, thus loosening the cement and causing corrosion? G. J. W.

The only remedy is to make as good a juncture as possible between the cement and terminals, and to provide a small vent, but this will not insure permanent protection. The terminals may be effectually protected against corrosion by keeping them covered with vaseline.

A friend contends that there are three classes of currents—direct, continuous and alternating; while I believe there are but two—alternating and direct. Who is right? A. C.

It is correct to say there are direct, alternating, continuous, pulsatory, undulatory, oscillatory, periodic and intermittent currents, and these possibly do not exhaust the list. The aim should be to know the peculiarities of currents, and not waste effort on academic distinctions.

A Wood arc machine flashes at the commutator and scars at every twentieth bar. Is the trouble probably on the line or in the machine? B. J.

The trouble is probably in the armature. After the commutator is thoroughly sandpapered, measure the resistance between the bars at the defective places, and also at several other points, thus determining whether any portion of the armature is short-circuited or contains a poor contact.

What is the weight of positive active material necessary in a storage cell for each ampere-hour of discharge? F. E. A.

According to the chemical theory, for each ampere-hour delivered, 4.45 grams of peroxide of lead are converted into 5.65 grams of sulphate of lead; that is, about 1 lb. of peroxide per 100 amp.-hours. In practice, all the peroxide of a plate cannot be utilized, and from two to six times more than the above amount of peroxide is used.

What is the probable cause of armature sections burning out, the commutator not sparking? A. M.

Among probable causes are insufficient insulation; connecting up several coils backward; cutting out several coils or parts of coils lying within a half circumfe ence, which unbalances the two paths of the winding, causing one-half to force current through the other under conditions similar to a short circuit.

1. Can storage cells discharged to different degrees be recharged in series? 2. Could part of sixty cells be connected in multiple on a 110-volt circuit and properly charged? 3. What resistance would be required for two sets of thirty cells each in parallel, if charged from a 110-volt circuit? 4. For what capacity should a booster be wound to fit the above requirements? L. T.

1. Yes, but at a loss and with obnoxious "boiling" on the part of the cells least discharged. 2. Yes, but the cells in multiple would only take half the current of the others, which would "boil" and give off noxious gases while the charge of the former was being completed. 3. Thirty cells would take about 75 volts, and the resistance required would be, in ohms, 35 divided by the charging current. 4. Forty volts and the amperes of the charging rate.

What is the relation between the ampere turns on an electromagnet and the lines of force which pass between its poles? C. A. S.

The magnetomotive force is the ampere-turns multiplied by 1.257. The flux (or number of lines of force) is the quotient of the magnetomotive force by the reluctance of the magnetic circuit. The reluctance depends upon the dimensions of the magnetic circuit and the specific reluctance (reluctivity) of the materials entering into it. The reluctance of air is unity through 1 sq. centimeter 1 centimeter long; that of iron is what the air reluctance would be for the same section and length, divided by the permeability of the particular iron used, as found from its magnetic curve.

## GAS ENGINES: HOW THEY ARE MADE

The industrial world is becoming more and more impressed with the value of the gas engine as a factor, both for power and for driving electric current-generating machines, and those who have not given much attention to the matter will be surprised to learn to what magnitude the industry of making this class of engines has developed in recent years. Among the manufacturers of this type of engine the White & Middleton Gas Engine Company, of Baltimore, hold a prominent place, and it is the province of this article to describe some of the particular features of this make of engine and the shop methods employed in their construction, as noted on a recent visit to the works.

The works occupy a substantial brick building, 220 ft. x 85 ft., located on Charles and Winder streets. The main floor of the building is divided lengthways into three bays, with a high monitor roof over the middle one. A traveling crane spans the middle bay, and each of the others are provided with two lines of shafting, from which, by means of belts, the machine tools are driven, so that there are no belts crossing the middle bay. The company believes in taking their own medicine, and employ two of their 25 h.p. engines for driving the shafting. These are located at the back end of the main floor, and power is transmitted to the shafting by means of them.

In this connection it may be noted that the two engines employed are of the vertical type, and gasoline is used as fuel, the supply being drawn by means of a pump from an underground tank, located in the yard some distance from the building. A pump is attached to each engine, and runs continuously, forcing the oil into a small reservoir at the end of a standpipe, at an elevation a little above the engine cylinder, from whence it flows by gravity to the spraying mechanism. The reservoir holds less than a pint, and is provided with an overflow pipe through which any surplus oil is led back to the tank, so that there is only a very small quantity at any time inside the building.

The output of the works includes both vertical and horizontal engines, rated from 1 to 65 h.p., and designed to consume either gas or gasoline. In both types of engines the cylinders are water-jacketed, and when gas is employed the charge is ignited by means of an electric spark, a small battery of two or three cells being employed for generating the current. For employing gas a chimney with the usual igniting flame replaces the sparking apparatus, and the latter will be described later on.

In each type of engine a trunk single-acting piston is employed, which serves as a crosshead with the walls of the cylinder as guides, and in the vertical engine a phosphor-bronze connecting rod is employed. In both types a forged crank shaft receives the force of the impact, and is in all cases provided with two heavy fly wheels. The governing mechanism is driven by a train of gear from the main shaft and is extremely sensitive and accurate. The valves are of the spindle type and are mounted in cases, which are inserted and bolted to the head of the cylinder. One is made a little smaller than the other, so that by removing the cap of the larger one, the second may be taken off through the same hole.

A feature that attracts the attention of a visitor is the extreme accuracy employed in fitting the different parts, especially the bearings, which for all moving parts are of phosphor-bronze, even for the crosshead pin. All the journal bearings are first planed up, then the two halves soldered together, when they are turned off to accurately fit the boxes, which are previously turned and fitted. The bearings are then broken apart, and each half is riveted to the box with countersunk copper rivets. The shaft is then mounted, and the bearings scraped until an accurate fit is had over the entire surface. In the final fitting of the piston they are ground and polished on an emery wheel, as are also the valves and some of the parts of the governing mechanism. All parts of the engine are made standard size, so that they are interchangeable, and duplicate parts can always be supplied.

Each engine is carefully tested and rated before shipment, provision being made to connect with the city gas mains for the gas engines with large meters, which measure to one-tenth of a foot, so that it is easy to determine the amount of fuel each engine consumes. There is also provision for testing with oil fuel, so that the capacity of each engine is known and recorded for future reference.

The spark-igniting mechanism for the oil fuel supply consists of a combined case of porcelain and brass, with the terminals of the moving points placed at right angles to each other, and terminating in platinum buttons, between which by a make-and-break process the spark is produced, the platinum buttons being so attached that they can be turned should the contact points be consumed by the arc.

The engines are not only designed for stationary work but also for supplying power to small launches, in which line there is a large demand, and in connection with which Tobin bronze propellor shafting and small propellors are manufactured.

The offices of the company are located on the second floor, over the front portion of the building. Both Mr. White and Mr. Middleton give attention to the affairs of the company, while Mr. G. W. Stanton is superintendent of the works.

## CARD SYSTEM OF CENTRAL STATION RECORDS.

The card system of records is rapidly displacing the cumbersome and expensive methods of former years wherever the volume of business renders it applicable. Both in saving of expense and in convenience, the advantage is so great that once adopted the user would never think of returning to old methods. By means of this system, two subscription clerks in the office of the AMERICAN ELECTRICIAN do the work that would by old methods require four or five, and in an enormously more accurate and satisfactory manner. In the advertising department the system so simplifies advertising records, that a glance through a case of cards will, in a moment, give almost any information desired.

CENTRAL STATION RECORD CARD FULL SIZE.

The operation of the various departments of an electric lighting plant demands a system of records which is elastic and will readily adapt itself to the varying growth and changes incidental to such a business, and is therefore an almost ideal case for the application of the card system.

The problem which confronts the manager of an electrical plant is how to handle the multiplicity of records necessary to the proper management of his system without duplication of labor, and consequent loss in clerical help. The card system of records as adopted by many of the larger Edison stations in this country, seems to meet the peculiar requirements of the case. In the underground, installation and contract, meter and accounting departments, are cabinets containing various colored cards, arranged alphabetically, by location, in consecutive or numeric order, as the case may be, and bearing projections or

Digitized by Google

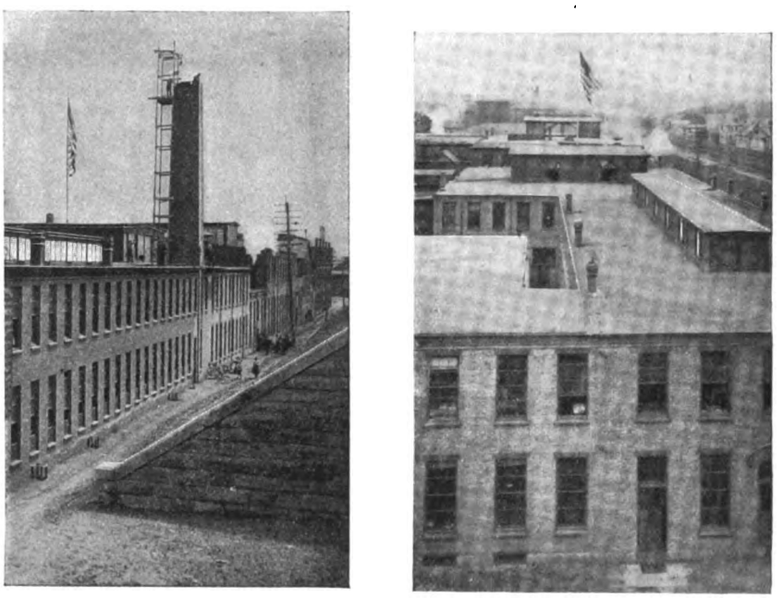
tabs in various sequences. This apparently complicated collation is plain and simple to the accountants who handle the records in each of these departments.

For example, one list comprises all the consumers, arranged each upon a card in alphabetic order, while the tabs in different positions automatically indicate the time of burning of the lamps used by these consumers. A similar system of cards is adapted for the classification of the power users, and in each case at least two records are thus combined on one card, and half or more labor saved. Where a consecutive numeric arrangement is desired, as in the case of meters, a clever device presents itself. This system consists of cards, such as the one illustrated herewith in facsimile, bearing tabs in ten distinctive positions, running from left to right, and designating the units. Guide cards are inserted at intervals of ten, so that the operator may run his eye down a list comprising perhaps 25,000 meters, and instantly detect any number without handling the cards, or looking from one to the other to locate the one desired.

The card system for central stations as devised by the Library Bureau, 125 Franklin Street, Chicago, is adapted for both large and small plants, and for both simple and complex system of records.

## EXHAUST STEAM HEATING.

Heating a city or village from a central station through underground pipes by steam is now so common an occurrence that no argument is needed to convince people of its feasibility, the system of the American District Steam Company being in operation in a large number of places—in many, for fifteen to twenty years past. The efficiency of the exhaust steam system has been tested under the most trying circumstances and always with the most favorable results. During the extreme cold of the second week of February of the present year, the steam companies kept their customers warm, while in some of the natural gas towns, where a steam system was also in operation, the gas people were nearly frozen out. The New York Steam Company, supplying 1500 or more customers with heat and power, kept steadily along through the extreme cold and blockade of snow and ice, while many office buildings, heated in the usual way, were compelled to suspend until the blockade could be raised.



The electric light and electric railway companies are beginning to realize that they have resources which they have not properly appreciated. They have seen nine-tenths of their steam flowing from the exhaust head, regarding it as a waste product of no value. They find now that there is as much demand for heat as for light or for power, and that by piping their exhaust steam around town to heat all kinds of buildings, many thousands of dollars may be realized from the sale of this waste product. The heating fits in nicely with the other branches of the business, requiring no additional office force, and very little additional fuel.

In laying steam pipes for this purpose, as in other branches of business, it pays to do thorough work. When properly insulated and drained, tests show that in a mile of continuous pipe the loss by condensation will not be more than 1 per cent to 5 per cent, depending on the size of the pipe; while with slip-shod work where the protection is a box made of boards, the loss will be 25 per cent, as some have found to their sorrow. When there is a continuous loss of this kind the aggregate soon becomes startling. This emphasizes the necessity of thorough work whenever it is undertaken. Steam being a light fluid, it flows rapidly to its destination, requiring only the pressure generated by the boiler of the central station, hence its adaptability to use in long pipe lines.

One exhaust electric plant now in operation is heating 12,000,000 cu. ft. of space through 5600 ft. of pipe, and with the mercury 11 deg. below zero, an initial pressure at the station of only 4½ lbs. was required, no part of the pipe being larger than 12 ins.

## DRAFT WITHOUT A CHIMNEY.

Two years ago at Jamaica Plain, in the suburbs of Boston, there stood a tall chimney upon which the B. F. Sturtevant Company was entirely dependent for producing its draft for the operation of its boilers.

STURTEVANT WORKS, WITH AND WITHOUT CHIMNEY.

Changes in the arrangement of the works necessitated moving the boiler plant, but, of course, it was out of the question to take the chimney along. In its stead a fan blower was installed on top of the boilers and provided with a special engine to drive it at just the speed required. It is automatically regulated so that less than 1 lb. drop in steam pressure greatly increases the draft, starts up the fire and brings the pressure back where it belongs. It is thus kept the same hour in and hour out, and the fireman has nothing to do but shovel coal.

The fan works by suction, draws the gases from the boiler flue and forces them out through a short stack extending only 31 ft. above the boiler room floor. The draft which may be produced is two or three times stronger than that of the chimney which has been discarded. The weather makes no difference, the draft is just as strong on damp and muggy days as on those that are crisp and bright.

Though it barely extends above the roof of the surrounding buildings, no trouble whatever is experienced from smoke, for the simple reason that when draft is produced in this way, no smoke is made. The utter uselessness of the old chimney has been so clearly demonstrated that it has just been taken down for the sake of the bricks it contained. There is thus presented the novel sight of a large manufacturing plant covering a half a dozen acres with no apparent means of producing the draft; the little steel plate stack being visible only from certain points.

The cost of the entire mechanical draft equipment including the stack was less than one-half that of a new chimney, because of the stronger draft much cheaper fuel is burned than was possible with the chimney, the saving being nearly a thousand dollars a year. In another boiler plant of 1000-h.p., the full saving is $6,500 per year. At the same time the amount of steam generated may in either case be readily increased to double that for which the boilers are rated. In other words, it is possible with mechanical draft to use much smaller boilers and still produce the required amount of steam.

The fan can be built of any size and exactly adapted to any location and regulated to suit the requirements. No heavy foundations are required, it seldom requires valuable floor space, and being portable need not remain, like the chimney, a monument of departed industry.

# New Apparatus and Appliances

## INCANDESCENT LAMP PHOTOMETER.

The accompanying illustrations show a modification of the Queen Standard Photometer as made especially for incandescent lamp photometers, in which but a small amount of time can be placed individually on the lamps in testing them, yet great accuracy is required.

Fig. 1. shows the complete instrument. At the left is a pedestal of iron carrying a stage, screen and curtain, and supporting one end of the photometer bar. An adjustable lamp support on the stage holds a secondary standard, a 16-c.p. incandescent lamp. This is standardized by comparison with a pair of certified lamps furnished with the photometer.

The pedestal on the right supports the other end of the photometer bar and carries a screen and an automatic rotating socket. The photometer bar carries a metal scale graduated in inverse squares and having the 16-point centrally located. By this arrangement the photometer reads directly in candles when using a 16-c.p. standard. The scale is inclined from the vertical so as to be illuminated by the test lamp and render the graduations legible.

The photometer carriage illustrated has a screen of the Lummer-Brodhun type, an optical screen of great accuracy. When so desired either a Bunsen or Leeson screen may be substituted.

The two rheostats below the photometer bar are for controlling the potential on the standard and tests lamps respectively. They have each about 900 steps and permit of so small a variation of the c.p. or potential as to be imperceptible on the most sensitive voltmeter.

The rotating socket supported by the right pedestal is more clearly shown in Fig. 2. The main driving shaft, A, is hollow and journaled in a step, U. It has attached to it a pulley, D, driven from some power shaft and a friction driving pulley, B. This shaft runs at 180 r.p m. Within this shaft is a central one, E, carrying a plate, C, and the screen, F. Upon the plate, C, are mounted two rotating sockets, G, H. They have journals swung from centers at X, and adjustable boxes at the bottom. Spring plugs keep a suitable pressure between the friction pulleys, B, I, and I. Collecting rings and brushes carry the current to the lamp.

At J, is a lever which engages in the plate, C, preventing it from moving. Under this condition, the main shaft, A, which is continuously rotating, will cause both lamps to revolve about their own axes at 180 r.p.m. If, however, the lever, J, is momentarily released, the lamps will revolve about the axis of the main shaft and one replace the other.

At K, is a release which attaches to a pedal below. Depressing this throws over the shaft of the rotating socket which happens to be there, releasing the pulley, I, from the driving pulley, and at the same time stopping the lamp.

The operation is as follows: When the operator at the photometer has tested the lamp, Y, the operator at the socket trips the lever, J, and the lamps exchange places. In so doing they exchange brushes, and, therefore, circuits. This construction is to permit of having lamp at Y, on normal voltage and lamp at Z, on low voltage. By this arrangement the operator in adjusting lamp at Z, is not annoyed by a strong light. After exchanging the lamps, the operator depresses pedal and by means of the release, K, stops lamp Z. It is then removed and another substituted. Releasing the pedal starts the lamp rotating slowly or fast as may be desired. If not running truly, it may be pressed to one side and it will stay where it is placed. This is accomplished by using a special socket, N. It is adapted to take lamps without base and has fluted contacts to secure a proper adjustment of the lamp terminals. When the lamp runs truly, the lever, J, may be tripped, exchanging the positions of the two lamps as before.

It will be seen that the apparatus, of which Queen & Co., 1010 Chestnut Street, Philadelphia, are the manufacturers, is well made, serviceable and quite automatic, enabling lamps to be tested with great accuracy and facility.

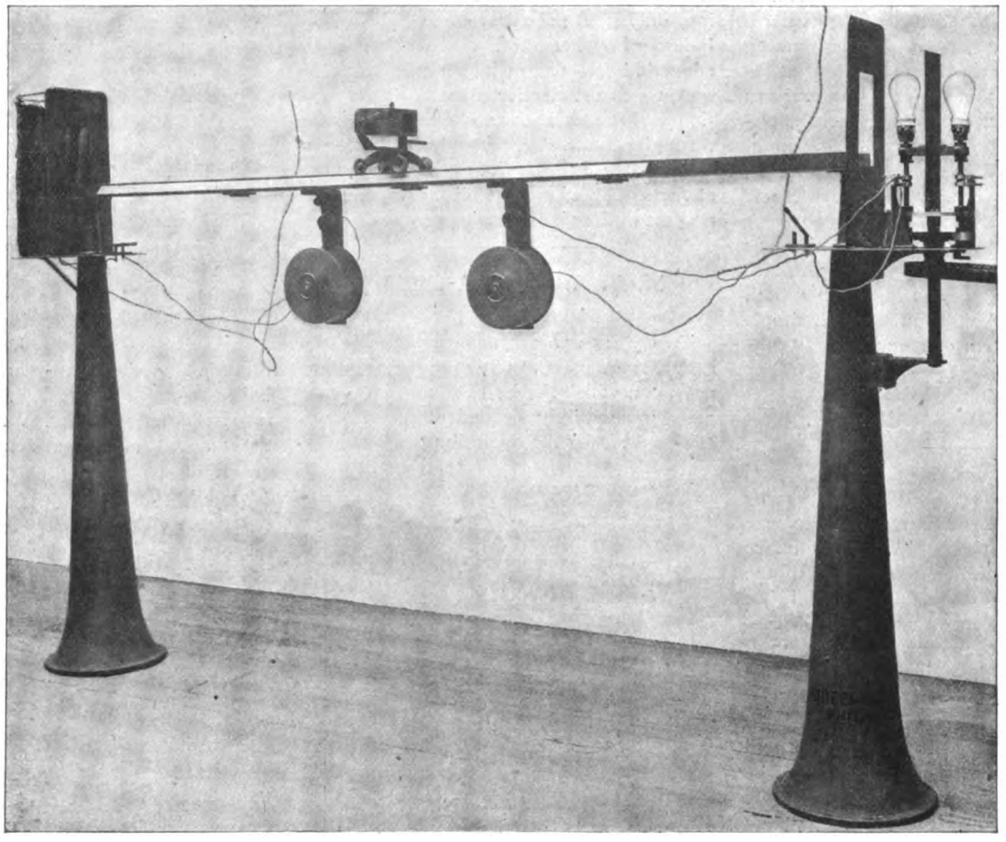

FIG. 1.—INCANDESCENT LAMP PHOTOMETER.

TELEPHONE MAGNETO BELLS.

The magneto bell illustrated herewith is intended especially for telephone service, both local and long-distance. In the construction of the generator a departure will be noted in the manner of securing the permanent magnets to the field. Usually this is done by bolting through from one side to another, and if the bolts are tightened up sufficiently to keep magnets in place during transit, they are liable to spring the field, thus causing the armature to bind. In this case the magnets are held by short bolts which enter into projections in the field pieces, and can therefore be firmly secured without danger of any springing resulting.

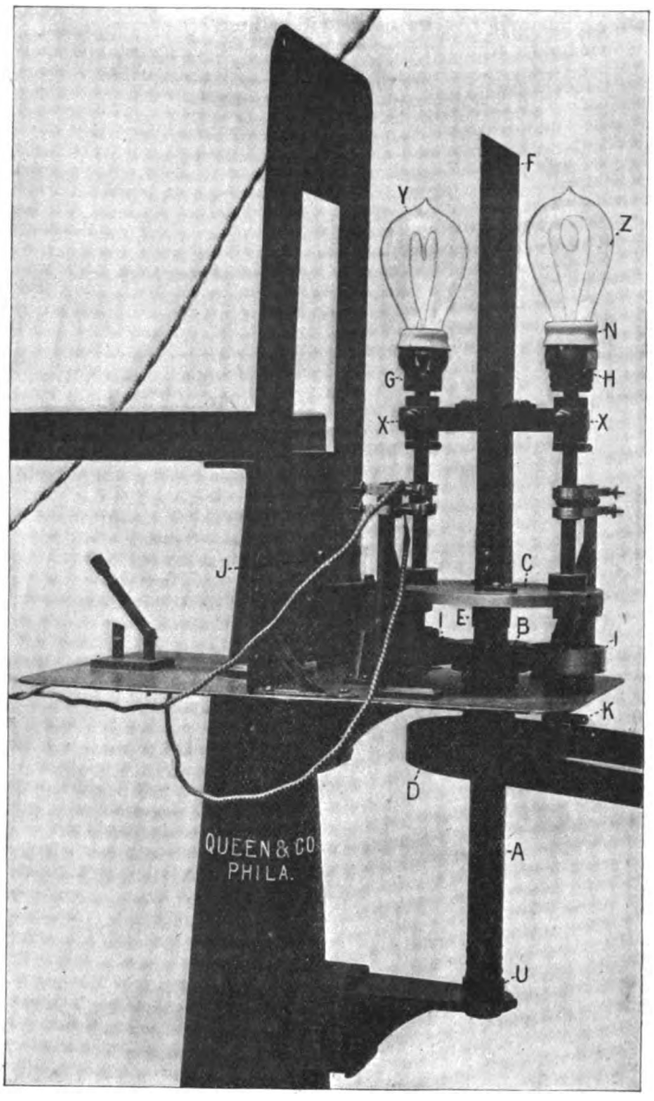

FIG. 2.—INCANDESCENT LAMP PHOTOMETER.

The generators are equipped with gears or chain and sprocket, the former being the method illustrated. The gears are finely cut, have an extra wide face and are practically noiseless in operation. The flexible method shown in the illustration for attaching the pinion to the shaft, assures a steady and uniform movement of the armature while passing through the varying magnetic field.

The armature is made of soft laminated iron, assembled on a steel shaft, accurately fitted and thoroughly insulated. Nearly twice the output is secured by this kind of armature over the usual cast-iron form.

As the shunt depends for its operation on natural forces only, there are no springs to get out of order, and it is reliable under all conditions. The slightest movement of the armature opens the circuit immediately, yet a circuit of practically no resistance is positively established whenever the armature comes to rest. The granules are silver plated, which insures always a reliable contact. The case is hermetically sealed, which effectually prevents any oil or dirt reaching the contacts. The illustration shows the shunt as it appears, both open and closed.

The method of supporting the armature

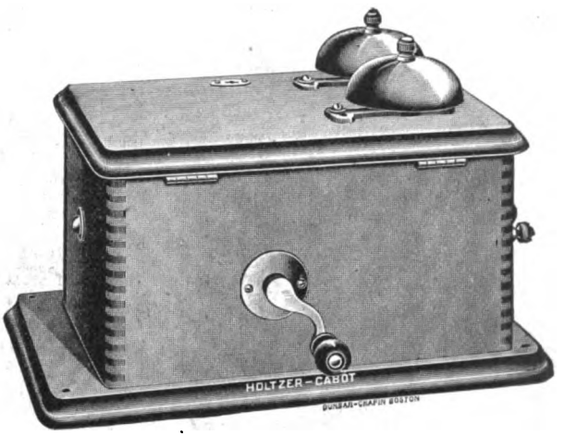

FIG. 1.—TELEPHONE MAGNETO BELL.

and at the same time holding the few parts rigidly in proper relation to one another, the facility with which such adjustment can be accurately made, simply by turning one screw, which raises or lowers the yoke carrying the armature, will commend the striker used to telephone men generally. It will be observed that the armature is always maintained centrally over the pole pieces, and in the best possible relation to them as well as to the permanent magnetic field.

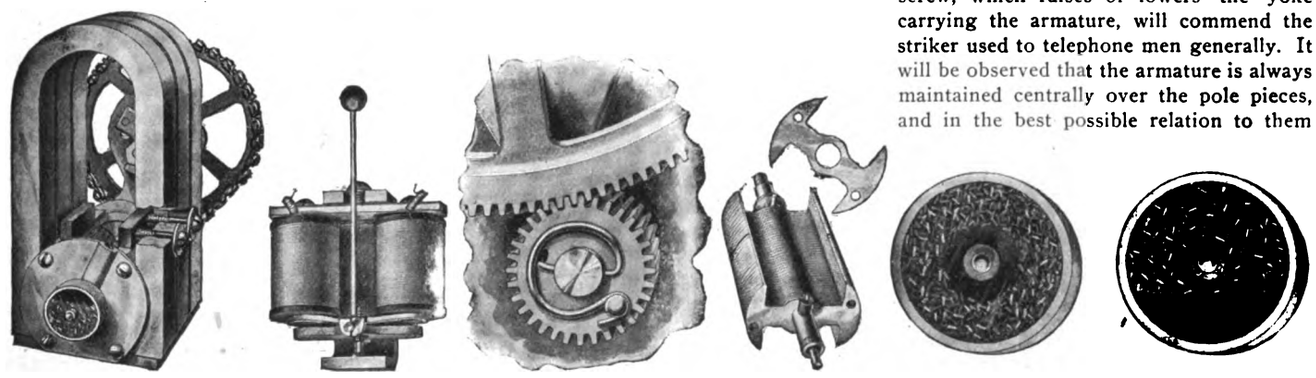

FIG. 2.—DETAILS OF TELEPHONE MAGNETO BELL.

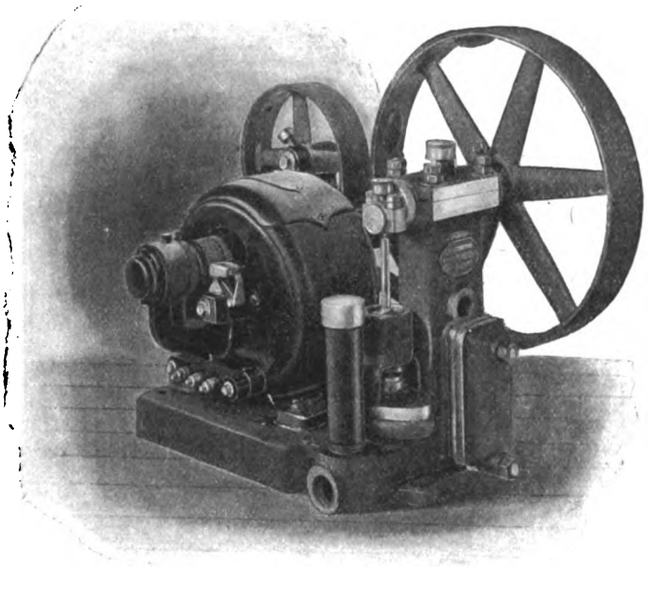


The method used of hardening and tempering the permanent magnets, which are made of a special grade of magnet steel,

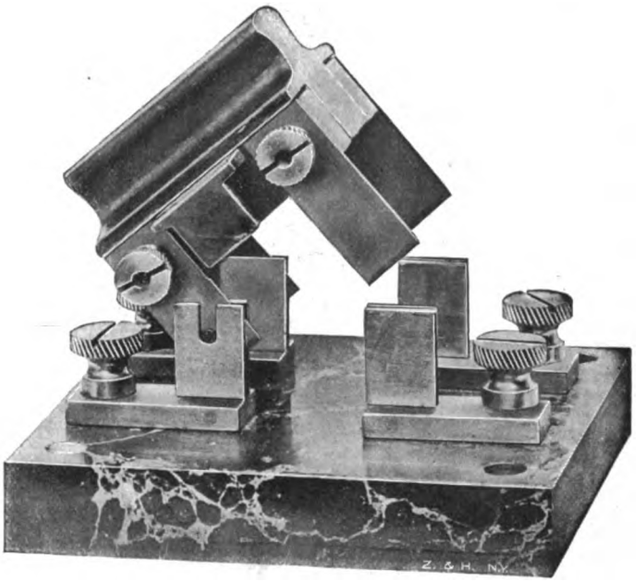
Digitized by Google

gives them the greatest possible degree of magnetic saturation. Each magnet is carefully tested and has to lift a standard soft iron bar before being passed. The manufacturers are the Holtzer-Cabot Electric Company, Brookline, Mass.

### ELECTRIC PUMPING.

A neat and compact pumping outfit for house tank and similar service is shown in the accompanying cut, being a Worthington pump direct-connected to a General Electric motor. The pump is of a type which is in use for a great variety of purposes, but is especially designed to supply the reservoir tanks of high office buildings and residences, where the pressure carried in the city mains, insufficient to elevate water above the lower stories, must be reinforced by pump pressure. The motor is connected to the pump entirely by belt, and

ELECTRICALLY DRIVEN PUMP.



as no cut gears intervene, its operation is noiseless.

The motor is of the C. A. type—a type designed and manufactured by the General Electric Company to meet a demand for motors adapted to the direct application of power to small machines. It is built in capacities of 2 h.p., 1 h.p., ½-h.p. and ⅛-h.p. The first three are wound for use on 115, 230 and 500-volt circuits, and the ⅛-h.p. being wound for 115 volts only. They are light and compact and occupy very little floor space, while they may by a single change in the position of the bearings, be run in any position. The magnetic circuit is of laminated instead of cast iron; the armature and toothed laminations with coils made up and insulated before application. The motor is mounted upon the base of the pump, making the combination one of the most compact on the market. The motor is stopped and started by an automatic switch operated by a float on the water in the tank. These pump combinations are built for capacities of 200 and 500 gals. as required.

### REMOVABLE FUSE HOLDER.

We illustrate herewith a little device in the shape of a removable fuse holder, which is coming into favor with engineers, architects and contractors. As its name implies, it is a fuse holder which can be removed at pleasure from the circuit. In fact, in connection with suitable clips, it constitutes a switch in which the fuse connections are made on the movable part. As will be seen from the illustration, the fuse is attached directly to the switch blades, and thus does away with the necessity of having separate fuse connections provided on the clip blocks.

The two blades at one end are provided with pins which fit into appropriate slots in the clips, and when so arranged the fuse holder can be operated in the same manner as an ordinary knife switch When the fuse melts from any cause the fuse holder can be lifted out and taken away to be re-

REMOVABLE FUSE-HOLDER.

fused at any convenient place. Or, as the fuse holders are interchangeable, a previously fused holder can be substituted.

Guards are located over the fuse, and prevent the fused metal from reaching the hand should the fuse blow while the holder is being inserted on a bad circuit. These guards also prevent the fused metal from dropping on other fuses and blowing them, as sometimes happens in panel-board work, where a precaution of this kind is not taken. While this fuse holder is primarily intended for use on panel boards, it can also be used for any other purpose that a knife switch is ordinarily used for.

The manufacturers are Zimdars & Hunt, 127 Fifth Avenue, New York.

### WATER-TUBE BOILER CLEANER AND FLEXIBLE SHAFT.

The tube cleaner shown herewith is for removing scale from the tubes of boilers of the water-tube type, the use of which type is so largely increasing in central and power stations.

The cleaning device consists of a conical shaped head, having a taper of about ¾ in., and composed of discs with pivoted arms between each pair. At their outer extremities these arms carry tooth cutters about 1⅛ ins. in diameter, and these arms with their cutter discs are set spirally in the head. A series of guide bars placed on the shaft back of the head not only serve to guide the tool in the tube, but provide bearings in which the operating shaft revolves.

In the process of cleaning, the cone, which is somewhat smaller than the tube, is inserted and given a rotary motion up to about 1600 r.p.m. The centrifugal force causes the arms to fly out, bringing the cutters by the impact of vibratory movement in contact with the scale on the walls of the tube. This action causes the teeth to cut into and disintegrate the scale, which is then flushed out by means of a stream of water at hydrant pressure that is fed continuously into the tube by a hose as the process goes on.

The cutting wheels not only remove scale, but when it is removed they lose their vibratory motion and simply burnish the tube, and do not injure or expand the tubes, no matter how thin they are. The effect of burnishing the tubes after cleaning serves to polish the interior, by removing even the mill scale, and so makes it impossible for mineral to adhere tenaciously. This renders subsequent cleaning relatively easy, while it adds greatly to the efficiency of the boilers by improving the circulation, increasing the absorption, and thus economizing in fuel consumption.

The head is adjusted in the tubes by means of a sectional rod united by snap couplings. The rod is given a rotary motion by means of a driving pulley having a sleeve with a key-way through which the rod slides, and by means of a handle at the outer end, the operator can move the head at will back and forth in the tube, while the rotary motion continues.

Digitized by Google

For cleaning curved tubes a flexible head of the same shape and a flexible shaft are employed. This shaft, as shown in Fig. 2, is composed of solid brass links of peculiar shape, which hook into each other, and in turn are inclosed in a closely-fitting spirally-wound tube, flat on the inside, which provides a smooth bore in which the link chain operates. The whole is then encased in a tube of specially prepared rubber, not affected by oil, which allows for oil lubrication of the flexible shaft, while it protects it from flushing water, which is led into the tube in the same way as described for the straight shaft.

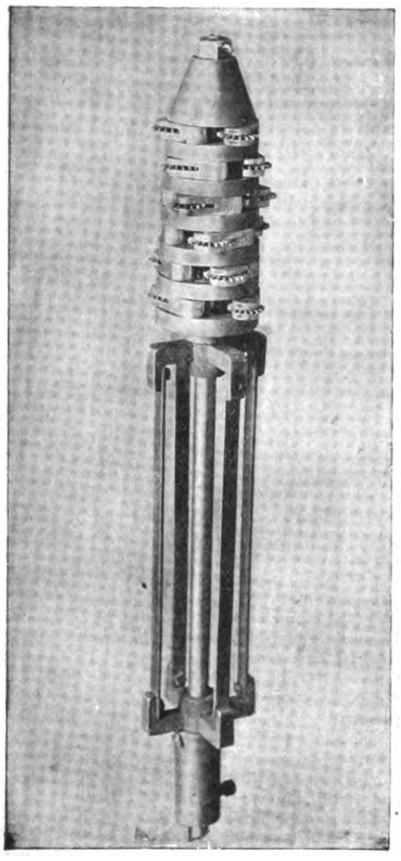


FIG. 1.—WATER-TUBE BOILER CLEANER.

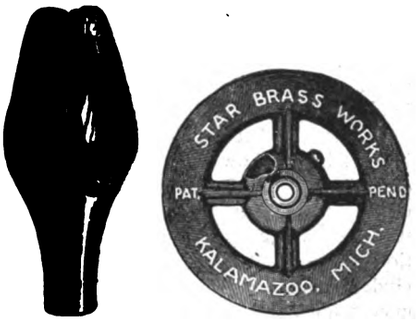


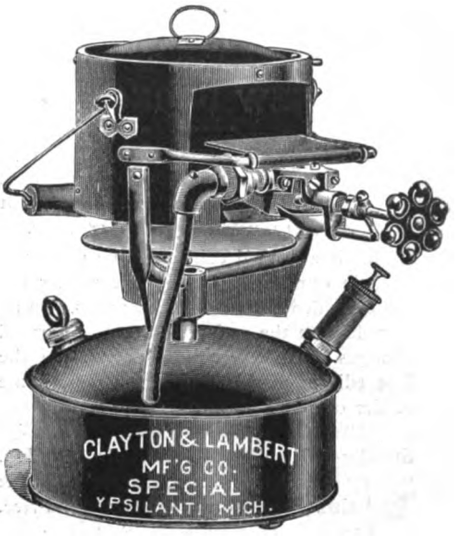
The use of the flexible shaft, which the same company also manufactures, is not confined to the operation of the tube cleaner, but may be employed in any situation where power is to be transmitted, or has been transmitted by any other type of flexible shaft. It is stronger in construction than most shafts of this character, and is especially adapted for use with portable electric motors for drilling or reaming bond or bolt holes in track rails or steel plates of any description.

The tube cleaner and shaft above described are manufactured by the Union Boiler Tube Cleaner Company, Imperial Power Building, 241 Penn Avenue, Pittsburgh, Pa.

### TROLLEY WHEEL FOR HIGH SPEED.

With the high speeds incident to interurban and suburban electric traction, it has been found that the wear on trolley wheels of the usual type is excessive. The accompanying illustration shows a wheel especially designed for the service referred to, though, of course, also applicable to ordinary service and with advantage.

The hub of the wheel is cast hollow and filled with oil, and an orifice leading to the bushing renders the wheel self-lubricating. The wheel is of soft metal, so that it will not injure the trolley wire, being made of the best lake copper especially treated for this purpose by a process owned and controlled by the makers of the trolley. The wheel is made in the standard sizes, 4 ins. and 6 ins. in diameter, and will fit any standard harp. A harp of special design is made, however, so shaped that it will not catch on switches or overhead work should the wheel leave the wire. The forks of the harp are provided with sufficient clearance next the body so that the wheel cannot injure the harp or contact springs.



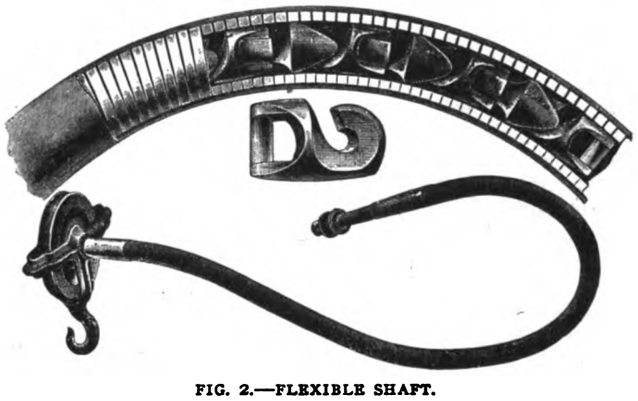
HIGH-SPEED TROLLEY WHEEL.

It is claimed that this wheel is a conductor of very low resistance and that its operation when the wire is covered with sleet is much more satisfactory than that of the ordinary run of wheels. This wheel is used on all of the long-distance lines running out of Detroit, where the service is especially severe, as in some instances the cars are run at from 30 to 40 miles per hour for long distances. The makers are the Star Brass Works, Kalamazoo, Mich.

### ELECTRICAL FIREPOT.

The illustration shown herewith represen an electrical firepot which, it is claimed, will work in the heaviest wind and maintain the highest temperature and efficiency under all conditions of work. The burners of this firepot have cast generators, easily cleaned. A kettle of solder and a pair of coppers can be heated at the same time. When desired the top section of the hood can be removed, converting the firepot into a torch or brazing fire. The burner hangs on a swivel, can be turned in any direction and burns equally well either side up. The manufacturers are the Clayton & Lambert Manufacturing Company, Ypsilanti, Mich.

ELECTRIC FIREPOT.



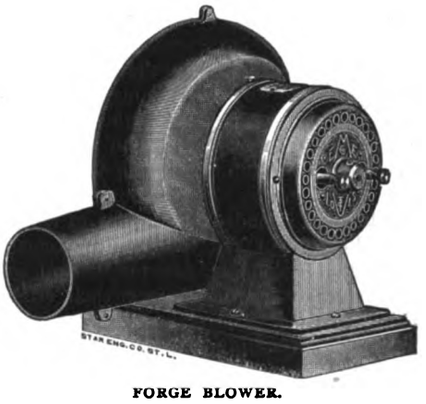


FIG. 2.—FLEXIBLE SHAFT.

### ELECTRIC FORGE BLOWERS.

We illustrate herewith a valuable adaptation of small electric motors for use as forge blowers, and which well deserves the attention of central station men. This is not only the cheapest, but is also the best

FORGE BLOWER.

Digitized by Google

method of furnishing blast for all sizes of blacksmith forges. The air pressure is very much heavier than can be procured from any bellows or hand blowers, and in addition it allows the workman to do at least one-quarter more work, as the blast is ready at all times and it is not necessary for him to devote any of his time to producing the air pressure. A great many of these are being used in some of the largest blacksmith shops in the country, and it is found that with its use it is possible to get an even welding heat on a 4-in. axle much quicker and better than can be done by any other system.

The motors furnished, being of the induction type, have no brushes or commutator or other small parts to need adjustment or repair. The Emerson Electric Manufacturing Company of St. Louis, Mo., are the manufacturers.

## NEW BOOKS.

Lighting by Acetylene. By William E. Gibbs. Second edition. New York: D. Van Nostrand Company. 161 pages, 64 illustrations. Price, $1.00.

This is a second edition of the work noticed in our January issue, the matter being extended from 141 to 161 pages. In an introduction the author discusses the rapid changes that have taken place since the first edition was issued, and revises some of the opinions therein expressed.

Standard Handbook for Railroad Men. By A. Kilburn. Chicago: Lee & Laird. 142 pages, illustrated. Price, $1.00.

Why this odd jumble of descriptions, catechism, practical instructions, mileage blanks, "Personal Cash Account," etc., should be called a "Standard" handbook is not easy to see. As much information of direct practical value is contained, the book should, nevertheless, prove of some value to those interested, after he has become acquainted with the arrangement of the matter.

Commercial Management of Engineering Works. By Francis G. Burton. Manchester, Eng.: The Scientific Publishing Company. 310 pages. Price, $4.00.

A systematic treatise on the management of engineering works—shop management—is somewhat of a novelty to the American reader, but there are few who would fail to derive some information of value from the present work. The author states that the book is intended for the use of engineer, the student and the junior foreman, modestly disclaiming any purpose of inducing seniors to depart from their established systems. The various chapters consider the accounting, managing, sales and drafting departments, the shop departments, estimating, forms of shop orders, receipt and issue of material, stock-taking, etc. The division of the book into paragraphs with bold side-heads renders the work particularly convenient to the reader in search of hints that he may apply to a system already established.

Slide-Valves. By C. W. MacCord, Jr., M. E. New York: John Wiley & Sons. 168 pages, 101 illustrations. Price, $2.00.

Of the many books that have been written on the principles and designs of valve gears, the present one appears to be one of the best for the instruction of the practical man. The author does not introduce painfully involved diagrams that will always remain mysterious except to the author, but prefers to use the standard graphical construction, with some simplifications. About a third of the contents is devoted to the shaft governor, which is simply and thoroughly explained. One of the valuable features of the book consists of practical information in detail for setting the various types of valves described.

Electrical Testing for Telegraph Engineers. By J. Elton Young. New York: D. Van Nostrand Company. 264 pages, 91 ilustrations. Price, $4.00.

The object of this book is primarily to supply a manual for submarine cable electricians, comprising a more complete exposition of previous knowledge and a fuller account of its latest development than has yet been published. Overland line testing is, however, included as a necessary part. The work should also prove of service to telephone engineers, and to those in charge of cables for the distribution of light and power. An appendix includes a number of tables and a chart of curves for the localization of total breaks in submarine cables.

Arithmetic of the Steam Engine. By E. Sherman Gould. New York: D. Van Nostrand Company. 77 pages. Price, $1.00.

For the engineer who wishes to know the principles of steam and the steam engine, this little book will be found very useful. Simply-stated explanations are given of such principles, and their application then illustrated by numerical examples. This method serves to impress on the mind of the reader the theory involved, and at the same time enables him to apply it to a practical end. Unlike many elementary books on steam and the steam engine, it is reliable scientifically, and entirely devoid of the padding in the form of mere twaddle, in which "practical" writers so delight to indulge.

Continuous-Current Dynamos. Theory and Practice, with Details of Methods and Formulæ Used in Construction. By T. Fisher Hinnen. London: Biggs & Co. 417 pages, 276 illustrations. Price, $4.00.

This work is an excellent practical treatise on the principles and design of the direct-current dynamo by the late chief draughtsman of the famous Oerlikon Works. The twelve chapters are on theory; armature calculations; design of field magnets; experimental determination of the permeability of iron; graphic solutions of practical problems; relation between brush lead and sparking; design of dynamos for special purposes; constructional details; descriptions of types; relation between weight, dimension and price of dynamos; recapitulation of designing formulæ; tables and diagrams. Five folding plates are included, containing designing curves, an order form and a sheet of cuts showing types of fields. Considerable practical data is scattered throughout the pages, including a table of dimensions and windings of armatures of different types. The book can be recommended as probably the best practical treatise thus far produced on the subject treated. What may be considered a disadvantage by some is the use of the metric system throughout.

## OBITUARY:

MR. EDWIN STANTON CARPENTER, assistant treasurer of the Westinghouse Electric & Manufacturing Company, died in New York last month, at the age of thirty-seven years. His remains were taken to Pittsburgh on Feb. 16 for interment.

JESSE H. BUNNELL, one of the pioneers in the electrical commercial field, and senior member of the firm of J. H. Bunnell & Co., died in Brooklyn on Feb. 8, of heart failure at the age of 56. Mr. Bunnell entered a telegraph office when 11 years old, and at the beginning of the war was an operator at Pittsburgh. Entering the army field telegraph service, Mr. Bunnell served throughout the war; acting as Gen. McClelland's personal telegrapher during the Peninsular campaign, and later joining the army of Cumberland. He made an enviable record, not only as an operator of unusual skill, but for coolness under fire and fertility in expedients. Mr. Bunnell became associated about twenty years ago with Chas. McLaughlin in the electrical business, in which he was engaged at the time of his death. The house he founded will, we understand, be continued under its present name.

MR. JOHN KREUSI, the chief mechanical engineer of the General Electric Company, died on Feb. 22, at his home in Schenectady, his death resulting from an attack of grip, after an illness of only three or four days. Mr. Kreusi was born in Spercher, Canton Appenzell, Switzerland, in 1843, and went to work in a machine shop at an early age. From 1867 to 1870 he lived in Paris, working there in various mechanical industries. At the outbreak of the Franco-German war he went to London, where he stayed for some months, and finally resolved to make his home in the United States, which he reached in December, 1870. After serving with the Singer Sewing Machine Company at Elizabeth, N. J., for two years, he entered the employ of Mr. Edison, with whom he remained as foreman and assistant in experimental work until 1881, when he became general manager of the Electrical Tube Company. Two years later this company was merged into the Edison Machine Works, of which he became assistant general manager, retaining that position both in New York and after the removal of the works to Schenectady. Upon the formation of the General Electric Company in 1892, Mr. Kreusi was made general manager of the Schenectady works, and in 1896 he became chief mechanical engineer to the company, which position he held at the time of his death. During his long connection with Edison, Mr. Kreusi made many important improvements and inventions in machine tools. He was also, from his thorough understanding of the strong and weak points of apparatus, a salesman of more than average ability, when his services were wanted in this capacity. He had a large and varied electrical knowledge, particularly in his keen recollection of numerous experiments which had turned out failures, and of the reason why success along some particular line could not be achieved. Most of all, he was prized by troops of friends, friends for the absolute honesty of every side of his character.

Digitized by Google

## PERSONALS.

W. F. D. CRANE, for seven years past with the electrical department of the H. W. Johns Company, has accepted a position with the Electrical Vehicle Company of New York. Mr. Crane being a graduate from the electrical engineering department of Cornell University, unites professional knowledge with commercial training, and is therefore excellently equipped for the duties of his new position.

LIEUT. MANNING K. EYRE has resigned his position as manager of the Edison lamp works at Harrison, N. J., to enter into partnership with Dr. Louis Duncan, the firm name being Duncan & Eyre, engineers. Lieut. Eyre, who is a graduate of the United States Naval Academy, made an enviable reputation as manager of the lamp works, where he had more than a thousand employees under his charge. Uniting with his professional qualities those of a keen business man, he is a valuable addition to the engineering field.

W. W. CHURCHILL.—One of the many characteristics of Westinghouse, Church, Kerr & Co., the well-known engineers, is the promotion of their old employees along with the progress and development of their business. The most important appointment recently made by this company was the promotion of Mr. Churchill to the position of mechanical engineer. Mr. Churchill has identified himself with all of the important contracts handled by Westinghouse, Church, Kerr & Co. during the past nine years. He graduated with the class of '89 at Cornell University, and remained at that institution another year as Sibley Fellow in Mechanical Engineering.

HENRY J. CONANT, who has been well-known as the manager of the Boston office of Westinghouse, Church, Kerr & Co., has been called upon to give his attention to the larger business problems of that concern. Mr. Conant will, however, continue to make Boston his headquarters. As is well known, the entire contract for the new Boston Terminal was executed by Mr. Conant. He was graduated from the Massachusetts Institute of Technology with the class of '87. This, with his many years of experience with Westinghouse, Church, Kerr & Co., makes him thoroughly capable of meeting the greater responsibilities of his new position.

## TRADE PUBLICATIONS.

THE BATES MACHINE COMPANY, Joliet, Ill., has issued a handsome lithograph of the Cookson feed-water heater, which they wish to place in every engine room in the United States. Engineers are requested to write for same.

NEW FAN MOTOR CATALOGUE.—Messrs. D. L. Bates & Brother, Dayton, Ohio, have recently issued a handsome pamphlet describing their fan motors. They will be glad to send a copy to any one interested.

INTERIOR TELEPHONE SYSTEMS.—The Allen-Hussey Company, 211 Randolph Street, Chicago, in a new catalogue illustrates and describes various systems and apparatus for interior telephone communication. Among matters of general interest are a number of covering diagrams.

ESPERSEN SHADE LAMP.—A recent circular issued by the Pacific Electric Company, La Crosse, Wis., shows a number of convenient mountings for the Espersen adjustable shade lamp, the different ones illustrated adopting the shade to almost every possible condition of use.

ROYAL ALTERNATORS.—In an eight-page octavo bulletin the Royal Electric Company, Peoria, Ill., describes its latest type of inductor alternator, which is illustrated in detail by six excellent half-tone engravings. The text consists of an excellently written technical account of the machine.

"NEW LYNN" INCANDESCENT LAMPS.—The Lynn Incandescent Lamp Company, Lynn, Mass., describes in a recent circular its new type of lamp. One of the features consists in anchoring the filament to the glass stem without introducing, as in most cases, an element tending to shorten the life of the lamp.

ELECTRIC MINE LOCOMOTIVES.—The Jeffrey Manufacturing Company, Columbus, Ohio, has issued a pamphlet, having for its subject electric mine locomotives. A number of types are illustrated, varying in size from 2 to 15 tons, and including a switching locomotive which is built up to a capacity of 6000 lbs. draw-bar pull.

THE ANCHOR ELECTRIC COMPANY, 71 Federal Street, Boston, is presenting to its friends a handsomely bound diary memorandum book, containing also much information for ready reference. One excellent feature is a keyed map of the United States, with references for locating 1800 towns and cities, the population and county being also given in the index.

LIGHTNING ARRESTERS.—The Garton-Daniels Electric Company, Keokuk, Ia., has issued an 1899 edition of its catalogue of lightning arresters, in which the latest types are illustrated by excellent engravings. The descriptive matter explains clearly their manner of operation, and incidentally the theory of lightning arresters in general.

LUDEWIG-THURBER MANUFACTURING COMPANY, LTD., 565 Old Avenue, Pittsburgh, Pa., is sending out a work containing 100 views of Pittsburgh. The contents consist of half-tone illustrations of the principal business buildings, residences and general views of various industrial establishments and localities of note in and about the city.

WESTINGHOUSE ENGINES.—The list of artistic engine trade publications has received another addition in a fifty-three-page pamphlet on the Westinghouse standard engine. The engravings are the highest expressions of the half-tone art, and the typography, paper and presswork are in keeping. The pamphlet is largely a technical description of the engine considered, which is illustrated in minute detail.

FAN MOTORS.—The first catalogue of fan motors to reach our desk is a forty-page pamphlet issued by the Western Electric Company. No less than seventeen types of fan motors are illustrated and described, and in addition there are many cuts of accessories, such as receptacles, etc. The descriptions are to the point, and, where necessary, accompanied by instructions for setting up and oiling.

THE AMERICAN ELECTRICAL WORKS, Providence, R. I., celebrated this year's anniversary of Washington's birth by distributing to the trade a fine engraving of the Mansion House at Mount Vernon, the home of Washington. Accompanying it, on a separate sheet, are some interesting facts concerning this historical building and its locality.

THE CARLISLE & FINCH COMPANY, Cincinnati, Ohio, has issued a catalogue of its search light projectors, handsomely illustrated with half-tone illustrations of its various types of lamps, together with a diagram of the connections. The company is now making lamps for all purposes, from a 7-in. lamp for a naphtha or steam launch to the most powerful marine projector. The lamps are said to operate under the most severe conditions, and are not affected by rain, snow, ice, dust, etc.

SYRACUSE ELECTRIC HEADLIGHT.—The Crouse-Hinds Electric Company, Syracuse, N. Y., have issued an extremely unique publication in the shape of a portfolio containing reproductions of letters of indorsement of the Syracuse electric headlight. The portfolio itself consists of a handsomely embossed colored wrapper with a lapel. The letters are produced in fac simile with respect not only to text, but also to size and color of the originals.

MACHINERY AND TOOLS.—The 1899 edition of the Brown & Sharpe Catalogue of Machinery and Tools has grown to 445 pages, in which are included numerous tables which make the book of especial value to workmen as a book of reference. Many additions to the list of machines and tools appear in this edition, in cutters—angular, gear, corner-rounding, double-angle, milling, face-milling, side-milling, etc., grinding, milling, gear-cutting, threading machines, etc.

FIRE AND BURGLAR PROTECTION.—In an artistic twenty-four-page pamphlet the Montauk Multiphase Cable Company, 100 Broadway, New York, sets forth the chief merits of its electrical system of fire and burglar protection. The cheapness and simplicity of this system of protection are, in view of its absolute reliability, among its striking characteristics. As the pamphlet puts it, the multiphase cable is equivalent to a human being in every room or closet on the constant watch to discover and report fires or burglars, with the added advantage that "it never sleeps."

HUNT HOISTING ENGINES, manufactured by the C. W. Hunt Company, New York, are described in a new catalogue recently issued by this company. The illustrations of the electric engines include one of a 20-h.p. electric conveyor driver, built for the Boston Electric Light, Heat & Power Company. The Hunt Company builds electric hoisting engines of various sizes to correspond with steam hoists of like sizes, but makes special hoists for greater or smaller weights, or variations in the speed of hoisting. The motors are wound for 110, 220 or 500 volts, according to the current used. The hoisting speed is varied by controllers and resistances of standard types, and the motor is protected by a circuit breaker, which cuts off the current in case of overload.

MESSRS. BROOMELL, SCHMIDT & CO., LTD., York, Pa., have issued a very complete catalogue devoted to the American fuel economizer, which is a sectional multiple water heater set up in a flue or passage leading from the boilers to the chimney. It is so arranged that the feed-water for the boilers is pumped into it at the end farthest from the boilers, and is discharged at the opposite or hot end of the economizer and delivered into the boilers very hot, from 225 degs. to 350 degs. These economizers can be attached to any type of boiler without stopping the works. In the design of this economizer all packed joints have been eliminated and taper fits are used throughout. Diagrams are given showing the application of the American economizer to various types of boilers.

MECHANICAL DRAFT.—"Artificial draft," so states Mr. W. S. Hutton, "can be readily adjusted to effect the combustion of different kinds of fuel at different rates of combustion. It permits efficient combustion of fuel of inferior quality, and enables a steady supply of steam to be maintained independent of climate and weather. It enables the supply of air to be properly distributed to the fuel in the furnace to effect economical combustion. The supply of air above the fuel can be readily adjusted to effect combustion of the gases evolved by the fuel, and the supply of air below the fuel can be regulated to effect the combustion of the solid portion of the fuel, and the movement of the hot gases can be readily controlled." There is no valuable feature of the chimney that is not possessed by the fan to at least the same, and in many cases to a more marked degree. The very features which are most conducive to economy are those which are incidental to the use of the fan for draft production. While the recent extensive introduction of induced draft in stationary practice has done much to emphasize the advantages of this system, the general superiority of mechanical draft, properly applied, has long been recognized by those who have given careful consideration to the matter.—Extract from Treatise on Mechanical Draft, published by the B. F. Sturtevant Company, Boston, Mass.

## BUSINESS NEWS.

MESSRS. PASS & SEYMOUR have appointed Joseph M. Zamoiski, 515 Equitable Building, Baltimore, as their representative for the Southern States.

ELECTRIC LOCOMOTIVES.—The power and mining department of the General Electric Company has now under consideration twelve electric locomotives for domestic use.

EUGENE MUNSELL & CO. of New York and Chicago, report a very gratifying demand for their India and amber "mica," of which they make a specialty for electrical insulation. Some very large orders have been received at both their Chicago and New York addresses.

Digitized by Google

ARTHUR ORGAN, who for several years past has been connected with the Sawyer Electrical Company of Philadelphia, has severed his connection with that company, and is now representing the Jandus Electric Company of Cleveland, Ohio, with an office at 552 Bourse Building, Philadelphia.

THE AMERICAN IMPULSE WHEEL COMPANY, 120 Liberty Street, New York, reports that it has some very large electrical transmission work in hand, and that users are obtaining everywhere the most gratifying and valuable results from their installations of the impulse wheel.

THE GARTON-DANIELS ELECTRIC CO., of KEOKUK, Ia., has just appointed Messrs. Mayer — Englund, 10 South Tenth Street, Philadelphia, Pa., its representatives in the Middle States territory for its line of railway lightning arresters.

JOHN I. DRAKE, 174 Weybosset Street, Providence, R. I., has opened an office at the above address as a consulting engineer. He will also carry a line of electrical and street railway specialties, giving particular attention to the line of switches manufactured by the Hope Electrical Appliance Company, of Providence.

ELECTRICIANS' TOOLS.—A line of screwdrivers which will be found useful in electrical work, such as putting up wires, fixtures, etc., has recently been put on the market by the Sawyer Tool Company, of Fitchburg, Mass. Prices for these tools will be furnished on application to the manufacturer.

DRY BATTERIES.—The Excelsior Dry Battery Company, 8 Third Avenue, Mt. Vernon, N. Y., now manufactures eight standard sizes of the Excelsior dry battery, using round or flat carbons. Two small types, 3 ins. x 1¼ ins. and 2¼ ins. x 1¼ ins., are especially made for use with miniature incandescent lamps.

THE PEERLESS RUBBER MANUFACTURING COMPANY, 16 Warren Street, New York, states that over 1500 tons of "Rainbow" packing were sold during 1898, and that the demand for its packings has increased to such an extent that it has been necessary to run its factory day and night to fill its orders promptly.

MR. JOS. SACHS has been appointed electrical engineer for the Johns-Pratt Company, Hartford, Conn., and the H. W. Johns Company, of New York. The above companies will soon place upon the market an indicating inclosed fuse of Mr. Sachs' invention, which will be introduced to the public at the coming electrical exhibition in the Madison Square Garden, New York.

ELECTRIC MOTORS WANTED.—Leber & Meyer, exporters, 78 Wall Street, New York, request us to say that they want catalogues and prices on electric motors for export, as follows: D. C., 110 and 220 volts, from 1-12 to 1 h.p.; A. C., 110 and 220 volts, 7200 alternations, from 1-12 to 7 h.p.; fan motors for 110 and 220 volts, both D. C. and A. C., 7200 alternations.

THE JENNEY ELECTRIC MANUFACTURING CO., Indianapolis, Ind., U. S. A., at its annual meeting in January, authorized an increase of capital stock from $50,000 to $80,000. Its trade is growing so rapidly that it was thought best to prepare for the rush of trade during 1899. The "Jenney" dynamos and motors are so well known for efficiency and good workmanship that the agents report them very easy to sell.

"JAGABI" PORTABLE TESTING SET.—James G. Biddle, Drexel Building, Philadelphia, has received from the general superintendent of the Canadian Telegraph Service a letter commending highly the "Jagibi" portable testing set in use in that service are stated to have given "perfect satisfaction." A letter from the Somerset Lighting Company, Somerville, N. J., is equally commendatory of this set.

JAMES S. BARRON & CO., 24 Hudson Street, New York, state that they have recently received, among many other foreign orders for their H. P. electric pocket light, orders from such personages as the Duke of York, King of Belgium, Khedive of Egypt and Pope Leo XIII. This device is entering largely into use in the United States Army and Navy and very generally among engineers, machinists, miners, masters of ships, etc.

PRESTON, COHEN & CO. is the name of a new firm of manufacturers' agents for electrical and street railway supplies, recently established in Philadelphia. The office of this concern is at 1004 Real Estate Trust Building, Philadelphia. The firm consists of Albert Preston and Louis Cohen, who have up to recently been connected with the Franklin Electric Supply House of Philadelphia. John M. Young is also a member of the firm.

THE AMERICAN ENGINE COMPANY, Bound Brook, N. J., has received a $30,000 order for its engines from the Louisville "Courier-Journal." This company has also just equipped two large Southern plants with American Ball engines, direct-coupled to generators. These plants are for the Porvenir sugar estate, in Santo Domingo, and the Trinidad Sugar Company, of Cienfuegos, Cuba.

SNOW PUMPS.—The Snow Steam Pump Works, Buffalo, N. Y., and 126 Liberty Street, New York City, have been awarded a contract for a 15,000,000-gal. triple expansion pumping engine for the Calumet and Hecla mines, to be operated with a steam pressure of 185 lbs., the pump to be tested by E. D. Leavitt according to specifications prepared by himself as engineer of the Calumet and Hecla works.

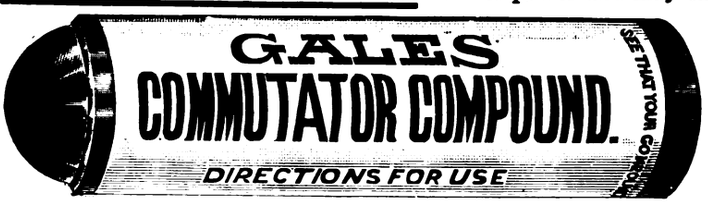
ROTH BROTHERS, whose temporary address is 236½ East Madison Street, Chicago, suffered through a disastrous fire on the morning of Feb. 23, the total destruction of its factory. This will cause a delay in the delivery of many orders, but patrons and the general public are advised that they will resume business at once, or as soon as a suitable location can be found and equipped for manufacturing purposes, which they hope will be very shortly.

CAHALL BOILERS.—The Cahall sales department has found it necessary, owing to the very rapid increase in price of raw materials entering into boiler construction, to advance the price of all boilers of their manufacture 20 per cent, to take effect March 1. This advance has been delayed as long as possible, but materials have risen so rapidly in price and continue advancing so sharply that this step became imperatively necessary.

THE CRANE COMPANY, Chicago, has made plans for the erection of a large new additional plant to its present one on the south side of Chicago, at the junction of Judd and Canal Streets. The new plant will occupy a space of 228 by 94 ft., and be six stories in height, and will cost about $500,000. It will be equipped with the most improved modern machinery, and will also contain a complete electrical equipment for power and lighting.

MR. H. B. MARSH, of the Advance Electric Company, Indianapolis, Ind., spent a couple of days in Chicago recently. Mr. Marsh reports that his firm is doing an unusually large business this spring, and that prosperity is staring them in the face. It is the intention of this company to increase their facilities for the repair of street railway apparatus, in order to take care of the increased orders which they are constantly receiving.

CHAPMAN VOLTAGE REGULATORS.—Among recent sales by the Belknap Motor Company, Portland, Me., of Chapman voltage regulators, are one of 500 kw. to the Northern Electric Company, Philadelphia, and another of the same capacity to the Pennsylvania Light, Heat & Power Company, Philadelphia. Two regulators of 250 kw. each have also been supplied to the Cumberland Illuminating Company, North Gorham, Maine, to control 10,000-volt circuits.



THE FILER & STOWELL COMPANY, Milwaukee, Wis., has received from the Union Railroad Company, Providence, R. I., an order for a cross-compound engine to be direct-connected to a G. E. generator. The engine will have cylinders 28 ins. and 54 ins. x 48 ins., and a fly wheel weighing 100,000 lbs. The same company has also received an order for a cross-compound engine with 24 ins. and 44 ins. x 48 ins. cylinders for the power plant of the Edison Electric Light and Power Company, Erie, Pa.

ELECTRICIANS' TORCHES.—The Clayton & Lambert Manufacturing Company, Ypsilanti, Mich., manufacturers of fire pots, torches, brazing fires, etc., states that never in its history has it been so busy as at the present time. Starting in a small way ten years ago, its line of fire pots, torches and brazing fires is now absolutely complete, and in every possible design used by the average electrician, painter, plumber, tinner or bicycle manufacturer, while special designs are supplied for any purpose desired.

VAN ETTEN ELECTRIC COMPANY, St. Louis, Mo., successors to Ferguson & Van Etten, have just removed to 411 South Second Street, St. Louis, where they will have much larger quarters and increased facilities. This company is meeting with unusual success in the sale of their standard woven-wire brushes, and they are also receiving a large amount of business in the line of street railway repair work. The latter especially has increased to such an extent that the removal to larger quarters was necessary.

QUIMBY SCREW PUMPS.—An order for two No. 10 pumps, each to have a capacity of from 800

**SPARKING** reduces the working capacity of a motor or dynamo, wears out the commutator wastes power and may cause a fire. All of these may be avoided if you use

**The Only Article that will Prevent Sparking.**
**Will keep the commutator in good condition and Prevent Cutting.**
**Absolutely will not gum the brushes.**
**It will put that high gloss on the Commutator you have so long sought for.**

**50c. per Stick. $5.00 per Dozen.**

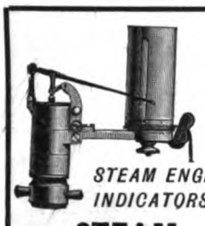
to 1000 gals. per minute, with direct-connected electric motors of sufficient power to pump against 150 lbs. to the square inch., has been received by Mr. Wm. E. Quimby, 86 Liberty Street, New York. These pumps were purchased by the Chicago City Railway Company, and are to supply water for the largest electric fountain in the world, to be erected in a park in the southern part of the city.

GATE VALVES.—The Roe Stephens Manufacturing Company, of Detroit, Mich., has recently brought out a new line of extra heavy pressure gate valves. These goods, it is stated, have met with an extraordinary demand during the active business of the past six months, both in government and private work, at home and abroad. They are used in a large number of the electric railway power houses and electric light plants, where high pressure is used, and in waterworks and other municipal plants.

THE LYNN INCANDESCENT LAMP COMPANY, of Lynn, Mass., has recently opened a New York office in the Electrical Exchange Building, 136 Liberty Street, and has placed Mr. Wm. N. Famous in charge. The company is just issuing a very readable little treatise on the renewing of burned-out lamps. Wherever it is possible an expert will be sent from the New York office to ascertain the exact requirements as to voltage, efficiency, etc., on receipt of inquiries or orders, and in this way suitable lamps will always be supplied.

MICANITE.—The Mica Insulator Company of New York and Chicago invites electrical engineers who are not already familiar as to the value of "Micanite" as an insulator for commutator segments and rings to write to it regarding the same. It makes a specialty of furnishing segments for any style or type of machine, and has manufactured some segments recently as long as 80½ ins. and 4 ins. in height. Builders of electrical apparatus will, upon application, receive a copy of the company's sheet insulation manual and data book. It not only gives the break-down tests of its insulations, but contains samples of the goods it manufactures.

THE PELTON ENGINEERING COMPANY, Cleveland, Ohio., has leased the property at 1076 Hamilton Street, now occupied by the Parrish & Bingham Company, and will take possession on April 1. It will at that time have under one roof probably the most complete electrical supply and repair house to be found in the Central States. The company is exclusive agent for the Eddy Electric Manufacturing Company, Shaeffer meters and transformers, and has several lines of station supplies, brushes, etc. It has just completed arrangements whereby it will put out an incandescent lamp bearing its own label, and also guarantee.



THE WARD-LEONARD ELECTRIC COMPANY reports strong and rapid increase in business since the beginning of the year. Its goods are used very largely abroad, and many very handsome orders have been received by the company lately, a single order from a German manufacturer being for over five hundred rheostats. The company makes the claim that it has never yet had a single case of repairs upon its circuit breakers, this being due to the fact that the two independent switches, one upon each pole, make the circuit breaker self-protecting. This feature in the Ward-Leonard circuit breaker is a strong point in its favor.

FLICKERING OF LIGHTS.—Evidently a remedy has been found for the most annoying trouble of flickering of electric lights. The Cling-Surface Manufacturing Company, of Buffalo, has received many unsolicited letters lately, expressing the effectiveness of cling-surface on dynamo belts by the prevention of all flickering of lights. It is self-evident that this flickering is caused by the slipping of belts, and, as a belt full of cling-surface runs steadily and positively, beyond all possibility of slipping, the importance of the fact can be seen at a glance. As all engineers know this flickering usually occurs when the plant is being pushed hardest, and when the best results are desired.

LOWE & LEVERIDGE.—Mr. Ernest A. Lowe and Mr. Charles W. Leveridge, late of J. Jones & Son, have entered into partnership under the above firm name, and will conduct a general electrical supply business at 183 Greenwich Street (between Courtlandt and Dey Streets), New York. Mr. Lowe has had thirteen years' experience in the electrical field, beginning in 1886 with Pearce & Jones, at 79 John Street, and was subsequently with the Western Electrical Company, United Electric Light & Power Company, and J. Jones & Son. Mr. Leveridge has been in the electrical field for seven years. Both of these gentlemen have had such a wide experience in construction work and in the electrical supply business that the new firm has every assurance of success.

RESISTANCE WIRE.—Wilbur B. Driver & Co., 126 Liberty Street, New York, make a specialty of resistance wires for all kinds of work. Their "Climax" wire for high resistance is claimed to have forty-five times the resistance of copper (almost three times 18 per cent German silver), and a temperature coefficient of .00042 per degree Fahr. For measuring instruments and work requiring constant resistance at all temperatures they have a material thirty times copper, and negligible temperature coefficient. Still another wire, with about the same resistance as German silver, has half the temperature coefficient of it, and is much better mechanically. These wires cover quite fully the demands for resistance material.

THE SHELBY ELECTRIC COMPANY, of Shelby, Ohio, manufacturers of the well-known "Shelby" and "Y-Ray" incandescent lamps, have opened a permanent office in New York City in the Fidelity and Casualty Building, 97-103 Cedar Street, with Mr. John F. Outwater in charge. Mr. Outwater's numerous friends in the trade will no doubt be surprised to learn that he has made the change from buyer to seller. For the past ten

WE GUARANTEE

That with the use of CLING-SURFACE all belts will stop slipping, that THE POWER WILL BE PERMANENTLY INCREASED, that belts can be run SLACK, that in leather belts the leather will become as soft as calfskin and ABSOLUTELY WATERPROOF, and furthermore that the INCREASE in power in a fair-sized plant will earn the cost of the sample can EVERY month, if used as directed. This applies to all belts, leather, rubber, cotton or a rope drive, whether they are new, old or oily. We will send you a sample can, or if you prefer, we will advise fully as to its nature.

CLING-SURFACE MFG. CO., 188-194 VIRGINIA STREET, Buffalo, N. Y.

Digitized by Google

years Mr. Outwater has been connected with the Brooklyn Edison Company, in various responsible positions; lately as purchasing agent, and the numerous friends which he has made as buyer will no doubt be glad to reciprocate when in position to do so, now that he is on the other side of the counter. Mr. Outwater states that he is in position to furnish the trade with any and all types of lamps, ranging from 1/5 to 50-c.p., and from 2 to 250 volts.

BOILER TESTS.—Prof. R. C. Carpenter, during the month of November of last year, made an interesting test of the boiler plant of the Youngstown, Ohio, light companies, the object being to determine the relative efficiencies of two sets of three boilers each, equipped with patent furnaces for smoke consumption and economy. The figures in Prof. Carpenter's report show that the three boilers equipped with Murphy stokers developed more horse-power than the three boilers of the other set, and evaporated more water per pound of fuel, notwithstanding that the former had somewhat less heating surface and height of chimney, and that they were fired by the regular fireman of the works, while the competing furnaces were fired by an expert fireman sent on from the works. The labor was also much less in the case of the Murphy furnace, the single regular fireman working alone and taking his coal from a wagon in front of the fires, while in the other case, the coal was laid down in front of the furnaces by helpers, and the work of the fireman was so heavy that it was necessary to relieve him for about two hours during the trial.

ST. ANTHONY FALLS POWER HOUSE.—The equipment of the power house at the lower dam of the Falls of St. Anthony at Minneapolis, Minn., is about to be completed, and the necessary arrangements have been made by the St. Anthony Falls Power Company with the General Electric Company, which manufactured and installed the plant now in operation. The hydraulic work and the power house were finished in the spring of 1898, and five three-phase alternators of 700 kw. each, and two direct-current generators of the same capacity, with the necessary rotary converters and static transformers, were installed. The full equipment of this power plant as originally laid down contemplated the use of eight alternators and two direct-current machines of a total capacity of 10,000 h.p. The present plant has been in full operation since May of last year, the current being used to drive the street and interurban railway systems of the Twin Cities Rapid Transit Company, which operates the electrical railways of Minneapolis and St. Paul. The additional equipment will consist of three 700-kw. three-phase revolving armature alternators, with rotary converter, step-up and step-down air blast transformers and switchboards for the generators and converter. The installation of this machinery will bring the generating capacity to the 10,000 h.p. originally contemplated.

LARGE CONTRACT FOR VITRIFIED CONDUIT.—The American Vitrified Conduit Company, of New York, has been awarded the entire electrical conduit contract for the city of Baltimore, which calls for several million feet of multiple-duct vitrified conduit. The ducts vary in number from two to sixteen. The Vitrified Conduit Company has various contracts on hand at the present time, including one for 1,000,000 ft of duct for the Narragansett Electric Light Company, Providence, R. I.; also one for the Edison Electric Illuminating Company, and another for the Western Union Telegraph Company, at New Orleans, La.

IMPROVED OUTLET BUSHING.—An investigation of electrical fires has shown that in house wiring considerable trouble has occurred at the outlets. It frequently happens that wires are brought out through ordinary bushings, which have resulted in a very unsatisfactory job, which seldom withstands the onslaughts of the lathers, plasterers and other artisans. The improved outlet bushing invented by Mr. Jacque Morgan, city electrician, Kansas City, Mo., is said to insure a safe and substantial job. After this bushing has once been nailed, it cannot be moved from its position. It is estimated that a saving of over 28 per cent on the gross cost of each outlet can be effected by using this device at list price. The bushings are extra heavy and made of the best porcelain. The dimensions are: Length, 3¾; inside diameter, ⅝; outside diameter, ¾ ins. Mr. Morgan will be pleased to give further information and prices of this and his other insulating specialties.

Greatest Fuel Saver on Record.

THE MASON HYDRAULIC DAMPER REGULATOR.

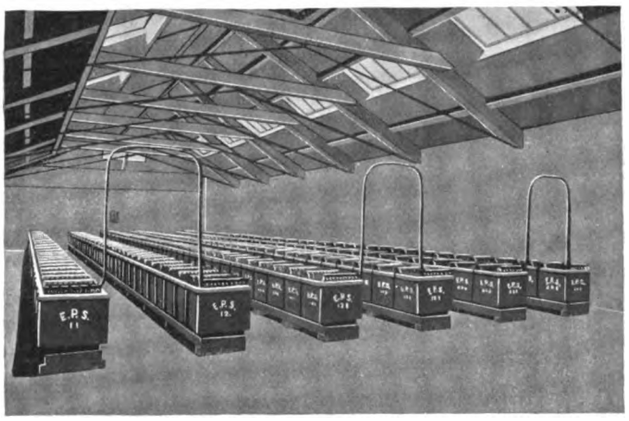
## THE POWER HOUSE OF THE STREET RAILWAY SYSTEM IN LIVERPOOL.

### ENGLISH AND AMERICAN PRACTICE COMPARED.

The City of Liverpool is unique in that the municipality owns and operates both a central station and the street railways, or, as the English would put it, the corporation owns the electricity works and the tramways. The electric lighting and street railway plants thus can be and are under one roof, taking steam from one battery of boilers and for the present utilizing but one type of engines and even of generators.



The main engine room, which appears in the accompanying illustration, is very long and narrow, with an astonishingly large number of small units, judged by American standards, running down one side of the room and flanked by their switchboards, which run along the wall just beyond the right hand limit of the picture. The three generating sets in the foreground of the view shown are devoted to the street railway load and consist each of a 300-h.p. Willans engine coupled to a bi-polar generator. The engines are of the three-crank steeple compound single-acting type, with the valves working in the piston rods, which are now coming to be known here through their more recent introduction on this side of the water.

THE ENGINE ROOM OF THE COMBINED LIGHTING AND RAILWAY POWER STATION IN LIVERPOOL.

In the Liverpool plant they are worked non-condensing. Each engine is coupled

Digitized by Google

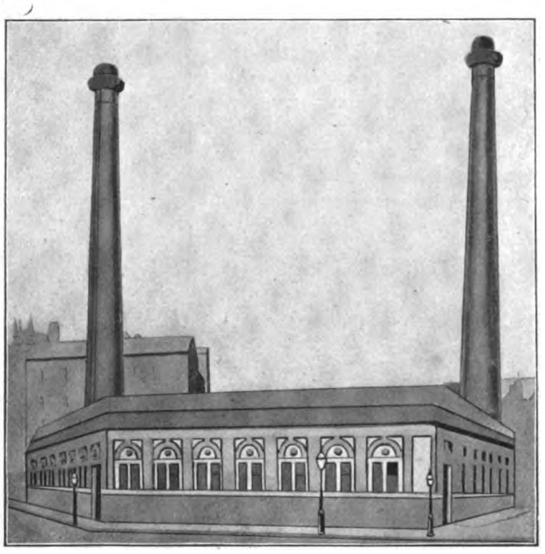
THE STORAGE BATTERY ROOM.

to a Siemens under-type bi-polar generator, similar in general style to the Edison machines manufactured in this country ten years ago. The dynamos are 550-volt machines with shunt fields and the field rheostats are mounted in a way that appears odd to the American engineer, that is, on the sides of the machines themselves. The vertical coils of resistance wire can be clearly seen in the illustration. The armatures of the dynamos are of the smooth body construction, that is, without teeth or slots.

This general design of direct coupled sets is very popular in England, being widely used for loads, which in this country would be carried by high-speed horizontal engines in small sizes and Corliss engines in large sizes, with multipolar generators in both cases. The Liverpool plant is to have three larger generating sets of the same type, each of 1500 h.p. capacity.

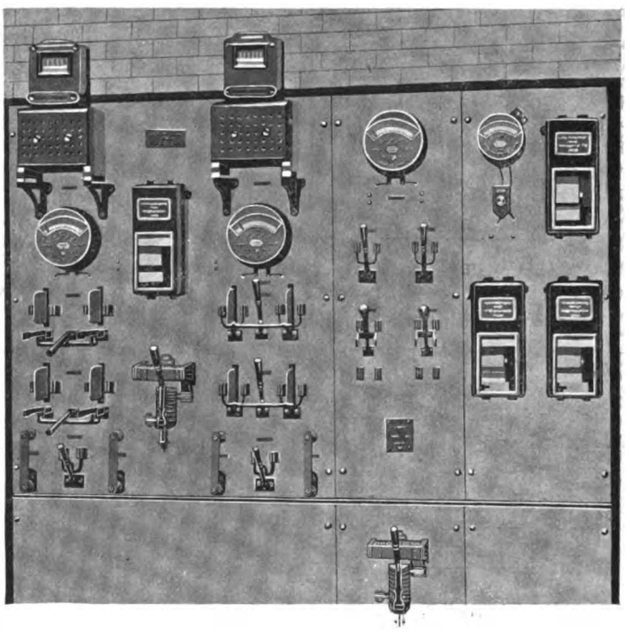
An idea of the dimensions of such units as compared with units of the same output of American manufacture can be gained from the fact that the floor space of those to come in Liverpool will be 24 ft. by 13 ft. 6 in., the overall height being 19 ft. 4 in. A feature about these large sets, which would horrify American street railway engineers, is the fact that they will have no flywheels, the weight of the armature alone being considered sufficient.

The switchboard of the plant is also shown in an illustration on this page. It carries three panels, the left hand one being the main board, the middle for the booster, and the right hand one what is called in England the Board of Trade panel. On the main panel are mounted four double-pole switches and single-pole fuses for connecting the three dynamos and the one storage battery to the one pair of bus bars, an equalizer bus being unnecessary in this station as the machines are not compounded. The switches differ from American instruments in that each pole consists of a U-shaped piece or knife working into clips, which are separated by a barrier. The I.T.E. circuit breaker in the middle of the panel and the Weston round type instruments are familiar, but the integrating meters at the top of the board and the recording meter above the circuit breaker are comparatively strange.



The booster panel contains switches by which the feeders may be thrown either direct to the main bus or through the booster. It appears that the latter is a group of three machines coupled together, a 500-volt motor driving two series-wound generators. These machines are capable of carrying the current in the long feeders and are adjusted to boost it by a voltage equal to the drop in the feeders, so that the pressure at the distant feeding point shall be the same as in front of the station. One of these generators is connected in the trolley feeders and one in the return feeders from the rail boosting thus both polarities.

The Board of Trade panel is a regular feature of English railway plans and is equipped with instruments which are required by the Board of Trade rules for determining and recording the drop in the rails, which is strictly limited to a a maximum of 7½ volts, and for measuring the current which can be picked up from a well-grounded plate.



The current is carried from the station to the points of distribution by underground cables with vulcanized bitumen insulation, both line and return current feeders being insulated. The cables are not drawn into conduits as is the practice in this country, but are laid solidly in cast iron troughs, so that the streets must be excavated when trouble occurs. The feeders end in switch pillars or pillar boxes where switches are located, by which they can be cut off from the overhead copper in one case, or the rails in the other case. Besides these cables there are what might be called pilot wire cables, one to comply with the Board of Trade regulations, its conductor connected to the rails to give an indication on the Board of Trade panel of the drop in the rail return.

Another cable with three conductors is also run out, two of these being used for telephone purposes and the third as a pilot wire. These cables are lead-sheathed and armored with steel tape and yarned, and are simply laid in the excavation without any conduits.

The storage battery consists of 246 cells, with a capacity of 480 ampere hours at a one-hour discharge rate They are located in a spacious battery room, the American practice of double-decking to economize space, not being followed. They are connected straight across the bus bars without a booster, the drop of the dynamo voltage with increased load serving to throw the fluctuations of the demand upon the storage battery.

# Electric Fan Motors—1899 Models.

Although the users of electric fans may be expected to devote little thought and less money to this piece of apparatus for a month or more to come, the supply dealers must at this early season take time by the forelock and plan for the demand which they have learned becomes greater year by year, and the manufacturers have already

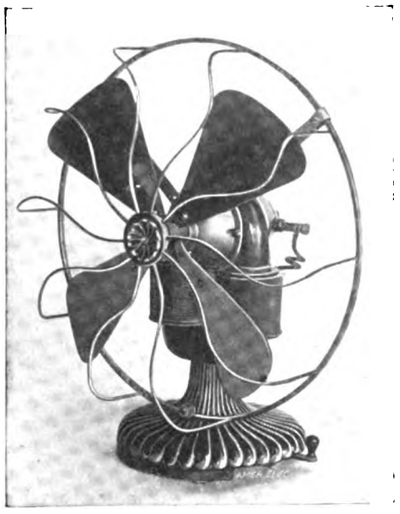

FIG. 1.—THE PEERLESS DESK FAN.

been busily at work for several months improving their designs, constructing special tools and industriously piling up a stock which they know will melt away when the hot weather arrives.

The improvements of this year's types over previous models exhibit more than ever before the care which manufacturers have learned must be taken in the minutest details of the construction of apparatus made in such large quantities as are fan motors. The general trend of design is clearly toward the abolition of cast iron in the magnetic circuit and the substitution therefor of forged, or, preferably, of laminated field magnets. In the matter of bearings, the self-aligning bearing, generally of phosphor bronze, has been almost universally adopted where two bearings are necessary, but one single long bearing with the armature overhanging one end and the fan blades the other shows an increasing popularity, due undoubtedly to its comparative simplicity and rigidity.

Practice is sharply divided on the question of enclosure, some motors being tightly enclosed, so that dust is kept out of the working parts, and others opened partly to give ventilation and warning in case trouble occurs with the brush or commutator, which, if enclosed, would often be utterly burned out before the trouble was detected. More care is taken this year than ever before in the concealment of wires and binding post within the motor shells and the packing of bearings to prevent the throwing of oil. Practice differs on the question of overhung or underhung oil cups, some preferring a grease cup above the shaft and others an oil cup below with an upwardly pressing wick. The use of waste saturated with oil and resembling in principle the ordinary car journal is recommended by some, while at least one maker uses the loosely depending oiling ring dipping into a reservoir, a miniature of the form so widely used in dynamo bearings.

The noise of what is called the "buzz" fan—originally due to faulty motor construction—has been of late years cut down practically to the humming of the blades. Some makers this year have produced a blade with a peculiar configuration, which they claim eliminates this source of annoyance. Besides the various general types of fans such as desk, bracket, ceiling, column, etc., made for the various kinds of voltages and current, some designs are specially strong in certain features, while others meet peculiarly well the individual requirements of certain applications. A study of the machines described and illustrated below may help those interested in the subject to find the fan which meets their particular needs.

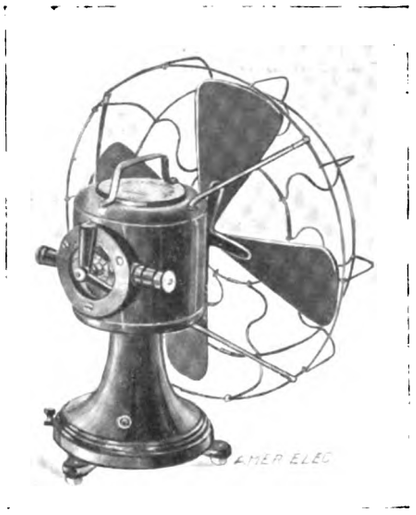

FIG. 3 —THE TOWLE DESK FAN.

Fig. 1 illustrates a desk fan for direct currents with the bipolar U-type field and hemispherical shells over the two ends of the armature, rendering it dust proof. The pedestal of the fan is fitted with the usual switch and a striking appearance is obtained by finishing the fields and base with a black enamel, making the enclosing hoods of lacquered brass, the blades and guard being of the usual polished brass.

A new model of fan motor with many interesting features is shown in the four il

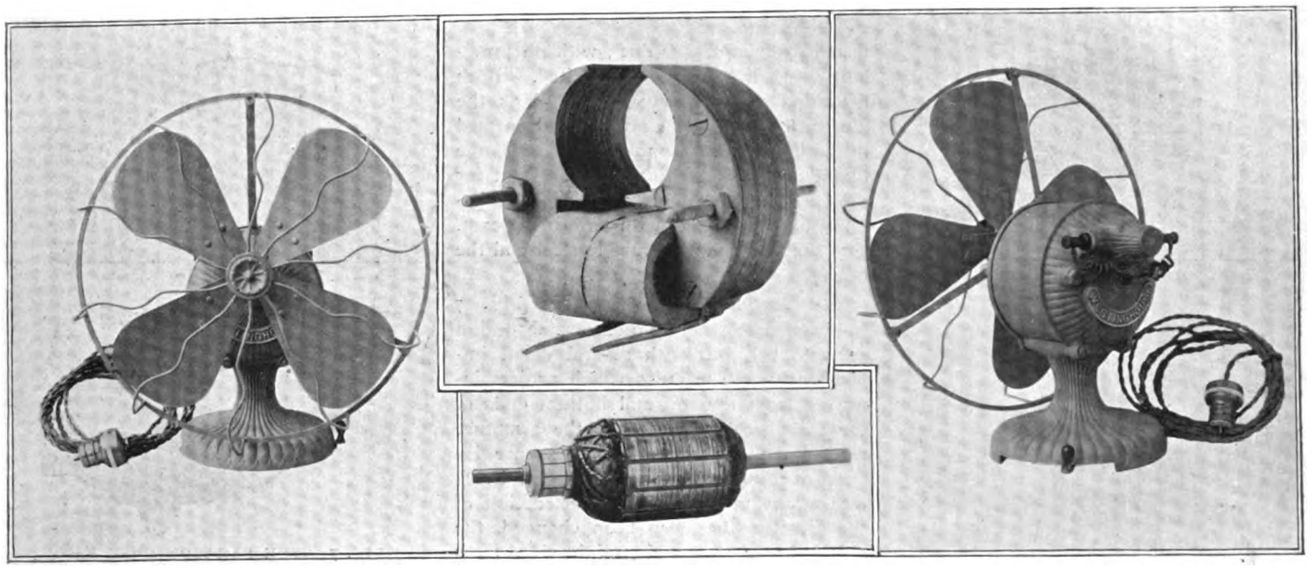

FIG. 2.—THE WESTINGHOUSE FAN MOTOR AND ITS PARTS.

Digitized by Google

lustrations of Fig. 2. As the detailed view of the interior parts shows. the field is crescent-shaped and made up of laminated steel plates, giving the body of the motor a circular contour with the fan centre above the centre of the body. The field laminations are tightly bound together by screws

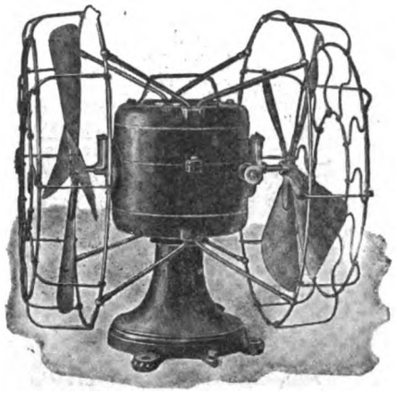

FIG. 4.—THE TOWLE DUPLEX FAN.

and the two through bolts which fasten the field to the end plates or brackets, maintaining the armature in alignment with the bore of the poles. The field is wound with two coils and these are so connected with the starting switch that either or both of them may be used, giving three different

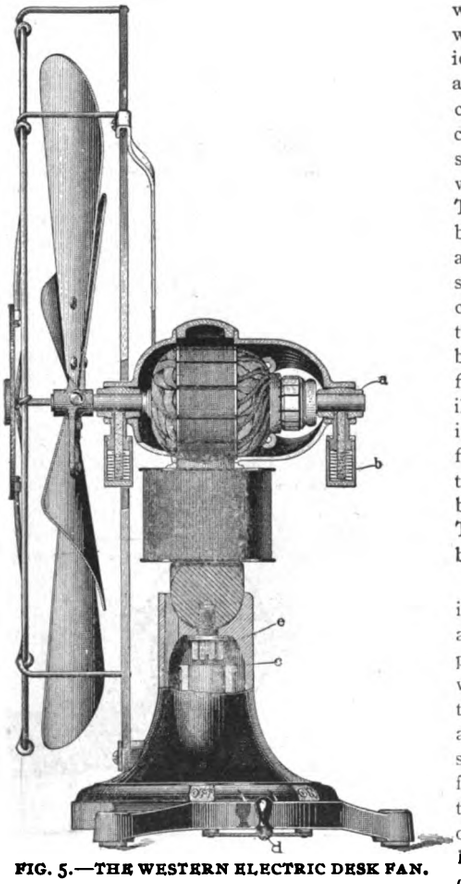

FIG. 5.—THE WESTERN ELECTRIC DESK FAN.

speeds, without the use of any dead resistance. The armature teeth overhang the slots and with insulating strips hold the conductors in place without binding wires. The motor complete with attachments weighs 23 pounds.

The desk fan shown in Fig. 3 has two special features, one the convenient handle screwed to the top of the case and the other the arrangement of the bearing at the commutator end. This is as shown mounted on a large circular ring with a three-arm spider allowing the inspection of the commutator, and of such proportions that its removal allows the ready replacement of the armature. The case is of the vertical cylinder type, which is coming into considerable favor in fan motor designs. A duplex fan, comprising a single motor, coupled to two fans with blades oppositely pitched so as to throw the air outward in each direction, is shown in Fig. 4.

The direct current fan shown in Fig. 6 differs only in minor details from those of the same make put on the market last year. The bracket fan is fitted with the usual two swivels, one allowing it to be rotated about a vertical and the other about a horizontal axis so that its blast may be delivered in any direction whatever. The view of the desk fan shows it with the back half of the iron-clad hemispherical body removed, exposing the armature and fields and showing the manner of their construction. It will be noted that field coils, which are form wound, are bent back so that the armature may be slipped out without disconnecting a single wire. There are no outside wires leading to the brush holders and further, while the fans are furnished with switches allowing four speeds, the contacts are completely enclosed in the base so that they are protected from injury or dust, with no possibility of their being short circuited. Both field and armature are laminated as the illustration clearly shows. Incorporated in the body of the fan are grease cups, one filling of which provides the lubricant for the entire season, doing away with the liability of dripping, as with an oil lubricant. The shaft is made of crucible steel and the bearings of phosphor bronze.

The familiar fan shown in Fig. 7 is in its main features of the same design as last year, but with several detail improvements. The poles which project inwardly from the top and bottom ends of the cylindrical field toward the armature are, in the 1899 model, made square instead of round, giving a greater useful surface at the air gap. The construction of the armature has also been changed, the old V-shaped slots and straight sided teeth having been replaced by tunnel slots and overhanging teeth, doing away with the need of binding wire, and improving the magnetic action. These changes, with improved materials, have allowed the weight of a 12-inch fan to be reduced by four pounds, bringing it down to about 13 pounds; the 16-inch coming down from 25 to 18 pounds.

In the simplification of details, the lugs by which the upper half of the field was fastened to the lower half have been done away with. The two screws which fasten the handle and name plate to the top of the motor now run straight down through and

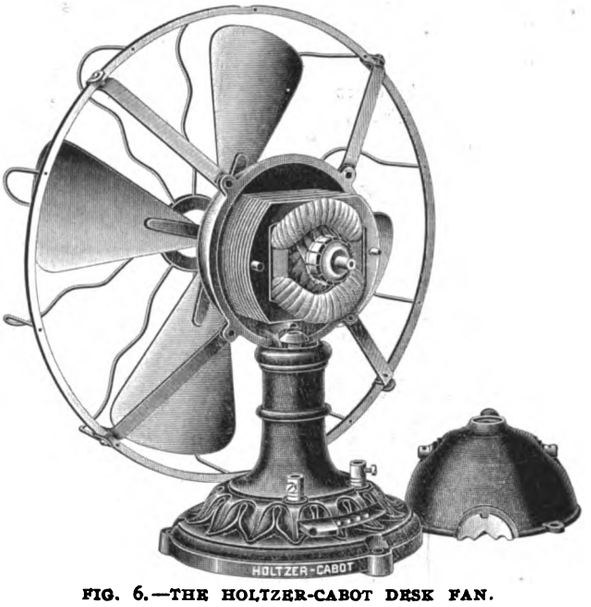

FIG. 6.—THE HOLTZER-CABOT DESK FAN.

fasten the two valves of the motor together, thus performing three useful functions. The carbon brush is now made with a square, instead of with the flat cross section of last year. and as before slides in a brass box in a black fiber tube. All wiring is done inside the motor shell, there being even no binding posts exposed, and the brass caps at the end of the brush holders are insulated, so there is no possibility of a shock or short circuit from the exposed parts of the motor. The bearings are self-aligning, and the front bearing is supported in a spider

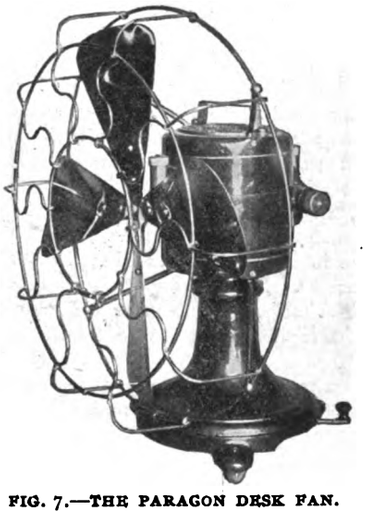

FIG. 7.—THE PARAGON DESK FAN.

which can be removed by taking out two screws, allowing the armature to be slipped out without taking the field structures to pieces. The starting rheostat under the base is of the enameled type on a porcelain plate.

A desk fan, which shows how ingeniously all the refinements of construction

Digitized by Google

can be obtained with the small number of parts allowable in a fan motor, is illustrated in Fig. 5. The motor is of the bi-polar type with a drop forged magnet and an enclosing shell protecting the commutator but leaving sufficient opening for the detection of sparking. The brushes are of graphite. The journals are self-aligning.

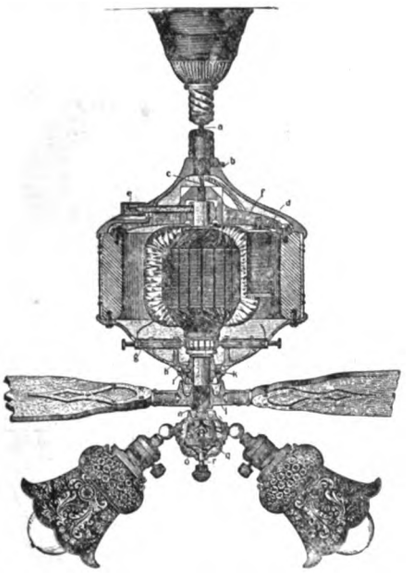

FIG. 8.—SECTIONAL VIEW OF WESTERN ELECTRIC CEILING FAN.

of Babbitt metal and slipped into cylindrically bored bearings in which they are retained by the stems of the oil cups. The chambers of the latter are filled with a heavy cylinder oil, which is carried up to the bearing by means of a wick pressed against the shaft by a coiled spring. A starting switch, giving three speeds, is mounted on

FIG. 9.—A WALL SWITCH AND RHEOSTAT.

a porcelain base under the pedestal which contains a rheostat of German silver wire insulated with asbestos and mica on a porcelain spool. The 550-volt motor is fitted with a double pole, quick break switch.

The ceiling fan illustrated in Fig. 8 shows evidence of the same careful design. The motor is bi-polar, with a circular enclosing yoke, the armature shaft running in self-aligning bearings similar to those in the desk fan. The armature shaft is tubular and inside of it is another tube through which run the wires to the switch and electrolier below the fan blades. The starting resistance is mounted on a porcelain spool inside the field frame of the motor. Below the upper journal is a small oil pan to prevent any oil coming from the upper bearing from running into the armature. A small hole leads from this pan through the tubular shaft allowing the oil to drain into the pan below on the top of the switch box. Still another pan in the hub carrying the fan blades catches oil from the lower journal.

For use with this fan there is provided a special wall switch rheostat, by means of which three speeds can be given to a single fan or to a group of fan motors connected in series on high-tension circuits. The style for a single motor is shown in Fig. 10 and for the group in Fig. 9. The latter is made up with the different resistances necessary for running various combinations of the different styles of fans on the different voltages customary on supply circuits.

An ingenious arrangement for reducing the speed of an alternating current motor

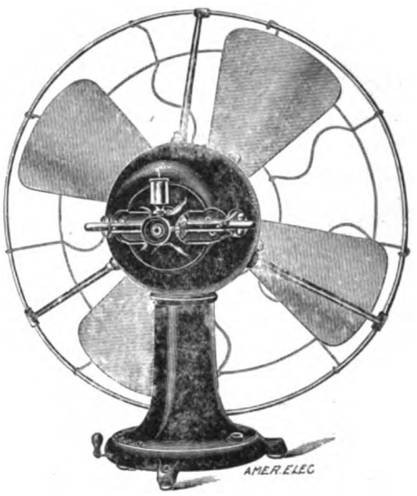

FIG. 12.—THE HURRICANE DESK FAN.

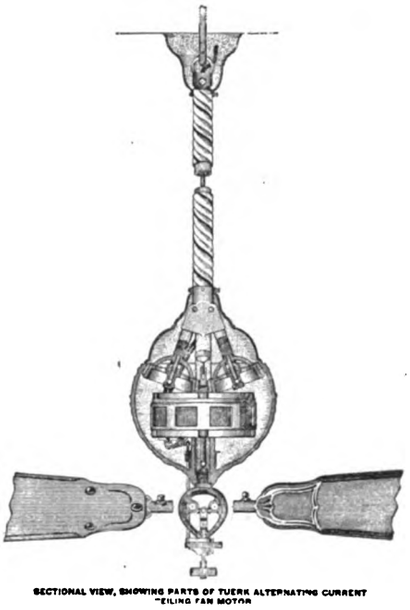
to that necessary for ceiling fan work without noisy gears or troublesome belts is shown in Fig. 11. Here the motor is shown mounted on a spherical ball bearing and driving a small friction pinion. This engages with two large leather faced wheels on hinged inclined shafts. On the outer surface of these wheels the spherical enclosing case hangs and to it are attached the fan blades. The motor armature runs at a high speed turning the intermediate pulleys at a moderate speed, and the outer case at a still lower speed. The whole constitutes a very compact and simple speed reducing device. The handle at the lower end of the motor is arranged to change the angle of the blades at will. A small wheel is also fitted with a rod running up to a switch within the motor casing.



Several improvements have been made in this year's construction of the Hurricane fan motor, as will be seen by reference to Fig. 12. The motor remains of the enclosed type with exposed commutator and brushes, but the field enclosing ring is now almost spherical in shape. The brushes are square and arranged for easy replacement. The bearings are of phosphor bronze self-aligning. The armature is easily removed by unscrewing the front

FIG. 10.—A WALL SWITCH AND RHEOSTAT.

bearing. A three-speed rheostat is fitted on a slate base. Double silk covered wire is used in the armatures of the 12-in. motors, and double cotton covered wire in the armatures of the 16-in. The wall fans are made with a ball and socket joint, so that the breeze can be directed both downward and to the side.

The fan shown in Fig. 13 has been de-

SECTIONAL VIEW, SHOWING PARTS OF TUERK ALTERNATING CURRENT CEILING FAN MOTOR

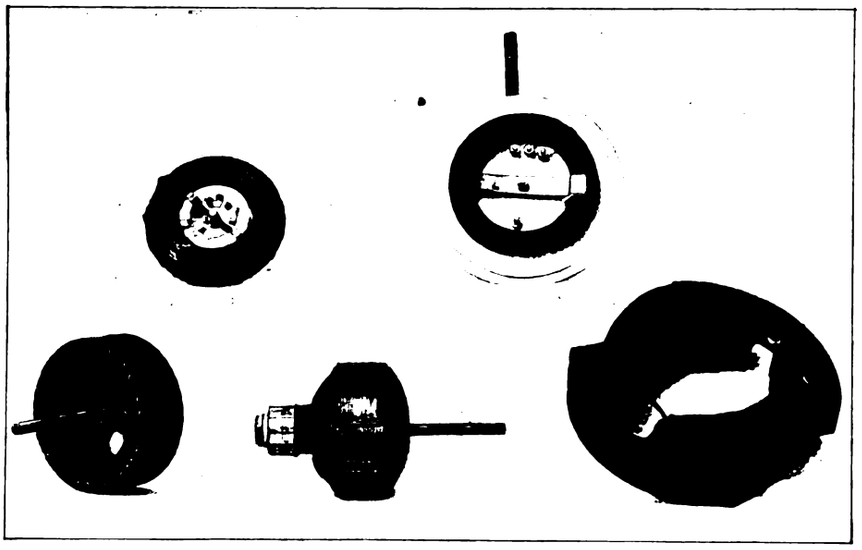
FIG. 11.—SECTIONAL VIEW OF TUERK ALTERNATING CEILING FAN.

signed with a motor body showing a spherical contour. The upper half of the sphere is removable to give ready access to the armature. One pole projects downward inside the upper hemisphere, and the other upward in the lower hemisphere, the

Digitized by Google

field coils filling the spaces between these polar projections and the shell, making a very compact motor, as all space within it is usefully occupied. The armature is as usual of the slotted type, with overhanging teeth and no binding wires, wound with double silk-covered wire. The crucible steel shaft runs in self-aligning bearings fitted with depending oil cups containing felt wicks. The guard is attached at its lower point directly to the base, without the usual yielding brace, making the guard remarkably stiff.

Some handsome designs of desk and bracket fans are shown in the group Fig. 14. Two models of the direct-current type are shown in the two right hand illustrations, that to the extreme right representing the new type known as the "house fan." It is a single speed fan intended to give a moderate breeze, with noiseless running and low current consumption. The motor is entirely enclosed and differs in that respect from its neighbor to the left, which is a more powerful multiple speed fan and



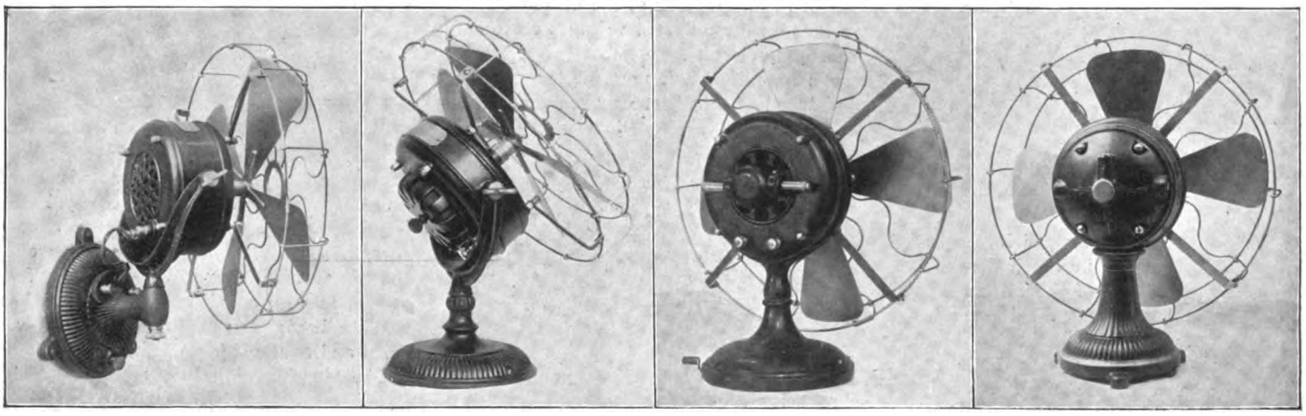


FIG. 15.—DETAILS OF GENERAL ELECTRIC FANS.

IG. 14.—THE GENERAL ELECTIC COMPANY'S ALTERNATING BRACKET, ALTERNATING DESK, DIRECT DESK AND DIRECT "HOUSE" FAN.

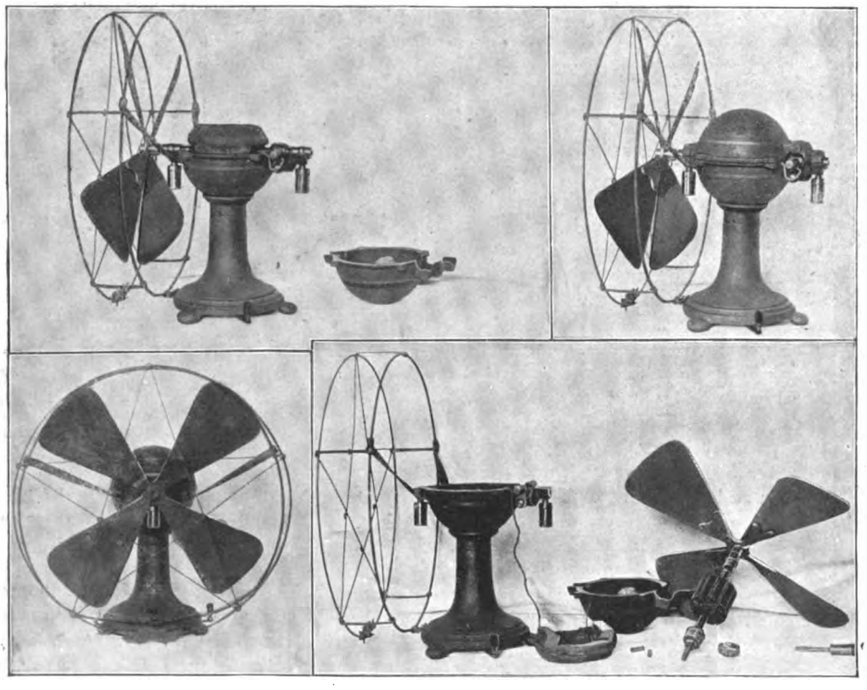

FIG. 13.—ROTH BROTHERS' FANS DISMOUNTED AND ASSEMBLED.

requires ventilation, for which it is provided with openings. This motor is peculiar in that it has only one bearing, an unusual feature in direct-current fans. This is a long tube or sleeve bushed with bronze and running deeply into the armature, the commutator over-hanging this bearing and projecting into a cup or bulb on the end plate of the case. This armature is shown clearly in the illustration of various details, Fig. 15, where its unusually large diameter in proportion to its length is clearly indicated. The same figure shows also the laminated steel field-magnet, which is ingeniously designed to give a bipolar field and to take form-wound field coils without any break in the magnetic circuit.

To the left of the direct-current motors in Fig. 14, are shown two alternating current fans, one designed for desk and the other for bracket mounting. The former has a speed controller, consisting of a coil concentric with the motor shaft and cut into or out of circuit by the thumb switch at its centre. The bracket fan has the same coil fitted within the base of the bracket, the thumb switch projecting through the casting. The motor is of the same construction as last year, with the pole-wound field having four poles for the

Digitized by Google

7200 alternation model, and the usual short-circuited squirrel-cage armature, a view of which is shown in Fig. 15. The rotating field for starting is obtained by means of short-circuited copper strips enclosing the corners of the poles and acting as "shading coils." These fans are made with trunion supports which give an adjustment much easier to control than does a ball and socket joint below the machine, as when the latter is loosened the motor tends to flop over.

The fan motor shown in Fig. 19 will be instantly recognized by electrical engineers as the well known design in which one single field coil, concentric, but not co-axial with the armature, energizes both poles. There are several great improvements in this year's design. In the first place, the cast iron field of former models has been replaced by drop forgings of high grade steel, the two which constitute the field poles and yoke being exact duplicates and interchangeable. The high permeability of this material allows a much thinner cross section, permitting the field coil to be twisted until its axis is more nearly in line with the shaft, so that the coil does not interfere with the endwise movement of the armature when it becomes desirable to remove or replace this part. The bearings are self aligning and fitted with hanging oil cups. The guard is of a very rigid construction, as the practical test illustrated in Fig. 17

FIG. 17.—THE LUNDELL GUARD.

clearly shows. Notwithstanding this rigidity it is of pleasing appearance. The guard is attached through only one brace, being fastened to the pedestal or base of the desk fan at two points.

The alternating current fan of the same manufacture is unique in that its motor is of the synchronous instead of the induction type, by which a much larger output from the same amount of material is obtained and the annoying lagging currents are entirely eliminated. The construction may be explained as follows: The external primary is built up of laminated iron with eight internally projecting poles, each wound with a coil supplied with alternating

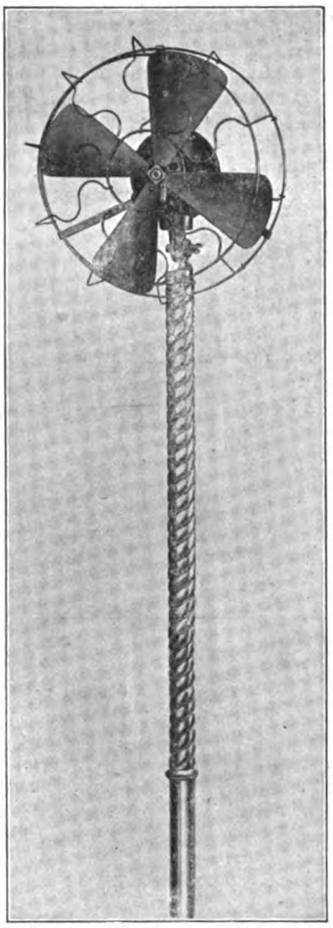

FIG. 18.—A LUNDELL "BUZZ" FAN ON A COLUMN.

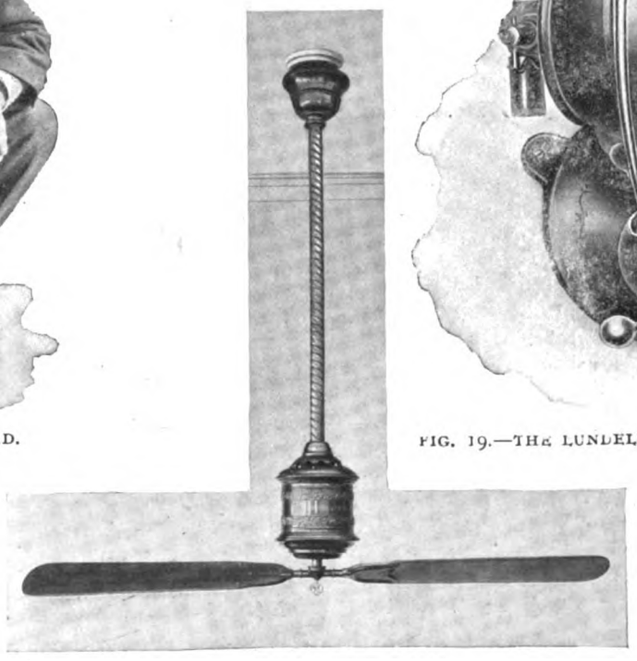

FIG. 16.—THE GENERAL ELECTRIC CEILING FAN.

currents. No auxiliary coils or phase displacing arrangements are used whatever. The internal rotating part or armature is laminated, slotted and wound with two circuits, one of which is short-circuited in a suitable way to act as a secondary to the eight poles. The other is connected up to a disc-shaped commutator. A pair of brushes bear on this commutator, connecting it in series with the field circuit. On starting, the machine acts as does any series motor, both armature and field magnetizations reversing simultaneously, thus giving a pulsatory torque always in the same direction. As the machine runs up in speed the short-circuited secondary winding takes hold and gives a powerful torque, as an induction motor running the speed almost up to synchronism. At synchronism the commutator obviously acts as a rectifier, giving a pulsatory direct current to the rotor winding connected to it. This pulsatory direct current sets up direct magnetic poles in the rotor which react on the a. c. field and make of the machine a synchronous alternating motor, with an internal rotating field magnet energized by the rotary transformer action of its commutator. At synchronism, of course, the short-circuited winding exerts no torque at all, but it does serve in connection with the self-induction of the rotor iron to smooth out by the currents induced in it the pulsatory magnetization of the rotor teeth, and

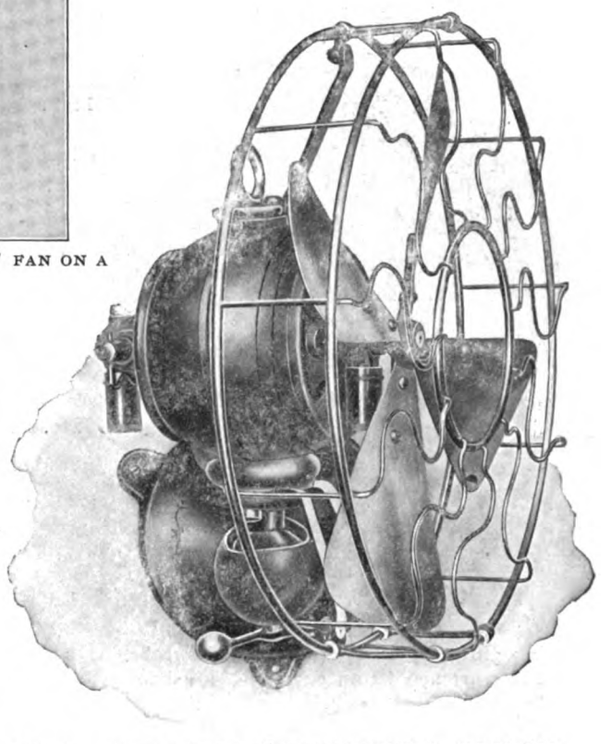

FIG. 19.—THE LUNDELL 1899 BRACKET FAN AND MOTOR.

thus renders this magnetization practically constant. This field can be made very strong, thus giving a high power factor or even leading currents.

An electrolier fan, wherein the four fan blades are attached above the moving part of the motor within the basket, is shown in Fig. 21. It is made in the usual voltages, 110, 220 and 500, and also for 167 and 250 volts for running in groups of three or of two, series connected across 500-volt circuits. The machine is provided with but

Digitized by Google

a single self-oiling bearing, extending the entire length of the motor. The armature hangs around this bearing much as do the rotating parts of the mammoth Niagara generators, giving a very stiff alignment of fields and armature. The switch at the bottom of the motor housing is inclosed

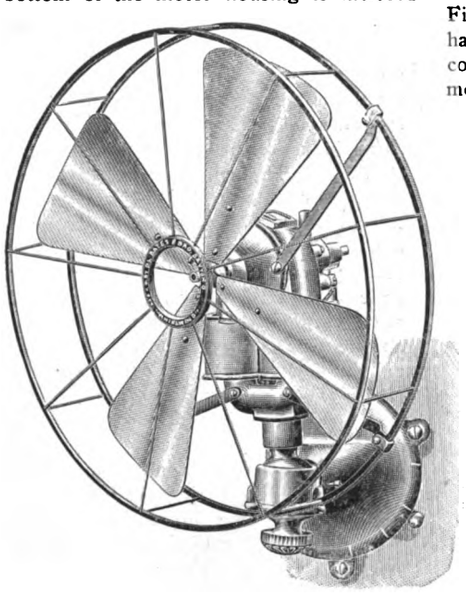

FIG. 20.—A 16-INCH BATES BRACKET.

FIG. 22.—FIELD OF EMERSON MOTOR.

in an inverted cup of the casing, so that the electrolier may be set on the floor without breaking off the switch handle. Fig. 20 shows a 16-in. bracket fan of the same make, built with a bipolar forged steel magnet. It is swiveled on one ball and socket-joint, allowing motion in any direction either vertically or horizontally. This fan is also furnished with a base when used as a portable desk fan.

An alternating current motor for desk or bracket fans which makes the term "buzz fan", a misnomer, is shown in its assembled form in Fig. 24. The most conspicious peculiarity about this fan is the novel ear-shaped configuration of the blades, the following edges having a peculiar curve which the makers claim does away with the buzzing noise so often an accompaniment of high speed fans. The details of the motor construction have been carried out with great care. In its general principles the motor is of the usual induction type with a short circuited secondary, the conductors of the latter being copper straps closed upon themselves as Fig. 23 clearly shows. The shaft is a case-hardened steel tube pressed into the back cover, the armature or rotor being mounted on a tubular hub or sleeve which slips on to this tubular shaft. The detailed construction of this bearing is shown in Fig. 25, where M is the central shaft with screw plugs C and I at its two ends and an oil well A, feeding oil to its interior. The

FIG. 23.—ARMATURE OF EMERSON MOTOR.

tubular hub of the motor armature bears upon the central shaft through two bearing sleeves F and oil is admitted to the wearing surfaces through the holes L. To absolutely prevent any throwing of oil a felt washer is mounted at D, which is obviously the only point at which oil can escape. By unscrewing the fan, which has a left-hand thread, taking off the front cover and removing the plug screw I the rotating parts may be slipped out. To prevent any oil from coming out from the front on to the fan blades and being thrown to surrounding objects, the fan hub forms a screw plug which seals the end of the armature head.

A similar blade to that described above is also used in the fan shown in Fig. 28, and is in this case termed by the manufacturers the "New Departure" blade. The

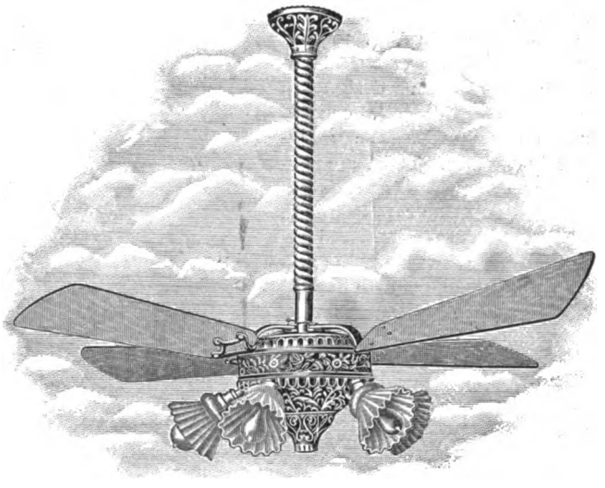

FIG. 21.—THE BATES STATIONARY ELECTROLIER FAN.

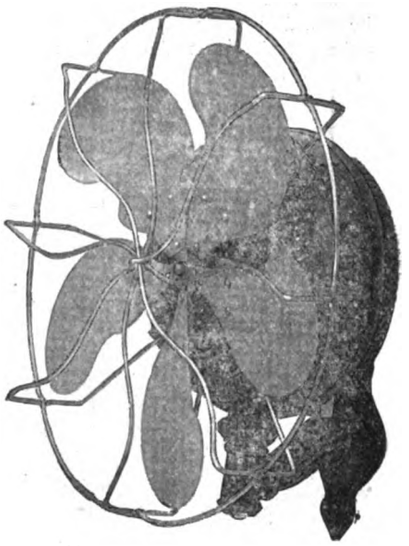

FIG. 24.—THE EMERSON BRACKET FAN.

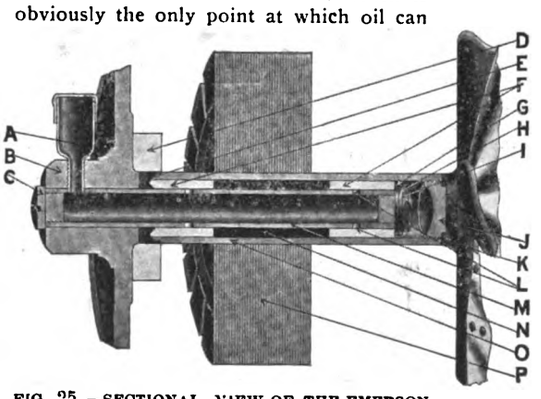

FIG 25.—SECTIONAL VIEW OF THE EMERSON BEARING.

ceiling fan of the same make is shown in Fig. 26. The peculiarity of this fan is the fact that the commutator, which is at the top of the motor, is always in sight. The armature is of the drum type with an external field

The construction of the motor of a ceiling fan with ingeniously arranged parts is clearly indicated in the cross section reproduced in Fig 30. The motor is bipolar with a field magnet crossing the shaft and wound with single coil N. This energizes the peculiarly shaped poles L, which have a deep channel section embracing three sides of the armature I. This in turn is fastened by screws X, to the lower part of the enclosing case, and

Digitized by Google

through it drives the fan hub A. The thrust bearing is immersed in oil in the chamber in this fan hub.

A view of the alternating current ceiling fan of the same make is shown in Fig. 29. Here the primary or field circuit is wound on a toothed and laminated core, mounted on the spider, and the armature or secondary revolves outside of it. The armature drives the fan blades through the lower part of the enclosing shell, the rotating parts resting on a ball bearing in an oil cup, and supported by the fixed hollow steel shaft, which is one inch in diameter. Fig. 27 shows an alternating current desk fan of the same make, which is fitted with a knock-down or removable guard, allowing an easy access to the blades and bearing. There is one bearing extra long of phosphor bronze and lubricated by an oiling ring, similar to those used on dynamos.

A fan called the "search light," because its blast can be turned in any direction, vertically or horizontally, is shown in Fig. 31. The flexibility of its support is obtained by the combination of a swivel and a trunion, the adjustments being maintained by hardened cup-pointed set screws. The motor body, although inclosed, is provided with openings for ventilation. The motor has two self-aligning bearings, and the cover on the commutator end is fitted with an extension inclosing the armature and a further extension carrying the bearing. The base of the motor is recessed for a snap switch, which is also a speed controller.

The construction of the motor of the ceiling fan manufactured by the same concern is admirably designed as follows: The upper bearing runs in an oil cup which is attached to and revolves with the armature shaft so that no oil can leak out of it into the armature. Its walls are contracted toward the top so that the oil will not fly out of it by centrifugal force. The lower bearing is imilarly arranged and the vertical thrust is taken up by a ring of hardened steel balls. Two different styles of field magnets are made for this fan, one of the circular yoke type, with removable steel pole pieces projecting inward toward the armature, and the other of a single iron casting, with poles ingeniously shaped so as to receive the field coils, as is shown in Fig. 32.

The detail construction of the motor of another direct current ceiling or column fan is extremely interesting, and is shown in Fig. 35. The armature is of the Gramme ring type, running in a bi-polar field, generated

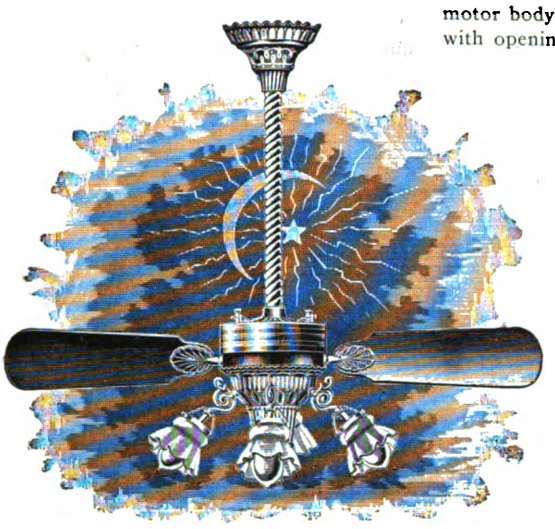

FIG. 26.—THE CRESCENT FAN WITH FOUR-LIGHT ELECTROLIER.

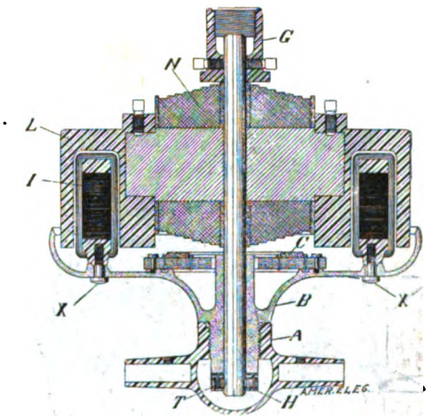

FIG. 30.—THE DAYTON DIRECT CURRENT CEILING FAN MOTOR.

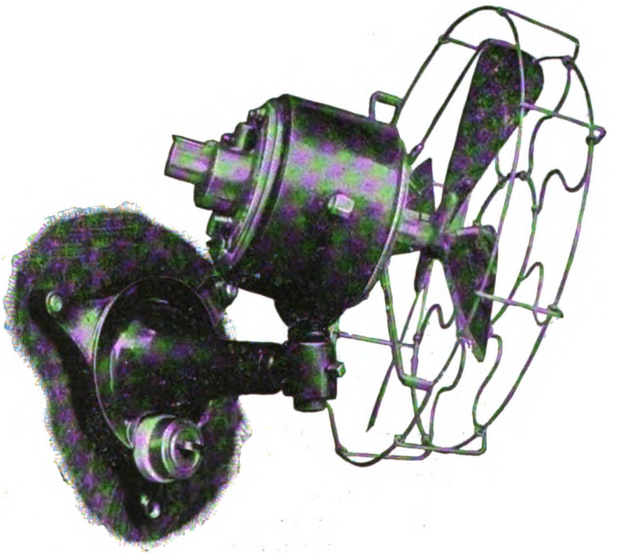

FIG. 31.—THE STANDARD SEARCH-LIGHT FAN WITH BRACKET MOUNT.

Digitized by Google

by a magnet immediately below it. The commutator is of the flat disc or radial type, with two downwardly bearing brushes pressing upon it. The shaft is a tube through which runs a rod attached to the switch below, and the armature overhangs the single long bearing running down through the field. Lubrication is effected by grease contained in a pocket in the middle of this long bearing and the construction is such that by no possibility can any grease escape from below, the hemispherical shell of the fan being integral with the hub of the blades and revolving therewith.

FIG. 32.—A FIELD MAGNET FOR A STANDARD CEILING FAN.

The ceiling fan shown in Fig. 38 is so arranged that by the removal of three screws the armature may be taken out without detaching the fan from the ceiling. The rotating parts are supported on a ball-bearing running in an oil cup of sufficient size to furnish lubrication for an entire season. Fig. 33 shows a desk fan made by the same manufacturers, the most prominent feature of which is the absence of any breaks in the magnetic circuit. The fan is not divided in a horizontal plane as is usual in fans of this shape, but is split vertically, the cover, which forms one side of the case, being removable without separating the poles.

A battery fan ingeniously designed to obtain maximum output from the small power available from a primary battery with the absolute simplicity of parts necessary in such a small motor is illustrated in Fig. 36. The motor has a single field coil and a pole-wound armature with six teeth or poles. The fan is fitted with four blades and the usual guard. The 6-in. fan requires two, the 8-in. fan three and the 10-in. fan four cells of Gordon primary battery.

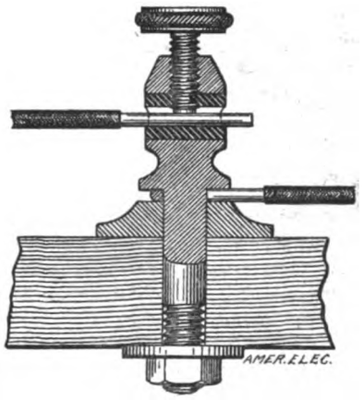

FIG. 34.—THE SWITCH OF THE FULLER FAN.

Fig. 37 shows a battery motor in which one part has been ingeniously designed to do the work previously required of two. The baseboard switch is replaced by a simple modification of one of the binding posts which will be clear on inspection of Fig. 34. The wire entering the binding post, runs through an insulated sleeve or bushing, through the wall of which the binding screw projects. By simply loosening the screw the current is turned off and by tightening it turned on again, so that the only addition to the parts otherwise required in a binding post is the insulating sleeve. This simplification is covered by patent.

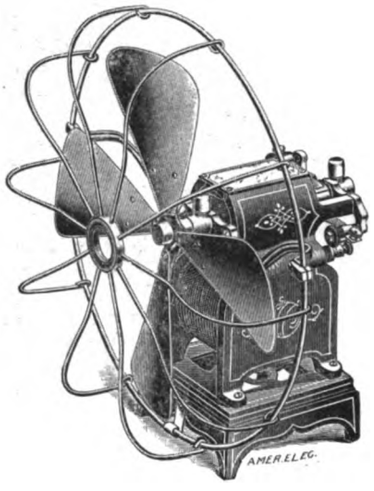

FIG. 37.—THE FULLER BATTERY FAN.

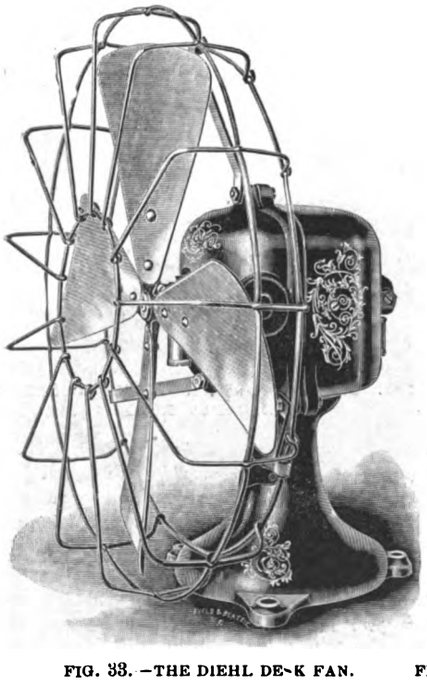

FIG. 33.—THE DIEHL DESK FAN.

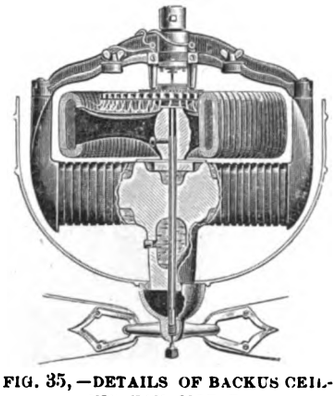

FIG. 35.—DETAILS OF BACKUS CEILING FAN MOTOR.

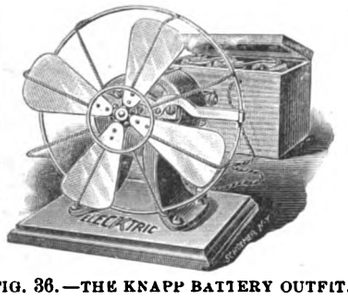

FIG. 36.—THE KNAPP BATTERY OUTFIT.

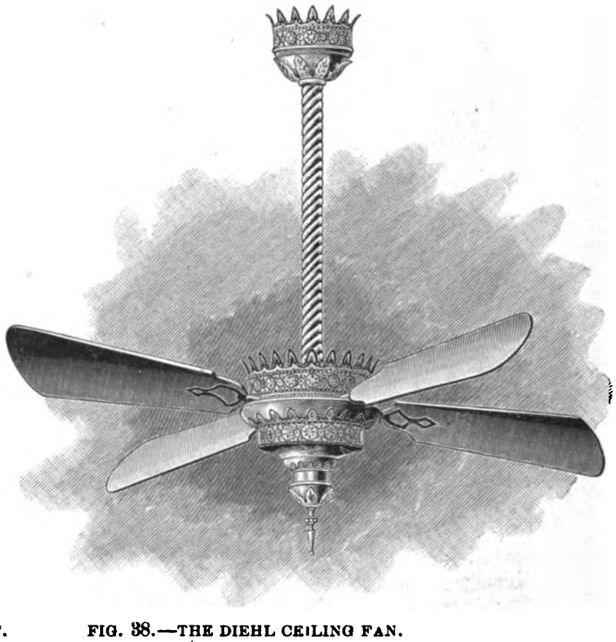

FIG. 38.—THE DIEHL CEILING FAN.

For locations where dynamo power is unavaliable, the primary battery must be depended upon for current, and good results can be obtained if a battery of sufficient output is installed. The ordinary gravity battery gives an economical source of current but will only stand a slow rate of discharge, so that a large battery would be required to give sufficient power to run a fan. By using a storage battery continuously charged by the proper gravity battery and intermittently discharged at a higher rate when the fan is used, a moderate sized gravity battery is made valuable for fans of no mean power. Such a combination is that represented in Fig. 40, which shows a box containing six "Ex-

Digitized by Google

cello" improved gravity cells charging a two-cell storage battery in a separate case, which in turn feeds a small four-volt motor carrying an 8-in. fan, represented on the lid of the battery box. In case continuous service is wanted from the fan, another primary battery of the same number of cells may be used in multiple with the first, and the storage battery dispensed with. The storage cells are practically sealed to prevent the spilling of their contents and are fitted with capped vent tubes, which appear in the illustration. The fan motor is of the ironclad type, fitted with one long self-oiling bearing.

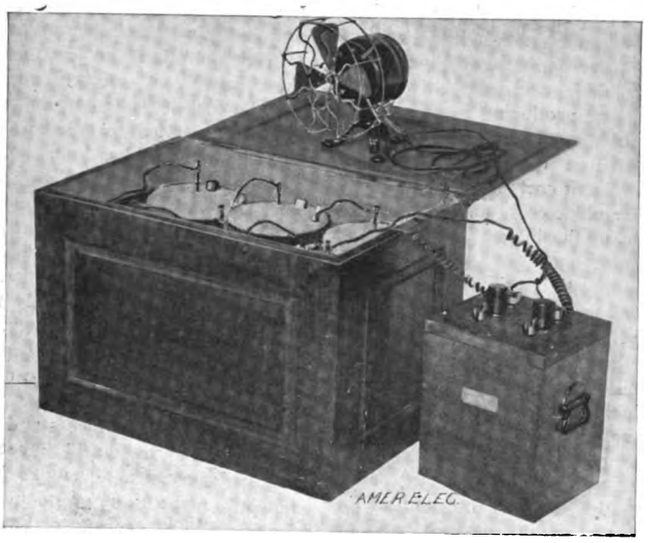

FIG. 40.—THE EXCELLO FAN AND PRIMARY AND STORAGE BATTERY OUTFIT.

An outfit specially designed for and of obvious value in a telephone booth is illustrated in Fig. 39. Its use is not limited to any time or season, as every telephone booth is close at any time of the year. The motor is specially designed to run noiselessly and produce no vibration, absolute requirements in this service. It is suspended from ornamental brackets by means of two helical springs. It is wound for battery voltage and may be connected in series with the incandescent lamp, if there is one, within the telephone booth, the switch on the motor starting both lamp and fan when the booth is to be used and cutting both off when the booth is vacant.

With the coming of hot weather the necessity arises for renewing the air in interiors as well as setting it in motion. For this purpose motor driven ventilating fans or air propellers are now very widely used. Fig. 41 shows a belted combination of this type using a single-phase self-starting induction motor. The motor and fan are provided with two-step cones, so that the speed of the fan can be changed by transferring the belt.

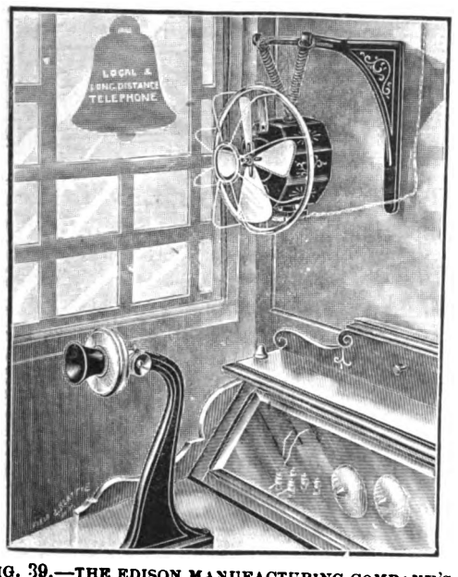

FIG. 39.—THE EDISON MANUFACTURING COMPANY'S FAN FOR TELEPHONE BOOTHS.

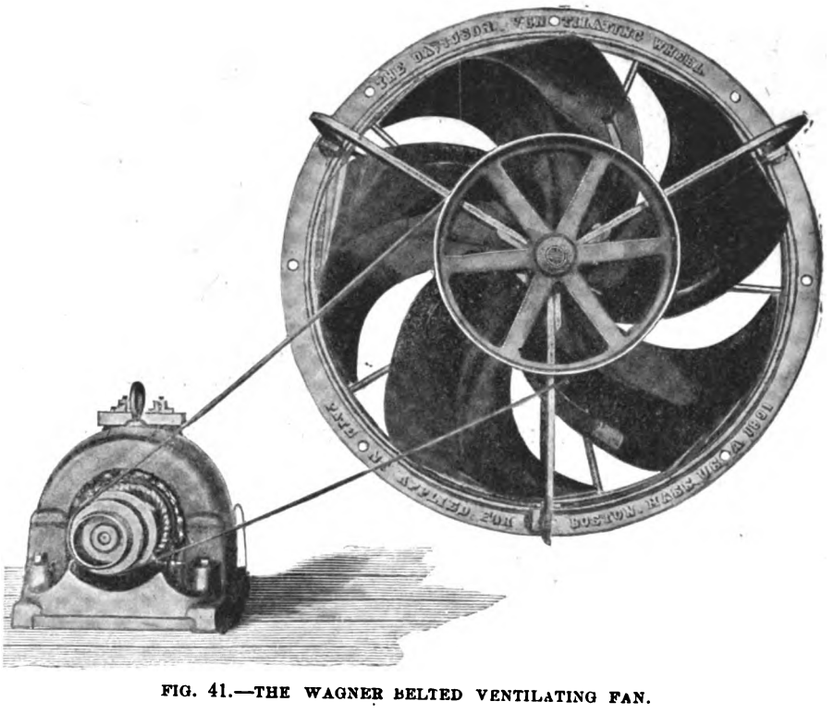

FIG. 41.—THE WAGNER BELTED VENTILATING FAN.

## THE ACCUMULATIONS OF CULM IN THE COAL REGIONS AND THEIR UTILIZATION FOR POWER PURPOSES.

BY HARRY N. GARDNER.

All travelers who have passed through the anthracite region of Pennsylvania remember the mountains of black waste piled around the coal breakers, which have possibly been looked upon as only making more unsightly an already unattractive scene, adding to the dirty appearance of a landscape that already looks as if in need of the cleansing powers of a second deluge.

These unsightly culm piles were for years looked upon almost as a curse to the region. But as the engineering and commercial eyes of the progressive nineteenth century have seen in Niagara's spray something more than picturesque grandeur, so they have seen in these heaps of waste coal screenings something more than mountains of dirt; they have looked beneath the unattractive exterior and seen the countless wheels that could be turned by these Niagaras of culm.

While these piles are looked upon as consisting of coal that is of no commercial value, the fact remains that a large percentage of many of the culm banks consists of good, heat-producing, power-generating fuel.

A quarter of a century ago it was thought to be impossible to burn fine coal, and everything that in the sifting graded smaller than chestnut was considered to be waste, and was consigned to the dump. Grates were then invented for burning pea coal, and gradually the size of commercial coal has been reduced until now there are four regular grades finer than pea.

This former distinction in the size of fuel

Digitized by Google

that was suited for commerce resulted in many of the older culm piles throughout the entire mining region containing a large percentage of coal that would now pass into the regular channels of trade.

One such pile of culm that stands almost in the business center of Scranton, encumbering what is now valuable real estate, was purchased a few years ago for a small amount, a breaker was erected at one end of it, chain conveyors running from the breaker to the pile drag in the coal, and this old dump is being resifted. The purchasers are making a fortune out of what was thrown away as waste.

Even with the more careful screening of coal used at present and the large decrease in the percentage of waste through the reduction in the size of marketable fuel, the fact remains that millions of tons of good fuel are every year being consigned to these dumps; and, because the better grades of coal are more inclined to crush, much of this culm is, aside from its size, the best of the fuel mined. One competent authority estimates that up to 1891, in the Scranton district alone, there had been 22,000,000 tons of clean coal thrown upon these dumps, and 1,330,000 tons are still being added every year.

Another problem confronted the coal operators a few years ago. Not only was there this large waste of fuel, but to get rid of it, it was necessary to take up space which in some cases would otherwise be valuable real estate.

Of course there has always been much thought expended on the matter of finding a use for this waste. One scheme that has been for years, and still is being, tried is to compress the culm into briquettes after mixing the dust with some kind of binding material. Such a course will probably always be a failure, not because the product is inferior, for it does make the best of fuel, but because of the cost of production. In many cases, as is being done in several places besides the one referred to, it will be possible to partially solve the problem by sifting over the old dumps.

Steam and mechanical engineers have long been working at the problem from another side, with better results, by trying to build furnaces and grates that will burn the culm just as it exists in many of the heaps.

There are piles that contain so much dirt, rock and slate that their contents are practically worthless for fuel; but taking the average dump, aside from these and those others that contain enough large coal to make it pay to resift them, and it is found that culm can be successfully burned, and that it has a heat producing value of about 70 per cent of that of egg coal. But as it takes more of it to generate a given amount of steam, it costs more to handle it, and the boiler plant costs more in the first place, adding to the interest and depreciation account.

When the question arises of using this fuel at a distance from the mines, a proportion is at once found where the extra freight for the increased tonnage, cost of handling and higher fixed charges for the steam producing plant take one side, and the difference in the cost of the two kinds of fuel at the mines the other. It is found that the former soon overbalances the latter, so that culm is not an economical fuel except within a certain distance from the mines. As to the economy of using culm in the mining regions, where it costs from nothing to 35 cents per ton, and egg coal costs $2.40 per ton, there is no doubt.

The Illuminating, Heat & Power Company, of Scranton, has culm furnished for its electric light plant by the Jersey Central Railroad, which, rather than encumber valuable real estate, delivers the fuel to the door free; thus the only expense which the company has for power is the cost of firing and the interest on the plant.

The Suburban Electric Company, of the same city, which is controlled by the same company that is resifting the large dump referred to, built its plant at one end of that dump, and the fuel costs the interest and depreciation on the plant, the dragging in of the culm with a chain conveyor and firing with an automatic stoker.

This dump is shown in the photograph. The small breaker for resifting can just be seen at the lower left hand corner of the picture. The electric light plant is out of sight, back of the culm pile.

From a set of tests carried out by skillful engineers and from computations furnished by the best engineering authority, it is found that power for driving machinery can be generated in the anthracite region at a cost of $10 per h.p. per year. This estimate includes the interest, insurance, taxes and depreciation on engines, boiler plant and buildings, the cost of firing and removing the ashes, the cost of fuel, figuring the culm to cost twenty-five cents per ton, and the cost of water (the water costs more than half as much as the fuel) power to be furnished for twelve hours a day for 313 days per year. This will be seen to be as cheap as it has ever been calculated that power can be furnished from Niagara Falls.

Besides the millions of tons of culm now standing in the dumps ready to be transformed into mechanical energy, there is fuel enough every year being piled upon these culm banks, in the Scranton district alone, to generate 75,000 h. p.

For years the engineers and manufacturers of the entire world have seen in the mighty cataract a few miles from Buffalo not only picturesque grandeur unsurpassed for its kind in the world, but commercial power developing possibilities equally unsurpassed. Now this engineering dream is realized, and the commercial wheels of Buffalo are being turned by the might of Niagara Falls, over twenty miles distant.

In the development which must necessarily come to the city by the lakes, because of the inducements offered to manufacturing enterprises by the cheapness of Niagara's power, the cities over the mines should not be overlooked; nor should it be forgotten that they can offer to manufacturing industries the inducements of even cheaper power.

And should the other engineering dream be realized, and electrical transmission of energy be perfected to such an extent that power from Niagara can be economically used to drive the commercial wheels of New York City, as has frequently been suggested, it is easy to see that the cheap power that can be generated in the mining regions is over 250 miles nearer to the metropolis than are the Falls, and it will have the fixed charges against just that many miles of transmission line in its favor for running metropolitan machinery by the Niagaras of culm.

A SOURCE OF CHEAP FUEL FOR THE SUBURBAN ELECTRIC COMPANY, OF SCRANTON.

## EFFECTS OF HIGH-PRESSURE STEAM ON ENGINE CYLINDERS.

BY F. W. ROLLER, M. E.

The numerous advantages in the line of efficiency that are gained by the use of steam at high pressures in steam engines have long been recognized, but the difficulties which became marked as the pressures approached 125 to 150 pounds, not so much on account of mechanical strength of fittings and parts as of lubrication at the high temperatures involved, seemed for a time a serious bar to further progress in that direction. Even at present it seems to be believed by a large majority of those having charge of the operation of steam machinery that markedly higher pressures are by no means commercially practicable or advisable except under special conditions, and that the old troubles of burnt-out piston and valve rod packings, and scoring of cylinders and valve seats would be sure to confront those who might attempt to employ appreciably higher values. This is well evidenced by the fact that only in rare instances are large plants designed for pressures of over 150 pounds in spite of economy and space being gained thereby, while in the large majority of cases much lower limits are assigned.

In the above connection it may be of interest to note that under that most trying of all services, namely marine work, the modern tendency is to make 250 pounds at the engine throttle a standard and even 350 pounds is being employed abroad in work of this class and giving the best of satisfaction.

The question of manufacture of fittings for these pressures was a comparatively simple engineering problem, involving, to be sure, careful testing and design, and equally careful workmanship, but nevertheless completely soluble.

The lubrication factor was, however, another affair, no oils either animal or mineral having been found that would operate continuously and satisfactorily under the high degree of heat. All proved, moreover, highly objectionable in that they coated the condenser surfaces with a non-conducting film that utterly destroyed the efficiency of this part of the plant and were equally troublesome where not positively dangerous when they reached the boilers. Plumbago, when used, in addition to being difficult to properly inject and distribute, had a cheerful habit of clogging all small passages and check valves and was also found to be unsuited.

The final solution of the difficulty has been to take the bull by the horns and simply dispense with lubricants altogether.

There seems to be a peculiar property of cast iron when employed for cylinders by virtue of which if it can once be run to a glaze without the employment of oil, it will acquire a polish far higher than is ordinarily seen and operate indefinitely without the use of lubricants, barring, of course, any introduction of foreign matter between the working faces. The action must be analogous to the increase of surface density caused by ordinary burnishing processes, and is perhaps still better exemplified by the surface hardening that takes place on the faces of the thread in the well-known screw type of elevator where the balls interposed between the screw and the threads in the anti-friction nut, rolling under great pressure between each, polish and compact their surfaces in a very similar way although not of course under such high temperature. Getting the initial glaze seems to be largely a matter of luck, as the most careful machining, cleaning and removal of burrs can hardly be relied upon to remove the almost infinitesimal chips or shoulders which start the cutting action and it takes a great deal of stoicism sometimes to refrain from starting up the lubricators when a cylinder commences to "squeal" and the pistons are traveling at a speed ordinarily considered to be, if anything, a little over the limit set by the best practice.

So satisfactory is this method of operation, however, that in the case of a large number of our torpedo boats, where 250 pounds is the standard pressure and the piston speeds run up as high as 1,400 feet per minute, the cylinder lubricators are dispensed with entirely, and the only oil that ever gets into the cylinders is introduced through the indicator piping and this only when it is known in advance that the engines will not be used for the space of twelve hours or more and that at the same time there will be no opportunity to take off the cylinder and valve chest bonnets to dry off and coat the surfaces with a thin layer of vaseline or the heaviest cylinder oil as a protection against the rapidly formed rust.

The valve stem and piston rod packings are of course subject to more severe service than the piston rings and cylinder liners as they work in whatever small amount of dust and dirt there may be flying about and moreover must be entirely steam tight. A sufficient number of metallic packing rings with a couple of turns of soft packing at the end have, however, in connection with the small amount of oil which would naturally find its way to the rods, been found to answer well here.

It has been generally considered that the moisture in the steam acted as a lubricant in the above cases, there being always, even under the best conditions, not less than 2 per cent. of this present. This seems to be disproven by the practice that has been universally adopted abroad and which will be employed on the new men-of-war contracted for by our own Government, in which, in order to get the advantage of the far smaller cylinder condensation losses following on the use of superheated steam, the boiler pressure is kept much higher than that at which the engines are to be run and reducing valves are inserted which by wire drawing, give the superheating effect desired. (The common practice is 300 pounds at the boilers and 250 pounds at the engines.)

This system has been in operation on a large scale and in a number of vessels for at least two years past with no objectionable results.

It will be noted that all the foregoing concerns engines of the vertical type. The writer is not aware of this having been worked on any scale with horizontal engines and it is possible that the weight of the piston riding on the lower surface of the cylinder would in this case render the attainment of the glaze difficult or impossible. If this should be so, however, tail rods, either open or covered by long bonnets are perfectly feasible and the marked gain in efficiency which high pressure saturated or superheated steam gives would be a large return on a trifling expenditure.

## THE WEHNELT INTERRUPTER.

BY CHARLES T. CHILD AND GEORGE T. HANCHETT.

Interrupting apparatus for the primary circuits of induction coils has received no little attention from inventors and students of late years, especially since interest in X-ray work has caused the induction coil to be the subject of much experiment. The desideratum in this form of interrupter is practically instantaneous closure and opening of the circuit, and experiments without number have been made for this purpose, most of them being with the ancient hammer-break or tooth-wheel contact in some form. With the sole exception of the liquid-contact breaks, recently patented by Mr. Tesla, there seems to have been no radical innovation in this field until Dr.

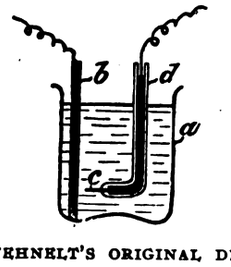

FIG. I.—WEHNELT'S ORIGINAL DRAWING

Wehnelt described, in one of the German papers, the remarkable invention which forms the subject of this article.

The drawing published with his description is reproduced in Fig. 1. The interrupter consists solely of a vessel, a, containing a plate of metal, preferably of lead b and a glass tube d having a bit of platinum wire sealed in its lower end, and filled with mercury. The cover, a, is filled with an electrolyte, preferably sulphuric acid and water in about the proportion used for accumulators. If this apparatus is connected into a circuit of sufficient power, so that the fall of potential between the two electrodes is more than about 12 volts, the well known forge-effect will take place if the metallic plate is the anode. The platinum tip c will be melted and the apparatus probably destroyed.

If, however, the connections are so made that the platinum point becomes the anode and the metallic plate the cathode, then there will be seen a yellowish glow surrounding the platinum tip, bubbles of gas will stream up from it, and the cell will emit a harsh, buzzing, definite sound, showing

Digitized by Google

that rapid vibrations of some character are taking place in it. Dr. Wehnelt's discovery was that the current was periodically interrupted by this simple apparatus, and that the interruptions are perhaps sharper and more definite than those due to any form of mechanical interrupter. Such an

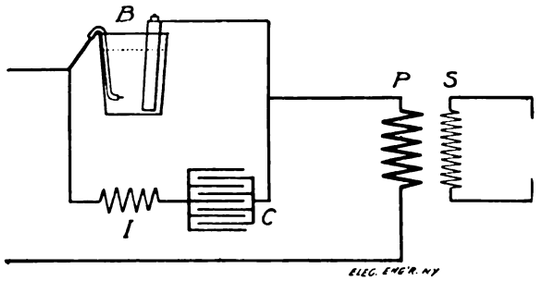

FIG. 2.—INTERRUPTER SHUNTED WITH CONDENSER AND INDUCTANCE.

apparatus connected in series with the primary of an induction coil gives surprising results. A stream of sparks of great intensity bursts from the secondary terminals, and if these are approached within a moderate distance of one another the sparks merge into a continuous arc, possessing all the qualities of the high-tension alternating arc. The effect upon vacuum-tubes is astonishingly powerful, but the production of X-rays by this means is not so satisfactory as might at first be thought, for the discharge seems to be almost purely alternating in character and not of the unidirectional sort necessary for this purpose.

The literature of this subject is doubtless destined to be large. So far, perhaps, the most important contributions to it are the results of experimental work published by Prof. Elihu Thomson in the "Electrical Engineer" of March 2, and in the "Electrical World and Electrical Engineer" of March 18, 1899. In Dr. Wehnelt's original paper the effect was noted that the frequencies of interruption increased with the voltage. The more recent work goes to show that the frequency of interruption depends upon the area of the platinum exposed, the inductance in the circuit and the voltage, and that it is important, in order to secure high frequencies of interruption, that the self-induction of the circuit should be as small as possible. This is well illustrated by bringing the secondary terminals of a coil actuated by a Wehnelt interrupter close together, so that an arc is established between them. This naturally reduces the inductance in the primary circuit and the note given out by the apparatus immediately rises in pitch. The size of the platinum determines not only the frequency of interruption, but also the amount of current that will pass under a given voltage, and interruptions, judged by the pitch of the sound given out, as frequent as 2000 per second may be had by using a platinum point of No. 24 wire about 1-16th of an inch long.

Prof. Thomson noticed that, as the frequency increases, the induction coil behaves more like a high-frequency apparatus and that if the interrupter be shunted with a condenser, as shown in Fig. 2, very brilliant high-frequency effects may be had. He also noticed that as the speed of interruption increased, the secondary discharges became more purely alternating in character.

This able experimenter has made the following tentative suggestions for an explanatory theory of the action of the interrupter: "On the attainment of a certain current density the wire becomes a veritable positive crater as in the arc, or at least the layer of electrolyte in close contact with the wire is so highly heated as to become disassociated into oxygen and hydrogen, with oxygen in excess from electrolysis. This layer insulates the wire as with a covering, stops the current, the gases reunite with explosion, casting out the excess of oxygen in bubbles, the liquid touches the wire again and the process is repeated indefinitely. This would explain why a certain current density as a limiting value must be attained at the platinum surface before the phenomenon can begin.

"If the resistance in the circuit is so great that this limiting value cannot be attained, the interruptions do not take place."

It was soon found that several of the interrupters would work perfectly well in parallel, though it is somewhat doubtful if

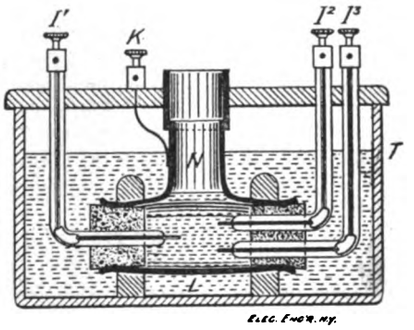

FIG. 3.—THOMSON'S ARRANGEMENT OF INTERRUPTER.

the interruptions in this case are as sharp as those produced by a single platinum point. The very simple arrangement suggested in Fig. 3 in which N is a tee of lead pipe, containing rubber stoppers through which the tubes bearing platinum points protrude, and filled with acidulated water, is a convenient form of the apparatus proposed by Professor Thomson. The outer containing vessel is filled with water for the purpose of keeping the apparatus cool. Professor Thomson found that the interrupter would work on alternating currents, provided its natural period is high enough to allow the current to rise to its critical value during one half-wave, or during one alternation. The secondary sparks obtained in this way seem to be unidirectional, and it is recommended to use a platinum foil cathode in place of the lead plate when working with alternating currents.

The inductance of the whole circuit, including the dynamo, is to be taken into consideration unless some other load, a battery, or a condenser, is also connected across the mains. If these loads are large enough the effect of the dynamo circuit inductance may be practically annulled, leaving the inductance of the coil in series with the interrupter alone to control the rate of interruption with a given surface of platinum anode. Professor Thomson speaks of the curious rise in brightness of incandescent lamps connected across the mains of the supply circuit near an interrupter when the latter was operated. This effect was due to reflection into the supply leads of high periodicity currents superposed upon the continuous currents in them.

For electric welding the interrupter has given very successful results when operated in connection with a small, open-core, welding transformer. The efficiency of transformation, even at the very high frequency arising from its use, is said to be very great. It was noted by Professor Thomson that an induction coil shunted around an interrupter, a condenser being interposed in the circuit, gave excellent results. The use of this apparatus furnishes a means for demonstrating many alternating-current phenomena where an alternating source of supply is not available. A coil of comparatively small wire, wound upon an iron-wire core, and an interrupter for small currents are all the apparatus needed. It is, of course, necessary that the cores for the coil used with the interrupter or other high frequency apparatus should be of the open magnetic circuit type.

Experimental work recently conducted by the writers demonstrated very clearly that the form of interrupter illustrated by Dr. Wehnelt can be vastly improved in practice. The difficulties surrounding its working are very great when it is attempted to force large currents through the apparatus. The platinum point must necessarily conduct the whole current and, while its rate of expansion is practically the same as that of glass, when it is rapidly heated by large currents its expansion frequently cracks the glass tube and spoils the apparatus. Further than this, the thin thread of mercury in a narrow glass tube, being heated by the current and by conduction from the platinum point, often becomes so hot as to volatilize, thus forming

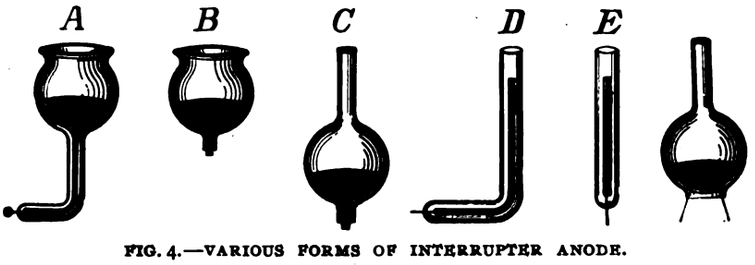

FIG. 4.—VARIOUS FORMS OF INTERRUPTER ANODE.

Digitized by Google

an arc with practically explosive action, which either bursts the tube or throws out the mercury. The function of the mercury is not only to conduct current to the platinum point, but also to keep it cool by conducting heat away from it. This is best accomplished when the body of mercury is as large as convenient. The forms of tubes shown in Fig. 4 illustrate some that were tried by the writers, the best results having been obtained from those in which the points projected vertically down into the electrolyte and in which the body of mercury is relatively large.

If it is attempted to force too much current through the interrupter, the apparatus will work for an instant and suddenly stop. The current seems to be permanently broken, as its value falls to a scarcely measureable amount, while small bubbles stream off from the juncture of the platinum point and glass tube. If the strain of a moderately high voltage is kept upon the apparatus when it is in this condition a yellowish glow is noticed, apparently creeping back along the surface of the platinum wire through the glass, as if the current were seeking to enlarge the area of contact or actually to burst through the insulating sheath of glass. If this is allowed to go too far, rupture of the tube results. If the current is turned off while the apparatus is in this condition, a curious sucking sound is heard and the apparatus is instantly ready to work again and repeat the same cycle of operations.

In operation, the acid bath rapidly becomes very hot and, when its temperature reaches a point near boiling, the action of the interrupter ceases. For this reason it is well to make up the instrument with a water jacket in order to keep its temperature as low as possible. Noticing the rapid heating of the acid, the writers endeavored to find what proportion of the total energy supplied to the circuit was dissipated in it, and were surprised to find that apparently over 90 per cent. of the total fall of potential took place between the terminals of the interrupter itself. While these measurements were made with apparatus not suited for this work, they are probably not inaccurate, because the intense heating of the electrolyte shows that much energy is wasted in it. A very curious phenomenon was noticed when the connections were made, as shown in Fig. 5, two induction coils being used, one in series with the interrupter and the other shunted around it through a resistance composed of incandescent lamps. Both coils worked violently and, when the interrupter was in the static condition mentioned above, the lamps in the shunt circuit glowed at about normal c.p. The instant the interrupter operated a sudden brightening of the lamps was noticed, apparently corresponding to a voltage nearly double that previously present. This effect is doubtless due to some resonant action in the circuit, or to the superposition of harmonics of very high frequencies upon the circuit, giving rise to some of the extraordinary effects previously described by Professor Thomson and others.

The field for usefulness of the Wehnelt interrupter is very large. While it is highly inefficient, in that it wastes much current, still it enables the operation of induction coils directly from electric supply mains without the use of condensers or shunt resistances, and furnishes the experimenter with a reliable and satisfactory interrupter which he can make in a few minutes himself at a trifling cost. It also provides a ready source of alternating currents of high frequencies, their periodicity being intermediate between those from the oscillatory discharge of condensers and those of commercial circuits, both of which have been of late so fully studied. On this account it will be of great interest, because there has not yet been much attention paid to phenomena produced by currents of intermediate frequencies. It also provides a simple and convenient source of alternating current for demonstration purposes. It is evidently yet too soon even to discuss the commercial possibilities of the apparatus.

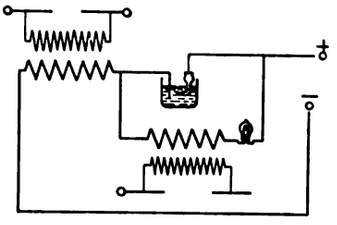

FIG. 5.—DIAGRAM OF SERIES AND SHUNT CONNECTIONS.

A word of warning must be spoken to experimenters with this apparatus. It should always be made up in a vessel provided with a cover or in such a way that it can be put out of harm's way, because there is an energetic spattering of acid drops and dissemination in the air of a fine liquid acid spray during the action of the interrupter. Induction coils of the ordinary type will probably be instantly punctured when attached to it, and only thoroughly insulated coils, or those having an oil insulation, should be used with it. Finally, the current used is generally so large that the secondary possess great energy, and much care should be used to avoid all danger of a shock from it, which, in the case of a large coil, would most probably be fatal.

## THE CANDLE-POWER OF ARC AND INCANDESCENT LAMPS.

### PHOTOMETRIC LIGHT STANDARDS.

BY PROF. WILBUR M. STINE.

The Improved English Candle.—Though all forms of candles have been shown by investigators to be unsuited for light standards, there are those who still continue a preference for them. Probably aware of the shortcomings of the candle they have scarcely more confidence in any of the substitutes which have been offered, even looking upon the Hefner lamp as an undemonstrated superior to the candle. In this belief recent attempts have been made to improve the English candle, and amongst such results are certain specifications announced in 1894.* A standard method is stated for obtaining the melting point of the spermaceti, which, when sufficiently pure should melt at 112 degrees to 115 degrees Centigrade. A point is also made of thorough cleansing of the wick to remove grease and mineral matter by immersion in ammonia followed by a second immersion in a dilute solution of sulphuric acid, and a final washing in pure water to remove all traces of the chemicals.

Certain Requirements for a Light Standard.—Before discussing the more scientific light standards it becomes necessary to formulate the conditions under which they will be estimated. With one exception these are readily understood. The excepted requirement refers to the inherent difficulty in all photometric work—that it is impossible to state an immaterial sensation in terms of matter and energy. Sights are psychological events, while standard lights are wholly physical phenomena. Then aside from all chemical and physical problems involved in the production of a standard for illuminating power, there is lacking even a partial agreement over what shall be considered as normal light. It is scarcely profitable to expand the discussion on this point, but recognizing that the color of the candle flame is unpleasantly red and that of the electric arc is usually too blue there must be an intermediate color of light which may be taken as normal for the eye.

A standard of light should be:—

(1) Normally white in color;

(2) Simple in mechanical construction;

(3) Not liable to especial deterioriation of any part;

(4) Renewable without change of light value;

(5) Constant in operation;

(6) Reproducable with accuracy.

The Methven Screen.—This standard consists of an argand gas flame burning at the prescribed height of three inches and surrounded by a straight glass chimney of the usual diameter for such flames. Immediately on the outside of the chimney a metallic shade or screen is attached, pierced by a slit of such dimensions that the light passing through it is supposed to be equivalent to two candles.

It is well to call attention to a fact frequently overlooked in the use of such standards as require a screen. The distance from such a light source to the photometer screen is measured from the slit and not from the center of the flame.

The Methven screen possesses the merit of great mechanical simplicity. But all manner of gas flames vary in light giving strength according to the quality of the gas burned and it is practically impossible to obtain gas of sufficiently known and controllable quality to insure uniformity of the light-emitting power of the flame. It is very singular, indeed, that the supposed principle of the Methven screen—that by taking a definite area of a gas flame of uncertainly variable illuminating power a constant light could be obtained—was not immediately seen to be fallacious, and that

*E. G. Love, in the "American Gas Lighting Journal," March 5, 1894, page 326.

Digitized by Google

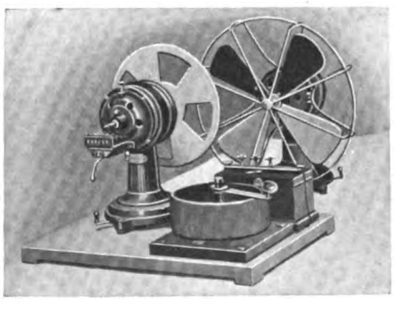
it should have ever received any acceptance.

The use of a glass chimney on a light standard is to be condemned, since the portion of the light absorbed by the chimney is variable and largely dependent upon the cleanliness of the surface of the glass; and by reflection from the inner walls of the chimney an error is introduced which varies in its influence with the change of the distance of the light from the photometer screen. The illuminating power of the Methven screen for any given quality of gas also varies with the humidity and the pressure of the atmosphere.

Numerous unsuccessful attempts have been made to carburet the gas burned, but without accomplishing the desired constancy of this light. The Methven screen is, however, useful as a secondary standard and is still employed at some incandescent lamp factories even as a primary standard.

The Pentane Lamp.—The Harcourt pentane standard has not been widely used in this country, though it has not lacked its stanch advocates. In its later form it consists of a lamp with a reservoir for holding the pentane with an appropriate wick and tube. The flame burns inside a metal chimney with an appropriate opening in the center and a gage for indicating the flame height. The combustible being so readily volatilized, the wick does not char, and alter the rate of the capillary feed of the combustible to the flame.

The pentane required for this lamp is a refined distillate obtained from gasoline. Pure pentane is a hydrocarbon of the formula, $C_5 H_{12}$. The liquid obtainable under this name consists of this substance and several similar and related compounds in solution. Aside from a few laboratory samples there is probably no pure pentane to be had. Here is a combustible eminently suited for a standard light, since it is chemically simple and burns with a clear, white flame, but not to be obtained commercially in sufficient purity. Though a committee of the British Association reported in 1888 that "the pentane standard of Mr. Vernon Harcourt is reliable and convenient, and fulfills all the conditions required in the adoption of a standard of light," their judgment has not been confirmed by subsequent practice with the lamp owing very largely to the uncertain quality of the combustible.



The Arc-Standard Light.—In 1878 Abney discovered that the intrinsic brightness—the amount of light emitted from unit area of a luminous surface, as the square millimeter of the crater surface of the arc—was constant for any one carbon independent of the power absorbed in the arc. Later investigators have fully confirmed this fact for such wide variations of absorbed power as 500 and 34,000 watts. This is explained by supposing that carbon reaches its boiling point near 3,500 degrees Centigrade, the approximately determined temperature of the positive crater. In the same manner that the temperature of water boiling at a definite atmospheric pressure remains constant during evaporation, so in the electric arc, the power absorbed heating the carbon to its boiling temperature, thus volatilizing it, the temperature would remain constant and the quality of the light emitted and the intrinsic brightness of the source, both being functions of the temperature, should also remain constant. Further, just as the temperature of water will remain constant at the boiling point whether evaporated slowly or very rapidly, the temperature of the positive crater of the carbon should remain constant independently of the current flowing or of the length of the arc.

The attempt has been made by Blondel, Violle, Swinburne and others to utilize these facts in realizing an arc standard of light. In this case a suitable screen with a circular opening of approximately one millimeter diameter is placed in front of the crater, and the amount of light thus obtained should be definite in quality and quantity. Yet no two investigators have obtained comparable results, nor has any one investigator shown invariable results with different qualities of carbon, or in fact with different carbons. If it is permissible to designate the carbon in such a case as the combustible it is seen that this attempted standard of light has failed where all other standards have failed with the exception of the Hefner lamp, and in this case the failure is due to the influence of the quality and character of the carbon on the quality and quantity of the light emitted, or what, perhaps, is the same thing, on the vaporization-temperature of carbon.

It has been frequently pointed out by the writer and others that hard carbon will, for given power absorbed in the arc, emit less light and a light bluer in tinge than that obtained from soft carbons under similar conditions.

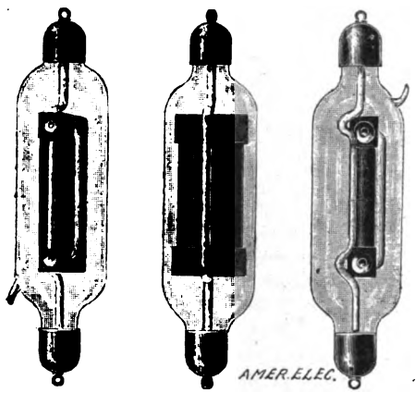
## Among our Foreign Contemporaries

**Measuring the Speed of Small Motors.**—In testing very small motors, difficulties arise in measuring the speed because the power is so small that if the usual speed counter is applied so much power will be absorbed that the speed necessarily falls. A very simple method of measuring the speed accurately, although it involves the use of a second motor, is described in a recent paper by Dr. Benischke in the "Elektrotechnische Zeitschrift." It is what is technically called a stroboscopic method, but is much simpler than some might infer from the name. The motor to be tested is provided with a fan or with a disc with

A SIMPLE STROBOSCOPE.

black marks or holes; the other is similarly provided with a disc with holes in it, and the two are placed nearly opposite to each other, as shown in the adjoining figure, the second motor being arranged with a suitable resistance in series so that its speed may be adjusted. The two motors are then run and the vanes of the fan are viewed through the holes in the disc; when the two speeds are equal the vanes of the fan thus seen through those holes will seem to stand still, provided the number of vanes is equal to the number of holes; for any other relation between them the necessary correction factor can readily be made. The speed of the second motor is therefore adjusted until these vanes appear to stand still, and at that moment the speed is measured by any convenient speed counter or other indicating device, as, for instance, a bicycle cyclometer, which, however, must first be calibrated for that motor. Before the speeds are exactly alike the vanes will appear to move slowly in one direction or the other.

Another application of the same stroboscopic principle is also described in that paper and can be applied to measuring the frequency of an alternating current. A bottle of water is placed upon a stand which is slightly flexible and is attached to the armature of an electromagnet through which the alternating current passes, the bottle being then vibrated slightly exactly as many times per second as the frequency of the current. By any convenient means such as a siphon or an opening near the bottom of the bottle, a small stream of water is allowed to pass out so that it breaks into drops, the number of drops being then equal to the number of oscillations. This stream of drops is viewed through the holes in the disc of the motor as in the test above described, and when the number of holes passing per second is equal to the number of drops, the latter will appear to be standing still; by measuring the speed of the motor and multiplying it by the number of holes in the disc the frequency of the current is easily calculated. An interesting observation is that when the speed is not exactly right, the drops will appear to move upward and pass into the bottle, a rather curious delusion.

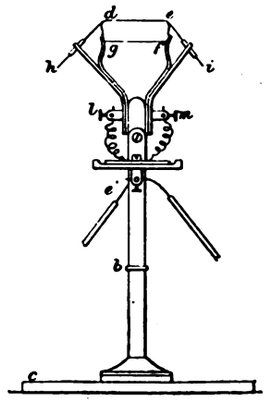


---

**Comparing Different Automobiles with Each Other.**—Unless all automobiles which engage in competitive trials are very nearly alike, a comparison becomes difficult, as various factors should be taken into consideration; it does not necessarily follow that the fastest one is the best. An

Digitized by Google

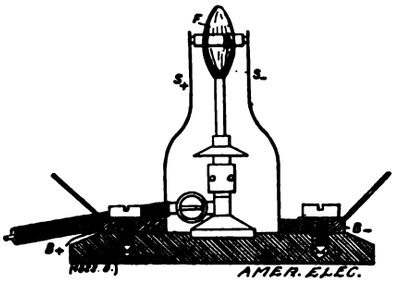
interesting method of comparing them, and one which seems quite rational, was suggested by Chauveaux and was mentioned in a recent lecture reprinted in an Austrian electrical journal. He assumes that a true measure of the practical effectiveness depends on the actual power of the motor, the speed of the vehicle and the number of persons carried. Such a factor is determined by dividing the h.p. of the motors by the product of the number of persons carried and the average distance traveled per hour; the smaller the factor thus calculated the better the automobile. This factor represents simply the power required per passenger and mile, also involving the speed, as the factor will be smaller the greater the speed. It is interesting to note that when applied to the automobiles in the recent test between Marseilles and Nice in France, the one that received the first prize would have been fifth, while an obscure vehicle which received no prize would have gotten the first one, as the factor for it was only about a quarter of the one that got the first prize.



**New Vacuum Telephone.**—There are a number of reasons why a microphone can be expected to act better if the carbons are enclosed in a vacuum. One of these is that relatively strong currents can then be used without such a risk of injuring the delicate contacts; moreover it is then also independent of atmospheric moisture and other external causes of failure. Such a microphone has recently been put on the market in England and is known as the Kilduchevsky telephone transmitter, although in this country it would probably be called simply a vacuum microphone. A very brief illustrated description is given in the London "Electric Review," the illustration from which is reproduced in

TELEPHONE TRANSMITTERS IN VACUO.

the adjoining cuts. Unfortunately they are not quite clear, but will give a general idea of the arrangement. As will be seen the leading-in wires are made thick enough to support the microphone. The brief description states that the current may be increased to any extent without liability of the oxidization of the contacts and that no packing can occur. The instrument is said to have been successfully tested in Russia over lines 2,000 miles long, a statement which requires some further modification, as the transmission depends on other things besides the length of the line; nevertheless the distance seems very great and speaks well for the instrument. In England it has been tested on an artificial cable of an equivalent length of about 200 miles, having a resistance of nearly 600 ohms and a static capacity of nearly 60 microfarads, thus giving a "K R" equal to nearly 36,000, this quantity being the product of the resistance and the capacity as its symbol indicates, and is considered by some to be a measure of the limiting conditions under which telephony is possible, a statement, however, which has been doubted by others as the value of the "K R," which was at one time considered to be the limit, has been greatly exceeded on the lines in this country.



**The Nernst Lamp.**—As with most new inventions, the first thing that those who did not invent it do, is to look up anticipations, and the Nernst lamp is no exception. The English papers more in particular have unearthed some early descriptions of lamps which must be admitted to be to a great extent close anticipations, at least in the general principles. While, no doubt, the future manufacturers of this interesting and much talked of lamp will develop many patentable improvements, yet the lamp in its most primitive form has been clearly anticipated and can be used by any one. It seems that the lamp is so easily made that almost any skillful mechanic can make one for himself, and wherever there is no great

AN IMPROVEMENT OF THE JABLOCHKOFF CANDLE

objection to spending a few moments in heating it with a Bunsen flame, the lamp may be used to advantage as it is so very much more economical than the usual incandescent lamp. One of the earlier forms, though not the earliest, is shown in the first of the adjoining illustrations, which was published in the London "Engineering" Oct. 14, 1881, as an improvement on the original Jablochkoff lamp. It will be seen that the rod of refractory material is held between two clamps which lead the current through it. The intention seems to have been to light it by means of what might be called a match, that is, the wire h d e i, which is connected with the same terminals and presumably was heated first by the current which soon melted it off, but in doing so heated the refractory material until it began to conduct, after which it gradually increased in conductance until it took the full current. It is said that this conducting match for lighting it was a carbonaceous mixture and that the arc resulting from its rupture would heat the non-conductor until it conducted. Wherever a Bunsen burner is handy, as is the case in many laboratories, probably this form of heating would be the simplest. The second illustration, by way of comparison, shows the Nernst lamp as illustrated in one of his first patents.

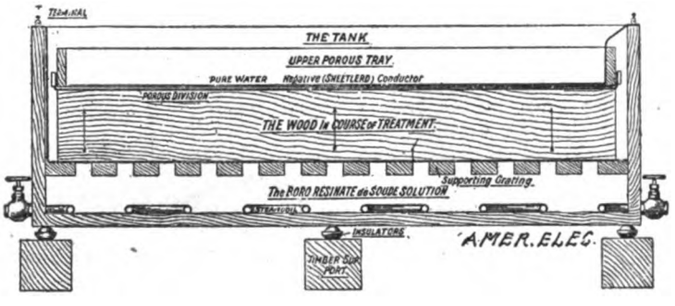
Mr. Fonta, in the London "Electrical Review," makes the statement that after experimenting with the Nernst lamp for some time and obtaining satisfactory results, he is now able to state confidently that lamps of any c.p. and voltage, and with an efficiency of 1.5 per candle, may be made. This efficiency is about what is claimed by others and is probably not questioned, but the fact that they can be made for any c.p. and voltage is of interest. But the most interesting statement that he makes is that no preliminary heating is required. Unfortunately, he does not describe how he gets over that difficulty nor does he give any further information. No

ONE OF THE NERNST DRAWINGS.

having heard of that writer before, we cannot say whether he is an authority or not.

In the later Nernst patents, it is stated that by adding certain materials in making the little rod, it is possible to start the lamp with only the heat from a match.

Many opinions have been expressed on the probable future of the Nernst lamp, and most of them seem to agree that while it may have very good prospects, yet at present it is only in the experimental stage.



**Best Strength of Acid for an Accumulator.**—The question is often asked whether or not an accumulator would be improved if the acid were stronger, and the reason that this is difficult to answer is that a difference in concentration has various effects, the choice of the best concentration being therefore by no means a simple one. Some time ago Mr. Jumau found that the capacity of an accumulator varied with the concentration of the acid, but that the variation was not a constant one as it increased at first with the concentration, then reached a maximum and then diminished again for greater concentrations, thus showing that there is a certain strength of acid for which the capacity was greatest. In order to find whether this was true for all rates of discharge he made some very elaborate experiments which are described in "L'Eclairage Electrique," but with the unfortu-

Digitized by Google

nate result that for different rapidities of discharge this best concentration was quite different, as it increased with the rate of discharge and soon got above 35° Baumé, which is about the practical limit as sulphating of the negative plate is apt to occur with greater concentrations. He also continued the investigations to find whether this best concentration was the same for the positive plates as for the negatives and found that for the positive plates the acid should be more concentrated to give the best capacity, and for the negatives less so, but in both it varied. Theoretically, therefore, the best conditions are obtained with different concentrations of acid which can only be had with the aid of a porous cup and that is not practical; moreover, there is a certain density which is the best for each rate of discharge. It is, therefore, possible to give only a general rule concerning the concentration, namely, that it should be greater, the greater the rate or rapidity of discharge.

**A Method of Measuring Inductance.**—One of the most unsatisfactory of all electrical measurements is to determine inductances, which are analogous to the moment of inertia in mechanics. A method which is said to be satisfactory was devised some time ago by Prof. Puluj, an Austrian physicist, and was recently described in the "Wiedemann's Annalen." In this method one inductance is compared with another, therefore one of them must be known. They are connected in two circuits in parallel and an alternating current passed through them, resistances in series with each being varied until the currents in both branches are in phase with each other, and when this point is reached, the inductances are directly proportional to the resistances in those circuits; knowing these resistances and one of the inductances the other is found by calculation. But this requires an instrument to indicate when the phases are alike. This may be made of two small coils at right angles, mounted so that they can be rotated; suspended in the middle of these is an aluminium or copper rod having a pointer. The two currents are passed through these two coils, and when they are in phase no deflection of the copper rod will be produced.

**Seasoning Timber Electrically.**—An interesting application of the electrical current for the somewhat odd purpose of seasoning timber is said to be used with success in Europe, and is about to be introduced into England. The general principle involved is that a current is passed through the wood across the fibres, while the wood is partially immersed in a preservative liquid, the action of the current being apparently to drive out the sap and replace it with the preserving liquid, which is a 10 per cent solution of borax containing 5 per cent of resin and 5 per cent of carbonate of soda. The adjoining illustration of the tank was published in "Lightning," an English paper, and will explain itself. It will be seen that the timber is placed on the lower electrode, which is the positive pole, the negative pole being a sheet of lead lying on the top of the wood, with a thin layer of felt intervening. The whole solution is kept warm at about 145 deg. F., and reaches within a few inches of the top of the wood at the start, being gradually lowered as the process is completed. It is said that a current of 600 amperes at 110 volts is used, but for what sizes of the wood to be dried, is, unfortunately, not stated. The sap which is displaced rises to the top of the solution. The process is said to require from 5 to 8 hours, depending on the condition of the wood, green wood being easier to treat than that which is dry. After treatment the wood is dried either in the open air or in a drying chamber. One report states that the current is 18 amperes per cu. ft. per hour, which at two cents per k.w. hour (a rather low figure), represents 0.04 cents per cu. ft. Another statement says that it takes 600 watts per cu.m. of wood. Still another says that one kilowatt hour per cu.m. is required.

CROSS SECTION OF TIMBER SEASONING VAT.

One of the peculiar results is that wood which is otherwise useless, like maritime pine, which never dries in the open air, can be perfectly seasoned and dried in this way. The treated wood is also said to be impervious to dampness and not liable to be attacked by insects.

**Measuring Condenser Discharges.**—It is sometimes of interest to measure the quantity of electricity contained in the discharge of a condenser such as a Leyden jar, or in general, the quantity of electricity in spark discharges, but such a measurement generally involves difficulties. What seems to be a simple and effective method was recently described by Prof. Cardani, an Italian physicist, in the "Nuovo Cimento." It is based on what the chemists call a volumetric analysis. A normal solution is prepared of sodium chloride, otherwise known as common kitchen salt, diluted 200 times. Electrodes are placed into this and it is put in circuit with the spark discharge so that the same quantity of electricity which is contained in the spark will pass through this solution and will decompose it to an extent which is exactly proportional to the quantity of electricity in the discharge. As this quantity is necessarily very small, it is determined by first coloring this solution with phtaleine of phenol, which gives a red color, and sufficient oxalic acid is then added to make it a pale rose. A sample of the original solution is kept to preserve its color for comparison. After passing a certain number of discharges through the solution, as many as possible, if they are small, the color of the liquid will have been changed by the electrolysis. Oxalic acid is then added to the electrolyzed solution until its color is the same as that of the sample; the quantity of oxalic acid thus added is measured, and from it the amount of sodium which has been liberated is calculated. As such a calculation may require the assistance of a chemist, a simpler way might be to make a second experiment with a very small, steady current, passing it through a similar liquid until the color is the same as that produced by the spark discharges; the quantity of electricity in this steady current is easily measured, either with a galvanometer or by calculation from the voltage and the resistance, provided the resistance of the liquid can be neglected. In these measurements, extremely small quantities are involved, as a spark, although very bright, really represents an extremely small quantity of electricity.

**A New Primary Battery for Power Purposes.**—A young Frenchman has devised a new form of primary battery in which the depolarization, which is generally that which limits the power output of a battery, is very energetic, and the battery is therefore adapted for strong currents; it is even claimed that it has been applied with success to automobiles in Paris. As a rule a primary battery contains much more energy per pound than an accumulator, and where weight is of so much importance as with automobiles, it is not necessarily absurd to consider it possible to use primary batteries for such vehicles; if a primary battery is cheap and easily handled, there might be a possible field for it for such vehicles. The distinctive feature of this new one is the use of the element vanadin or its salts or oxides. The battery is a two-fluid cell, with a porous cup; one compartment contains a solution of chloride of sodium, that is, common kitchen salt, in the proportion of 20 to 100 of water, and in this is placed the amalgamated zinc electrode. The other compartment contains a carbon plate surrounded, like in the Leclanche cell, with fragments of carbon and granulated manganese oxide, but to this is added some fused vanadin acid, together with some sulphuric, vanadic and hydrochloric acid, or this solution may be a mixture of chloride of potassium, with about 5 per cent of oxy-chloride of vanadin. The other compartment may also contain some

Digitized by Google

sulphuric acid. An addition of about 10 per cent of bichromate of potash in the compartment containing the carbon is said to increase the action. Such a cell is said to give 13 amperes at 2 volts and to be much more steady than the usual bichromate or Bunsen cells; unfortunately, however, the size of the cell is not given in the brief description in the "Electrotechniker," a Viennese journal, from which this description is taken. The description, too, is not as clear as might be desired.

**Cost of Lighting at Reduced Voltages.**—It is well known that when the voltage at the terminals of an incandescent lamp falls, there is much less light given out in proportion to the drop in voltage, but there is also less current used, and the question therefore arises, How much more will a consumer be paying for the light when the meter registers in k. w. hours. This is discussed briefly in London "Electrical Engineer," March 3, assuming the voltage to fall from 230 to 200. One contributor gives some tables showing how greatly the watts per candle diminish with an increase of voltage, and he finds that for a drop of about 10 per cent in the volts there is a drop in the efficiency of conversion of electricity into light of over 30 per cent; for still larger drops the efficiency of conversion falls much more rapidly. From this table an illumination of 144 candles is obtained by nine lamps consuming 756 watts when the voltage is 110, while at 100 volts there would have to be 16 lamps, taking 1104 watts. Another contributor shows that a drop of 12 to 13 per cent in the meter bill would correspond to a decrease of light of about 40 per cent, showing how very much more the consumer is paying for the light at the reduced voltage. Although the general fact that the light is more expensive at the reduced voltages is well known, the actual figures above given may be of some interest. Strictly speaking, an energy much used for lighting alone, should diminish in its reading in proportion to about the sixth power of the voltage.

**A Free Wiring System in England.**—A somewhat unusual system of what in England is improperly called "free" wiring, is used at the small station in the borough of Wycombe, as appears from a recent description in the London electrical journals. The company is by the franchise compelled to wire the premises of any consumer free of initial charge. Payment for it is then made at the rate of about eighteen cents per lamp per quarter until the cost of the wiring is worked off in this way, no interest being allowed on the cost price. The houses in that town are mostly small, and it is thought that this method will induce many of the occupants to adopt the electric light. Another innovation is that the company hire out arc lamps and motors at low rates to encourage those who cannot afford to buy them.

**Large Proposed Transmission Plant.**—According to the French journal, "L'Energie Electrique," a company has been formed to carry out what will be the largest transmission plant in Europe, while the distance of transmission is one of the greatest in the world. It is intended to transmit 3000 h.p., generated by a fall of 500 ft. of the River Loue, to a distance of 72 miles to the city of Dijon and the surrounding country in France, where the watch industry is flourishing. The total cost of the plant is estimated at a little over $1,000,000 and the cost of operation at $28 per h.p. per year, assuming it to be used fifteen hours per day.

**Induction of One Steady Current by Another.**—It is generally stated in text books that a steady current will not induce another current in a neighboring wire and that such induction takes place only when the currents vary or alternate. An interesting experiment described by Mr. Chabot in the "Philosophical Magazine," however, shows the conditions under which a perfectly steady current will induce another steady current in a neighboring circuit. As is well known, Ampere has shown that a current in a circuit will make a neighboring permanent magnet rotate about its axis, and it was shown by Farady that the rotation of a magnet about its axis will induce a steady current. Mr. Chabot has now combined these two, as shown in the adjoining figure, thus inducing a steady current by another through the medium of

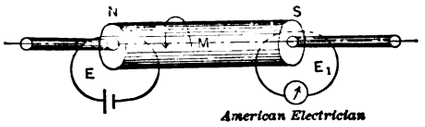


DIAGRAM SHOWING INDUCTION OF ONE STEADY CURRENT BY ANOTHER.

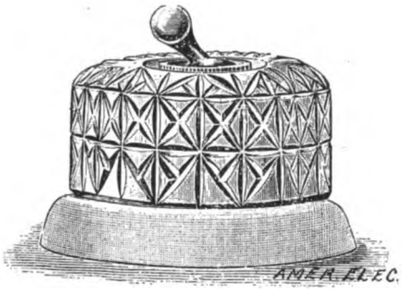
a revolving magnet. Let E be the first circuit, $E_1$ the second and M a permanent magnet capable of revolving about its axis over these two circuits. If a steady current passes through the first loop and the magnet be held so that it cannot revolve, a galvanometer in the second circuit will show no current, but the moment the magnet is allowed to rotate a steady current will be induced in the second circuit.

**How an Electric Spark is Produced.**—Numerous experiments have shown that an electric spark through the air prefers to follow the path of a previous spark. It appears that the first spark breaks a path through the air, which then becomes a tolerably good conductor, and any spark following the first one very quickly, will prefer to pass through this path. For this reason what appears to be only a single spark is often really a rapid succession through the same path. Some experiments were recently made by a German named Walter and described in the "Wiedemann's Annalen," in which he photographed sparks from induction coils, using plates in rapid motion, so as to separate the images of rapidly succeeding sparks. He found that a large spark was followed at very rapid but equal intervals of time by less brilliant ones, all in the same direction. But one of the results of special interest was that when the make and break was first started, only a brush discharge was produced, but these thin discharges became longer and longer at every successive break of the primary, growing, so to speak, toward the other terminal, and after having reached that terminal a stream of normal sparks followed. It thus showed how the first fine discharges bored holes, as it were, through the air before the spark discharges could pass.

**Interesting Coherer Experiment.**—The noted English physicist, Dr. Oliver Lodge, recently gave a lecture on coherers, on which subject he is probably one of the best authorities, and among other things showed the following striking result: He arranged two soap bubbles side by side, so that they were almost in contact. An electrical "splash" in the ether was then produced in the neighborhood and the effect on the two bubbles was that they came together and united, forming one large one. This experiment shows that there was some other action besides the mechanical action of bringing the bubbles together, as those who have experimented with soap bubbles will know, that two bubbles can be pressed together quite hard without uniting, and they will not join when merely brought in contact, except if the contact point is the bottom of one bubble, which always contains a drop of the liquid. In another experiment he illustrated the cohesion of metallic filings when they are influenced by Hertzian waves. On the flattened top of a brass ball some filings are placed, and then by means of a vertical wire these filings could be pulled up in a chain just as though they were magnetic.

**Multiple Terminal Connections.**—For making a number of connections with one source in laboratory work, a trough of mercury is often used, the wires being dipped into it. An improvement on this is known as the Carlin tube, a description of which was recently given in a paper by Mr. Dessauer read before a South African society. It consists of a half inch iron horizontal pipe which is plugged up at the ends and filled with mercury. It has holes drilled in through the top, the number of which correspond to the number of connections which are to be made, the size of the holes depending on the size of the wire to be used, suitable connections being also made with the pipe or mercury and the source of the current. Among the advantages of this over the ordinary mercury trough are that there is less loss of voltage, it being only 0.3 per cent for an 8-ft. tube with fifty-two connections as compared with 18.4 per cent with the ordinary trough, presumably meaning that the same amount of mercury was used. The mercury does not become oxidized or heated, and there is no danger of spilling and less loss by evaporation.

**Carbolite, A Substitute for Calcium Carbide.**—Notwithstanding the fact that the production of the carbide of calcium seems to be greater than the apparent demand, a German named Hartenstein recently patented a method of producing what he calls carbolite, a substance which is produced from the blast furnace slag as it comes



Digitized by Google

from the furnace and is therefore a bi-product, the value of which he considers is so great that he goes so far as to say that the pig iron would then be considered a bi-product, which if true, though not likely, would be of considerable interest to iron men. The slag as it comes from the furnace is mixed with pulverized carbon in some form, such as coke, with the aid of a blast in a suitable vessel such as the converters used in making steel. This molten mixture is then brought in contact with carbon bars which are heated to the necessary temperature to produce the carbides, by means of an electric current passed through them. "Kuhlow's Review," which publishes a description of this, comments on it unfavorably. In the first place such slags contain only about 50 per cent of lime, which would make rather a poor carbide for producing acetylene. Moreover, carborundum would be likely to be formed also and this gives off no gas. There would also be some aluminum carbide which evolves methane, a gas much less luminous than acetylene. Besides these there would be the impurity of the iron carbide, so that it is not likely that the material would be a good substitute for the calcium carbide. Moreover, these impurities all require an electric current to produce them, and the process cannot therefore be said to be very economical.

**A Method of Restoring Fogged Photographic Plates.**—Now that it is becoming possible to manufacture that very valuable gas, ozone, by electrical means and at reasonable cost, the uses of it are increasing. Quite an odd application of ozone is described by Mr. Andreoli, one of the leading champions of this gas in the London "Electrical Review." He repeated an experiment suggested some years ago which shows that a photographic plate which has been exposed to the light, may be regenerated, as it were, by subjecting it to the action of ozone, after which an image can be taken on it just like on a new plate. Moreover a plate on which an image has been taken but not developed can be restored to its original condition by submitting it to the action of ozone; it may then be used over again for another image. He made experiments by covering half of a plate and exposing the other half to sunlight, then treating it with ozone and taking an image on the whole plate, that is, on the exposed side as well as on the unexposed. A Roentgen ray picture taken on the whole plate was visible just as though the silver compounds had not been acted on by the light. He suggests using the method for restoring fogged plates to their original sensitiveness. It was also suggested that ventilation by ozone may prove beneficial in works where photographic plates are manufactured, by removing many causes of reduction of the silver salt which fogs the films. Some reproductions of photographs on restored films are promised in a subsequent issue of that journal.

**Printing Without Ink by Electricty.**—process of some interest was recently shown in London in which an electric current was used for printing from type without the use of any ink. A very brief description is given in "L'Electricien." It seems that the paper is first subjected to a chemical treatment in which it absorbs a certain chemical, the name of which unfortunately is not given; but it is one which will turn jet black when a current passes through the paper, due to an electrolytic effect. The paper passes over the type and while in contact with it a current flows through it into the type; wherever the paper is in contact with the face of the type, electrolysis is produced and the paper is colored black. No further information is given, except that the process has already been perfected to a sufficient extent to give interesting practical results. As the ink is not a very objectionable feature in the process of printing it is not apparent wherein the great advantage lies in this process, although it appears to be new and interesting.

**A Luminous Switch.**—An interesting form of switch, although its principle is not new, is described in the London "Electrical Review." The idea is to have the switch faintly luminous in the dark, so that it can be more readily found when it is looked for in a dark room, an idea which has already been frequently applied to matchsafes and other similar objects which are often looked for in the dark. The switch is shown in the adjoining illustration and is of the usual kind of tumbler

A LUMINOUS SWITCH.

switch, but the cover is of glass, ornamented so as to imitate cut glass, and it is coated internally with a luminous paint which absorbs the daylight, or artificial light, and which in the dark shows a phosphorescent glow, enabling the switch to be easily found.

**Amalgamating Zinc Plates for Batteries.**—The following formula s given in the "Elektrotechnische Zeitschrift" and is claimed to give good results. A saturated solution is prepared of the neutral sulphate of mercury to which a quantity of sulphuric acid is added, sufficient to make the solution complete. This is then mixed with oxalic acid until a greyish mass is obtained, having a consistency of cream, and a little salammoniac is then added. The zincs are rubbed briskly with this paste and if not to be used at once they should be well dried. It is claimed that with this method of amalgamation the zincs resist the acids much better than when the usual method is used.

**A Solder for Aluminium.**—According to "L'Electricien," an alloy of seventy parts of aluminum with twenty of tin and ten copper, makes a good solder for aluminum and will give perfect joints without galvanic action. The best flux to be used is potassium fluoride.

**High Resistance Materials for Heaters.**—A number of valuable advantages are gained in the construction of electric heaters, if the resisting material to be heated has a very high specific resistance and can be heated to a high temperature; that is, if the material can generate a relatively large amount of heat with a very small mass of the material. Less heat is then obtained in the apparatus itself and heating is accomplished more quickly, which reduces the stray cooling losses, as these continue for the whole time during which the apparatus is in use; with a small mass the heat losses after the apparatus has been cut off are also less; the use of higher temperatures also enables such operations as broiling or roasting to be accomplished.

Several devices have recently been introduced abroad with these ends in view, and from all accounts they seem to be quite successful. One of these is known as Parvillee heating material, which was recently described in most of the French electrical journals. He used a mixture of pulverized nickel with quartz, kaolin and some binding material, compressing it to 2000 kg. per sq. cm., and afterward baking it at a temperature of 1350 deg. C. Other metals will do, but nickel has been found to be the best. A resistance of 100 ohms is obtained in rods about 2 in. long, ⅜ in. wide and about ⅛ in. thick, which is claimed to be about a million times the specific resistance of the metal in it. Such a material can absorb 16,500 watts per kg. and will develop about fourteen times as much heat per square inch of surface as the usual materials, such as high resisting wires; the temperature is so high that a rod of copper touched to it will melt. Such a rod is said to cost only about 60 cents and will absorb 5 amperes at 110 volts. It seems that it does not deteriorate in course of time, at least not during 1400 hours, for which it is tested. Another advantage is that by having more of the metallic powder near the ends of the rods they can be made better conductors there, thus overcoming the difficulties in the conducting clamps. The heating apparatus is so arranged that the rods can be readily replaced, as they are inserted in clamps.

Somewhat similar advantages are also gained by what is known as the Le Roy heating device, which appears to be used in France, a brief illustration of which is given in "L'Electricien." It consists of a rod of silicon which, as it deteriorates in air, is inclosed in a vacuum tube provided with suitable terminals to enable the rods to be easily inserted between clamps or taken out, and as a number of them are usually used in parallel the amount of heat generated is easily regulated without external resistances. Some idea of the amount of heat generated by these is obtained from the following data: The little rods are about 4 ins. long, ⅜ in. broad and about ⅛ in.

Digitized by Google

thick, and will dissipate about 150 watts, or about 1½ amperes at 100 volts. This corresponds to a dissipation of heat at the rate of 5 kg. calories per square centimeter of surface, or a consumption of about six watts per square centimeter. The ratio of the radiating surface as compared with wires is about one to four or six, which means that a very much smaller amount of resistance material is required to produce the same effect.

## NOTES.

**Increasing the Range of Wireless Telegraphy.**—Signor Marconi announces that he has successfully transmitted messages across the English Channel between the South Foreland and Boulogne.

**The Increased Capitalization of the Long Distance Telephone Company.** — The American Telephone & Telegraph Company has increased its authorized capital stock from $25,000,000 to $75,000,000. It is unofficially announced that the money raised by the issuance of this stock will be used in the building of extensions, but it is probable that this is a step in the consolidation of the various American Bell interests in one corporation.

**Another Universal Exposition** — The city of St. Louis wishes to take its turn in the holding of a World's Fair and proposes to commemorate in 1903 the centennial anniversary of the Louisiana purchase, by holding an exposition which it ambitiously hopes to make second to none in history. Plans have been laid to raise $17,500,000, which it is hoped can be made to go much further than the $18,600,000 spent in preparation for the Chicago fair, owing to the longer time which the proposed exhibition will have for building.

**The Promoting of Electric Vehicle Interests.** — The Electric Vehicle Co., of New York, whose work has been previously described in these columns, will in future give up the immediate control of local installations to licensed companies, of which it will become the parent organization. The New York plant has been sold to the New York Electric Cab & Transportation Co. The sub-companies will pay a license tax of one cent per capita of the population of the territory in which they operate, in addition to a small percentage of their gross receipts. The Electric Vehicle Co. was fostered by and is closely associated with the Electric Storage Battery Co., of Philadelphia.

**Trunk Lines Between Independent Telephone Exchanges in Michigan.**—Detroit, Mich., is well known as a stronghold of the independent telephone interests, the Detroit Telephone Company having over 5000 subscribers to its system. Few realize, however, that this city is the center of a radiating system of trunks owned by the New State Telephone Company, with over 2500 miles of pole lines reaching about 4500 telephones and extending as far as Grand Rapids, that is, completely across the lower peninsula of the State of Michigan. The New State Company has also established exchanges in almost all of the cities within a radius of 150 miles of Detroit.

**Infringement Suit on the Magnetic Blow-Out.**—In the suit brought by the General Electric Company against the Bullock Electric Company alleging infringement of patents on the magnetic blow-out, an application for a preliminary injunction was denied on March 6. The complainant contended that controllers put in by the Bullock Company in connection with the motor-driven presses of the Textile Publishing Company, of New York City, infringed the fundamental patents granted to Elihu Thomson. Evidence showed that these controllers were fitted with powerful electromagnets with extension plates to carry the lines of force to the fingers which made contact with buttons on the rotating cylinders of the controllers. The defense was based on lack of invention and non-patentability, so that if the case is carried through to a successful issue by the defendants the use of magnetic blow-outs will be open to the public.

**An Instructive Accident.**—A peculiar accident, illustrating how dependent upon power all modern industry—even in office buildings—has become, occurred during the first week in March in Manhattan Borough, New York City. The fundamental cause of the accident was the damage of a hydrant near the steam generating station of the New York Steam Company. Water was turned off, it is alleged, without notice and the steam plant had to shut down for lack of water, so that many buildings in the neighboring business district suddenly found their power plants without steam. The elevator service in these buildings was, of course, suspended, and for two hours or more the occupants were compelled to climb from ten to twenty flights of stairs on foot; electric lighting isolated plants were shut down, and even the Western Union Telegraph Company was affected, as its generators are run by steam taken from the street supply.

**The Emissivity of Incandescent Bodies.** —Some views of interest in connection with the development now going on of new electric lamps have been given by Prof. Elihu Thomson, in a letter to the "Electrical Review." There is a great difference of opinion as to the value of different substances in emitting light. By Kirchhoff's law, a body raised to incandescence emits all the rays it otherwise would absorb. If carbon is used as the incandescent body, it gives out besides visible light rays the invisible heat rays with a longer wave length and the ultra-violet or the so-called chemical rays with a shorter wave length. On this account the efficiency of the carbon filament as a producer of visible rays is certain to be small. German scientists, notably those who have developed the Welsbach and similar systems of incandescent gas lighting, claim that certain materials, such as magnesia and the rare earths, have a peculiar selective emission, a remarkably large proportion of the rays they emit being visible and hence useful in illumination. Others dispute this idea, contending that the intrinsic brilliancy of all substances is practically the same at a given temperature. Prof. Thomson believes that such materials only possess this peculiar property under specific conditions of use in a reducing flame. He states that his experiments indicate that the light given out by the Welsbach mantle is largely due to the union of the gases taking place within the pores. It is well known that the calcium or lime light is far more intense when the lime is in the body of the flame than when it is in the tip where combustion is practically completed, although the temperature at the latter is probably as high as at the former point.

**New Telephone Rates in Germany.**—The telegraph administration of the German government has established a new tariff for telephone subscribers. It is based on the principle that the larger the number of subscribers to an exchange the higher is the cost per subscriber. The tariff is worked out on the message rate basis, the fixed charge increasing with the number of subscribers in the district reached. The lowest rate is the equivalent of $14.50 per year and applies to instruments connected with exchanges reaching less than 1000 subscribers, the sliding scale running up from this to $24 per year for instruments in districts having over 20,000 subscribers. In addition, service is paid for at the rate of $5 for the first 500 conversations per annum with a sliding scale running up to $13 for any number of conversations. Thus, the minimum cost of the telephone is about $19.50 per year, this rate applying to a telephone with less than 500 conversations per annum and in a city with less than 1000 subscribers. The maximum cost in cities of 20,000 subscribers or over, and with 3000 conversations per annum or over, is about $50 per annum. Long distance toll rates are also low compared with those in this country.

**Instructions to Exhibitors at the Street Railway Convention.**—The executive committee of the American Street Railway Association has made some unusually complete arrangements for the exhibitors at the coming convention, to be held in Chicago, Oct. 17 to 20, 1899. The exhibition and convention will be held at Tattersalls, the largest exhibition hall in the city. All stairways to the convention hall lead from the inside, insuring the attention of visitors to the exhibits. Friday, the 20th, has been set apart for the examination of exhibits. No session of the association will be held on that day and no entertainments whatever will be given by the local committee. Space will be sold at the rate of 10 cts. per square ft. No space of less than 100 square ft. will be assigned, but applicants may have as many multiples of this quantity as they wish, all in one body. Cars, switches and ploughs will be placed outside of the building on the street. The building has been rented from Oct. 10th to 24th, to give exhibitors an

Digitized by Google

opportunity to ship their goods early as well as ample time to remove them. Space must be applied for by Sept. 1. The committee on exhibits will make contracts with carpenters, electrical workers and so forth, so that the exhibitors will not be over-charged. The announcement also suggests that arrangements be made to have the building open in the evening on account of the interest which it is anticipated the display will occasion.

**Nikola Tesla on Liquid Interrupters.**—In an interesting letter to the "Electrical Review" Mr. Tesla tells some of his experiences with liquid interrupters of the type which has become connected with the name of Wehnelt. As is well known, Mr. Tesla has done some very elaborate work with circuit interrupters, chiefly of the type in which a stream of mercury is projected against metallic contacts or is itself broken by insulating teeth. With these he has attained a remarkably high efficiency of transformation, an essential consideration in his work of vacuum-tube lighting, so that the heavy losses in the Wehnelt interrupter appear to him to be a serious objection; but it should be noted that for an ordinary experimenter who wishes to obtain results by simple means regardless of the power used within certain limits, the Wehnelt interrupter is a highly effective device. Mr. Tesla states that, of the total energy supplied from the mains, there is obtainable from the secondary scarcely one-fourth of that which a well constructed mechanical break will give. He points out further that the small terminal is surrounded by gaseous bubbles across which the contact is made when the liquid is driven inward by the hydrostatic pressure of the fluid column. By increasing the height of the latter the frequency can be increased. He suggests the use of a vertical glass tube, six or eight feet long with the interrupting device close to the bottom. The electrode should be very small to insure regularity of operation and it is not necessary to use platinum.

**The Largest Transformers in the World.**—For the transmission of power from the Niagara Falls Power Company's hydraulic plant to the mammoth carbide plant to be erected by the Union Carbide Company, at Niagara Falls there have been ordered seven transformers rated at 2500 h.p. each. These will be used for stepping up the voltage from the generator pressure of 2200 volts two-phase to 4400 volts three-phase. They may also be used in stepping up to the 11,000 or 22,000 volts three-phase of the long distance lines to Buffalo and other places or as reducing transformers with the same ratios. At present the largest size of transformers in service the world over is rated at just one-half this output, 935 k.w. or 1250 h.p. Ten such transformers are in use in the Niagara Falls Power Company's plant. Others rated at 2000 h.p. have been ordered by the Union Carbide Company, but not as yet built. The new 2500-h.p. transformers will be built by the Westinghouse Electric & Manufacturing Company of its standard oil insulated and water cooled type, similar to three of 850 k.w. each, now in use in the Ohio street sub-station of the Cataract Power & Conduit Company in Buffalo. The estimated efficiency of the new transformers is remarkably high. At full load it will be considerably over 98 per cent, at half load, 98 per cent, and at one-quarter load over 97 per cent.

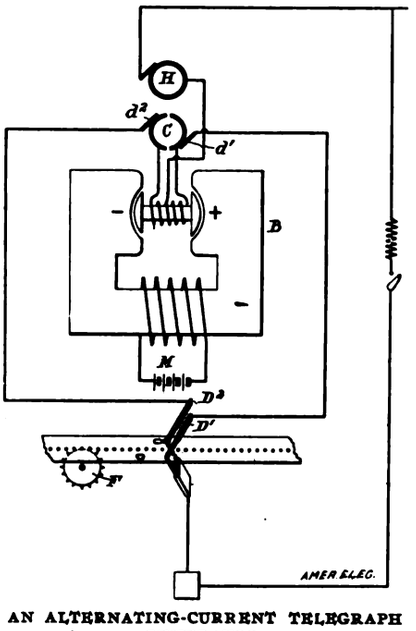
**The Propagation of Long Electrical Waves.**—At a meeting of the American Institute of Electrical Engineers held in New York March 22d, Prof. M. I. Pupin presented a paper describing some new experimental apparatus for studying the phenomena of the electrical waves which occur on long-distance telephone and power transmission lines. As is well known, when waves of current are sent into submarine cables possessing resistance and capacity, they become more and more attenuated with each mile of cable traversed, but in the case of overhead lines of comparatively low capacity and high self-induction the action is entirely different. The waves sent out from the transmitting end are reflected from the receiving apparatus, giving in the line a phenomenon corresponding to the interference of light and causing fixed nodes and loops; that is to say, the reflected waves at some portions of the line reinforce or add themselves to the outgoing waves and at other portions partly neutralize them, so that an ammeter inserted in a line would show permanently a greater current at some points than at others. The distribution of the voltage is similarly humped. Professor Pupin's theoretical discussion proves that this wavy distribution of the current along the line can be mathematically determined and a very simple analogue obtained in the vibrations of a cord or rope suspended at its two ends and loaded at its center. Professor Pupin has built artificial land lines corresponding to the Muirhead artificial cables, but possessing distributed capacity, self-induction and resistance. One form of these consists of coils wound with an intermediate sheet of tinfoil to give the distributed capacity, each coil having the properties of 10 miles of the telephone line now in service between New York and Chicago. It is hoped that with apparatus of this kind many of the phenomena of long distance transmission may be studied more scientifically than they have been in the past. But little is known about these waves, as the oscillations are forced and differ, therefore, from the free oscillations which, in the higher frequencies known as Hertz waves, have been very carefully studied. The general outcome of the study so far given seems to show that more distributed self-induction would improve the transmission of speech.

**Discovery of the Non-Arcing Metals.**—At a meeting of the New York Electrical Society, on March 9th, Mr. A. J. Wurts concluded his address on the subject of lightning arresters with an interesting account of his accidental discovery of the now well-known non-arcing metals in the shops of the Westinghouse Electric and Manufacturing Co.

He was experimenting with a system of lightning arresters, which consisted of a distribution of spark gaps over the line wires as line arresters and a common circuit-interrupting device in the station. In other words, he was trying to avoid the costly and unsatisfactory automatic lightning arresters used at that time. The arrangement consisted of spark gaps on the line between two carbon cylinders, and a circuit breaker in the station, which, upon a short circuit through any one of the lightning arresters on the line, would open and immediately close again. Upon experimenting with this system it was found that when a short circuit was established across any one of the spark gaps between carbon cylinders, the latter would become white hot, and although the circuit breaker operated promptly in opening the circuit, it also closed so quickly that the short circuit was re-established across the white-hot carbon cylinders.

To avoid this difficulty he immediately had cylinders made of brass, cut from brass rod. These were placed close together and connected across the terminals of a large 1000-volt generator, with the result that an arc started by a piece of tinfoil did not persist as one did started between the carbon cylinders. Thinking that the extinguishment of the arc was due to the cooling action of the metallic bodies, he had some large cylinders cast (dimensions, 3x3 inches. These were connected up with a source of powerful currents, and a discharge started, the result being utter disappointment as the cylinders were completely welded together by the violent arc that struck between them. On inquiry he found that these cylinders were made of copper alloyed with tin, while the rolled ones were made of copper alloyed with zinc. This gave a clue, which was followed by ordering cylinders of both tin and zinc. The former arced as badly as those of tin-brass, while the latter showed the remarkable suppresion of the arc which has since been ascribed to the formation of insulating metallic vapors.

Further investigation proved that of the base metals zinc, bismuth, antimony, cadmium and mercury exhibited this same peculiar property, the latter perhaps to a greater extent than any of the others. Mercury, of course, must be used as an amalgam on the surface of another metal. The useful life, therefore, of an arrester made with it is limited by the eating away of the amalgam. Zinc was found to give the best results at minimum cost. Pure zinc was found to pit badly, while copper, so used, forms beads. By the combination of the two metals the one effect neutralizes the other, giving a surface which is very little disturbed by repeated discharges.



**The New York Edison Company.**—The Edison Electric Illuminating Company of New York has issued its last annual report previous to its incorporation with the New York Gas, Electric Light, Heat & Power Company. The report, as usual, shows a gratifying increase in this very prosperous enterprise. The gross station earnings

Digitized by Google

were for the year 1898 approximately $2,900,000, against $2,460,000 of the year before. The total load connected, exclusive of emergency or break-down service, has grown to 890,000—16-c.p. equivalent. The most interesting part of the report is the description of the water-side station proposed for supplying the Edison system in general with high tension 3-phase current, which would be transformed into low tension direct current by rotary converters in sub-stations to which the present generating stations would be altered. With this general idea in view a high tension transmission line has already been established between the Duane Street and the Thirty-ninth Street stations. The transmitting system consists of rotary converters and transformers with a capacity of about 1000 k.w. at each end. This is used to transmit in either direction, one station helping out the other at any time. In connection with it a storage battery with a capacity of 4000 ampere hours at 250 volts has been installed at the Thirty-ninth Street end of the line. The water-side station was planned by an engineering commission consisting of Messrs. John W. Lieb, Jr., General Manager; John Van Vleck, Constructing Engineer, and Arthur Williams, General Inspector, who spent two months in Europe studying the problems of electrical and steam plants. The plans provided for a station approximately 200 ft. x 400 ft. in size which should have an economical rating of 90,000 h.p. and an overload capacity of 135,000 h.p., with the possibility of extending this to 150,000 rated or 225,000 overload horse power. The plan comprehended a central main operating room approximately 100 ft. wide, giving space for fourteen 6000 rated h.p. units in two rows, one on each side of a central aisle. Each of these units would consist of a triple expansion 3-crank vertical engine, built for superheated steam at 500 deg. F. and 200 lbs. pressure, coupled to a 3-phase 6600-volt generator. Two half size or 3000 h.p. units would also be included, these being of the double-current type, capable of giving either direct or 3-phase current. This main operating room would be covered by a steel truss roof and spanned by the usual crane, and flanking it on each side would be a long boiler-house with two tiers of boilers, one over the other, surmounted by coal bunkers and above them storage battery rooms and repair shops. All steam piping, auxiliary apparatus and smoke flues would be placed in a 10-ft. space, separating the boiler rooms from the main engine or operating room. The stacks, one for each group of four boilers, would surmount this intermediate 10-ft. space. It was hoped that on this plan the advantages of wholesale generation and high-tension transmission would be combined with the Edison system of supply from district centers at maximum demand and the general advantages of the Edison distributing system, with a relative economy that would prove exceptional, permitting reductions in price which would make electric lighting at last "the light of the people."

## SOME ELECTRICAL PATENTS OF THE MONTH.

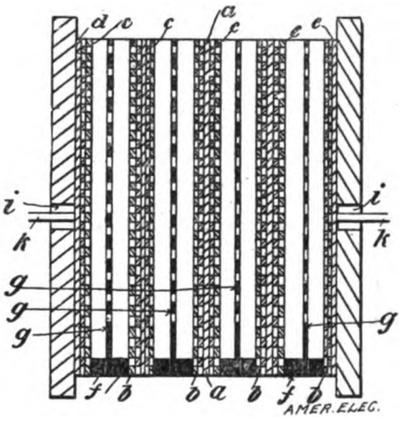
**An Alternating-Current Telegraph Generator.**—Some one has well said that telegraphy is simply long-distance transmission of power on a small scale. The development of power transmission has tended steadily from direct to alternating currents, and telegraphy seems to be following its example. The smooth, sinusoidal

AN ALTERNATING-CURRENT TELEGRAPH GENERATOR.

curves of current generated by an alternating dynamo seem to go through a highly inductive line or one like a submarine cable containing large capacity, more easily than do currents from a battery or a direct-current dynamo. The waves also reach the receiving end less distorted and less run together than do direct-current impulses.

A generator specially designed for this purpose has been patented by Messrs. A. C. Crehore and G. O. Squier, the well-known inventors of the synchronograph and other apparatus for high-speed land and submarine telegraphy.

For the production of signals it is necessary in such systems to omit various combinations of the alternating current waves, the half period of positive current or the half period of negative current being cut out by the operation of the transmitter. The general scheme of such a generator and transmitter is shown in the accompanying figure, in which B represents a bipolar generator with a shuttle-wound armature and a field excited by the storage battery M. The winding on the armature shuttle is tapped at its middle point to the collector ring H, and the two ends are brought out to the half rings of the rectifier C. On these bear the brushes $d^1$ and $d^2$ respectively connected with the contacts of the make and break device, $D^1$ and $D^2$. These bear on a perforated strip of paper, similar to that of the ordinary Wheatstone automatic transmitter. This is driven by means of the central row of perforations which engage with the teeth of wheel F, and this wheel is geared to the shaft of the generator so that it revolves at a speed exactly proportional with the frequency of the currents from the latter.



Holes may be punched in the tape such that they will allow contact of either one brush or the other for a time exactly equal to the time of a wave of the current. Obviously the rectifier C supplies waves of one polarity only to the brush $D^1$, and of the other polarity only to the brush $D^2$ so that holes punched in one side of the paper will allow only positive currents to go to line and on the other side of the paper only negative currents.

The patent further describes in detail bipolar machines of this type for the low frequency used in submarine work, and multipolar machines for the comparatively high frequency of land line transmission, with the necessary attachments for driving the paper tape, these driving attachments being operated through a clutch by which they may be thrown into or out of engagement.

Patent No. 620,746, issued March 7.

**A New Storage Battery Plate.**—There are now on the market electric storage batteries in which the positive plate of one cell becomes the negative plate of the next, and so on through the accumulator, thus giving a complete battery yielding 100 volts or more inside of one tank or receptacle. Such batteries are particularly convenient for electric vehicle use. Some new features in this line are described in the recent patent issued to Rankin Kennedy, the well-known English electrical engineer.

The accompanying figure shows a battery made up in this way containing three

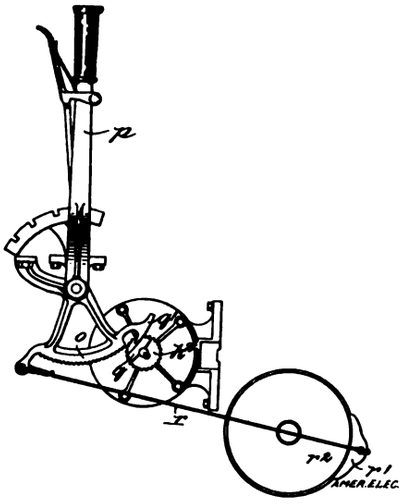
A NEW STORAGE BATTERY PLATE.

such double plates and two end plates, the whole constituting four cells, giving between 8 and 9 volts. The double plates consist of solid central sheets of lead a coated and prepared on one side with perforated sheets b and on the other side with perforated sheets c, treated as described below. Between the bottoms of these plates and up each side are run soft rubber gaskets f holding them a proper distance apart and between the gaskets are hard rubber

Digitized by Google

diaphragms g which prevent the plates from touching and short circuiting in case of extreme buckling. The whole structure is tightly bolted together between walls of an insulating and acid-retaining tank, preferably of wood. The terminals k and k are brought out through the holes i and i in these walls.

The plates are prepared as follows: After being cut to a uniform size the lead sheets are flattened and soaked in a hot solution of nitric acid and water of 5 per cent. strength, then washed in clean water, and the solid central sheet painted (while still wet) on one side with a paint composed of red lead and dilute sulphuric acid of a strength equal to 13° Baumé. The other side of the sheet is covered with a paint composed of litharge and dilute sulphuric acid of strength equal to 24° Baumé. The sheet is then allowed to dry slowly. The perforated sheets are, while still wet, coated with the red lead and litharge paints on both sides, care being taken not to fill up the perforations. Half of the perforated sheets are painted with litharge and the remainder with red lead. The sheets are allowed to dry slowly. By coating the sheets by painting litharge and red lead onto chemically clean surfaces the coating combines with the lead sheets and remains firmly attached thereto.



To form a complete plate, a central lead sheet is placed between one, two, three or more (according to the required capacity of the plate) of the coated perforated sheets, all the red lead-coated sheets being placed on the red lead-coated side of the central sheet, and all the litharge-covered sheets on the other side thereof. The whole is then riveted, fused, or soldered together to insure electrical contact. The complete plate is then made solid all around the edges by fusing or soldering, so that no liquid can escape from the plate. The lead sheets used to form the plates are about No. 24 B. W. G., and the completed plate is made up of a sufficient number of perforated sheets to bring the thickness to about ½ in. The perforations are from 1-16 to ⅛ of an inch in diameter.

Patent No. 620,593, issued March 7.

**The Controlling Apparatus of Electric Automobiles.**—Barring the uncertain elements due to the independent will power of the animal, the control of horse-drawn vehicles is accomplished by very simple means. With the automobile vehicle it is different. In place of the one pair of reins for controlling the speed and direction of motion, there is necessary, as a rule, a steering lever, a controlling lever and a brake. The simultaneous use of these three different pieces of controlling mechanism calls for a certain amount of training, which requirement makes the automobile unsafe in amateur hands.

Two of these controlling mechanisms, namely the brake and the speed controlling lever, are often interlocked, so that when the brake is on, the motors cannot be started, or the brake put on while the current is flowing through the motors. A new device, patented by C. E. Woods of the Fischer Equipment Company, of Chicago, goes further and makes the brake and the speed controller operative from the same handle, motion of which in one direction turns current into the motors, and in the other direction applies the brake.

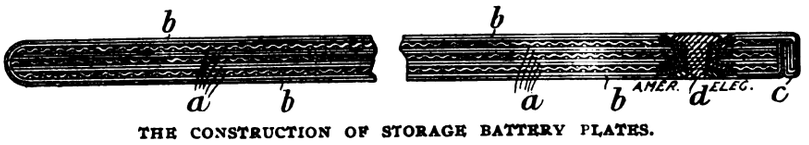
The general scheme of the apparatus is

THE CONTROLLING APPARATUS OF ELECTRIC AUTOMOBILES.

shown diagramatically in the accompanying figure, where p is the handle provided with the usual latch and connected to the segmental gear, o. Attached also to the main lever is the rod, r, which manipulates the brake shoe, $r^1$, on the brake pulley, $r^2$. The arrangement is such that this brake shoe is not drawn into contact with the wheel until the controlling cylinder is turned to the "off" position, where all current is turned off from the motors. Further the controlling cylinder is locked in this position by means of a cam or lug, q, on the controller shaft, engaging with the shoe, $q^1$, on the lever and gear shaft. These parts hold the controlling cylinder firmly in the "off" position and at a point suitable for the proper engagement of the segmental gear and pinion when the lever is again moved to a running notch.

Patent No. 620,628, issued March 7.

**A Paste for Accumulator Plates.**—A new method of making the paste which is applied to the plates of storage battery cells constructed on the Faure or pasted method, has been patented by A. Schanschiff. The specifications point out that the composition made in the usual way is not entirely penetrated by the sulphuric acid, so that the electric current has to pass through a dry resisting material on its way to the conducting grid, giving a high ohmic drop, and, in case of excessive overload, a heating which expands and disintegrates the plates. The new method consists in mixing finely powdered charcoal with formic acid and tartaric acid, adding sulphuric acid and afterwards adding the oxide of lead, minium for the positive and litharge for the negative plate. When cold this forms a dough-like paste, which is heated, compressed and applied to the plate. During the process of formation the organic acids are destroyed and the paste left porous, absorbent and highly conductive, owing to the presence of the carbon.



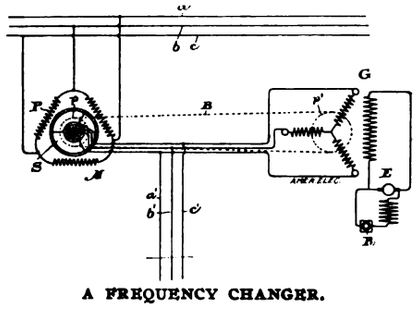
Patent No. 621,150. Issued March 14th.

**The Construction of Storage Battery Plates.**—A new method of constructing the plates for storage batteries of the Plante type has been patented by C. P. Elieson, of London, Eng., an engineer who has done considerable work in the development of automobiles. The improved construction of the plate is shown in the accompanying figure, which is a horizontal section. The plate is built up of several layers a of perforated and corrugated sheet lead, the corrugations of alternate layers running at right angles to each other so as to leave spaces between the plates for the materials developed during the process of formation.

As the figure shows, the outer lead sheet is wrapped around the others and folded or rolled in at one end as appears at c, the joint being afterwards lead burned. The assembled sheets are further fastened together by lead rivets d, also burned in, and the tops and bottoms of the plates are burned into lead channels which complete the enclosure and give good electrical connection between the various sheets. The assembled plate is then rolled or compressed to give a general flatness and is afterwards well coated over with a bituminous or resinous varnish to preserve the outer sheet while those within it are subjected to the electro-chemical formation.

Patent No. 621,048. Issued March 14th.

**A Frequency Changer.**—It is often desirable to transform alternating currents of one frequency to those of another. For example, on the Niagara-Buffalo transmission line, the frequency of the alternating currents is 25 cycles per second, while the currents delivered to the lighting mains in Buffalo must have a higher frequency for the satisfactory operation of incandescent and arc lights. In this case 62½ cycles is obtained by means of 25 cycle motors, coupled to 62½ cycle generators. All the power passing through the combination undergoes a double transformation from electrical to mechanical and mechanical to electrical power.



THE CONSTRUCTION OF STORAGE BATTERY PLATES.

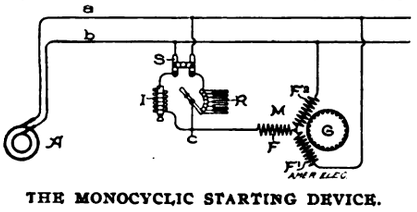
Another type of machine is used somewhat in which only a part of the power is transformed mechanically, the machine resembling structurally an induction motor, the armature of which is wound with coils connected to collector rings. The primary of this induction machine is supplied with multiphase currents at a low frequency, giving a rotating field, and the secondary is mechanically revolved by a motor in a direction opposite to that of the rotating field. There is thus impressed upon the

Digitized by Google

secondary a frequency higher than that of the currents delivered to the primary. Such a machine is used by the Kings County Electric Light & Power Co., in Brooklyn, to change the 25-cycle power generated at its union power station to 60-cycle power for its alternating current lighting circuits.

A very similar combination for changing from a high to a low frequency has been patented by Mr. C. P. Steinmetz, the general plan of which is shown in the accompanying figure, where a, b and c are the mains of a three-phase system supplying

A FREQUENCY CHANGER.



power to the primary coils, P, of an induction or rotary field machine, M. The rotating secondary or armature, S, of this machine is fitted with a winding connected through collector rings and brushes to the three leads a', b' and c', which are also connected with the three-phase winding of a synchronous machine shown at G. The induction machine and the synchronous machine are mechanically connected, preferably coupled together, but shown in the figure as joined by the belt B.

The rotary field induced by the primary P will drag the secondary S, which will in turn drive the generator G; but S and G must, on account of their electrical connection, run in synchronism with each other. The frequency generated in S will be proportional to the speed of the rotating field, minus the speed of rotation of the armature, while the frequency in G will be proportionate to the latter quantity. Thus, if G has the same number of poles as S and they are coupled together, S will run at one-half the speed of the rotating field induced by the coils P and the frequency on the mains a', b' and c' will be one-half that on the mains a, b and c. In this case one-half the power will be transformed magnetically from one circuit to the other through the transformer action of the induction motor and the other half will be transformed mechanically, being first turned over to the generator G and then changed back to electrical power. In case G has more poles than S, the mechanical rotation will be slower, the frequency reduction will be greater and the proportion of the power which undergoes the double transformation will also be greater. If the power is supplied at low frequency to the mains a', b' and c', and drawn off at a higher frequency from the mains a, b and c, the arrangement becomes exactly that referred to as used by the Kings County Electric Light & Power Co.

Patent No. 620,990. Issued March 14th.

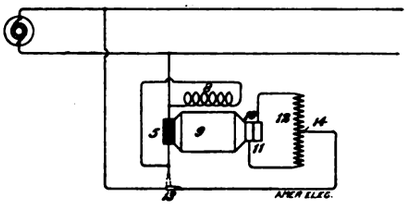
**The Monocyclic Starting Device.**—Alternating current motors of the pure induction type—that is, those having an armature winding simply closed upon itself and not connected with the source of current—when supplied with single-phase currents, run satisfactorily but have absolutely no turning moment when standing still. The single-phase current gives a purely alternating field across the air gap instead of the rotary field which can be obtained from multiphase currents. When the motor is running, the lagging currents in the secondary or armature winding develop a rotary field which will keep the motor in rotation practically as well as though it were run on multiphase circuits, but at standstill there is as great a tendency to run in one direction as the other, and unless some auxiliary device is employed to start the motor mechanically or to develop a rotary field, the motor is stalled.

One of the most satisfactory devices for temporarily giving the needed phase displacement to start the motor is the monocyclic starting device, patented by C. P. Steinmetz and E. J. Berg. The general plan of connections is shown in the accompanying figure, where A represents a single-phase alternator supplying current to the mains a and b. M is a motor shown with a short-circuited or squirrel-cage armature G and three primary windings, F, $F^1$ and $F^2$, Y-connected. $F^1$ and $F^2$ are in series

THE MONOCYCLIC STARTING DEVICE.

with each other across the mains and from their point of connection the third winding F is tapped off to the auxiliary starting device. This consists of a non-inductive resistance R connected in series with a highly inductive coil I straight across the two mains through the double pole switch S. The middle point C, between the inductive and non-inductive resistance, is connected to the motor winding F. The two resistances are shown with adjusting devices, the resistance R having a handle by means of which more or less of it can be cut out, and the inductive coil I an iron core which can be slipped into or out from the coil. The combination of the self-induction of I and the resistance of R gives to the coil F a current decidedly out of phase with those in $F^1$ and $F^2$, giving a rotary field.

Patent No. 620,988. Issued March 14th.



**Vacuum as a Dielectric for Cables.**—It is well known that dry air is one of the most satisfactory insulating mediums for telephone cables, owing to its low specific inductive capacity and high dielectric strength. For this reason untreated paper cables have come into considerable use. It has been proposed to maintain a pressure within such cables in order to prevent moisture from entering through any pinholes or other leaks through the lead sheath. A patent taken out by N. G. Warth makes the antagonistic proposition of maintaining a vacuum within the cable. The purpose of this vacuum is to further diminish the specific inductive capacity and increase the resistance and dielectric strength of the paper as well as to reduce the combustion in case of sparking across from conductor to conductor.

Patent No. 621,001. Issued March 14th.

**Method of Motor Speed Control.**—In general the control of the speed of direct-current motors on constant-potential circuits is accomplished either by inserting a resistance in series with an armature or by varying the strength of the field. The first method is wasteful of power and the second wasteful of motor output; that is to say, it involves an increase of the size, weight and first cost of the motor for a given load.

A novel solution of this problem has been patented by Mr. B. G. Lamme, of the Westinghouse Electric & Manufacturing Company. Referring to the accompanying figure, 1 represents a direct-current generator supplying power to the direct-current motor, the armature of which is indicated at 9. This, as shown, has its field winding, 8, connected in shunt across the brushes bearing on its commutator, 5. It is also connected with a pair of collector rings, 10 and 11, tapped into the same armature winding. The brushes bearing upon these collecting rings are connected to the opposite terminals of the inductive winding, 12, which is preferably a transformer core wound with a single coil tapped out at its middle point, 14.

When the motor is in motion there will obviously be generated between the two collector rings an alternating current which will be impressed upon the winding, 12, and choked back by the self-induction thereof. As the armature rotates, the commutator segment connected to the collector ring 10 travels alternately from one commutator brush to the other, and the connection of the collector ring 11 also travels from brush to brush, but always exactly opposite to that of collector ring 10. Thus as one terminal of the coil becomes posi-

METHOD OF MOTOR SPEED CONTROL.

tive the other becomes negative, and vice versa, the middle point of coil 12 remaining always neutral or with a potential midway between that of the line terminals. The motor is started in the ordinary way with the switch in the dotted position, but to increase its speed without weakening its field the switch 13 is thrown into the full line position connecting the full voltage between one brush on the commutator and the middle of the armature through the coil 12. This practically doubles the speed as the back e.m.f. of the motor is cut in two. The voltage across the commutator of the motor of course increases, and this increases the current in the shunt field 8, reducing somewhat the rise in speed.

**Removal Notice.**

On April 10th the offices of publication of the American Electrician will be moved to the Beard Building, New York City. Subscribers, contributors and other correspondents are requested to note the new address, which is 120 Liberty Street, New York.

**Publishers' Announcement.**

Owing to circumstances beyond our control, the preparation of the premium to subscribers who promptly renew their subscriptions direct to the publishers, has been greatly delayed. We are glad to say that the pamphlet "Diagrams of Electrical Connections," is now in press and will be delivered in the course of the month to those entitled to it.

**A New Department.**

Beginning with this issue of the American Electrician there will be published notices of those of the patents issued during the previous month which appear to the editor to be of particular interest. In many lines of electrical work, men with the real inventive instinct foresee the tendency of future development and improve the opportunity the government gives them to benefit by their foresight. Others disclose in their applications the results of much original and valuable research. A study of their opinions as disclosed by patent specifications gives much information that can be obtained in no other way. The descriptions in these columns are necessarily limited, both in number and in length, owing to lack of space, but the attempt will be made to make this department valuable to the reader by a few words showing the problem the inventor strives to solve and his method of solution. The criticism of the reader is invited in this department as well as in the balance of the paper.

**The Wehnelt Interrupter.**

During the past month the additions to the knowledge about this recent invention have been many and valuable. The advantages and disadvantages of the new instrument have been pretty well determined and the various explanations of its action are well on the road to unity in a fixed theory. While the instrument is by no means an efficient one, wasting most of the energy it receives, it is simple, cheap, not easily deranged and highly effective where induction coil discharges are wanted and the cost of a k.w. is of small consideration.

In general the value of an interrupting device depends upon the abruptness or suddenness of the break. The more nearly instantaneously its resistance runs from zero to infinity, the greater is the discharge given by the coil to which it is connected. When the circuit is opened in a mechanical break, the current tends to persist, volatilizes the metal terminals, and forms a small arc which gradually dies away. In the electrolytic interrupter considerable current is concentrated through a small area of contact between platinum and water. Electrolysis of the water evolves oxygen which forms an insulating sheath. The current apparently arcs across this for a very brief interval of time, but is quickly drowned out by the water or blown out by the expansion of the sheath when heated by the arc. The presence of water prevents the melting of the metal and gives the arc nothing to feed upon. The break thus effected is immediately followed by a make, caused perhaps by the inward pressure of the fluid column on the gaseous sheath.

In a contribution on other pages of this issue, by Messrs. Charles T. Child and George T. Hanchett, it is pointed out that a coil in multiple with the interrupter is affected very much as is one in series with it. In the latter case the break of the circuit in the interrupter suddenly stops the current flowing through the coil. In the former case the break suddenly removes a short circuit about the coil and forces current through it. An interesting possibility is the combination of these two actions within one induction coil, which could be accomplished by winding two primaries in opposite directions upon the same core, one of them connected in series and the other in multiple with the interrupter. The effect then would be to reverse the magnetization instead of simply increasing and diminishing it, in which case the output might be expected to be greater, the efficiency higher and the use of an induction coil or transformer with a closed magnetic circuit possible. The rapidity of the breaks of the interrupter is so great that the iron core of the induction coil probably does not get time to more than partially demagnetize before the circuit is made again. Hence the use of a reverse winding, such as that proposed, might be expected to increase greatly the demagnetization and to improve the action.

**The Problems of Fan Motor Design.**

One of the most popular luxuries available from electric power and one coming to be considered a necessity, is the small electric fan. So extensive has its use become in many cities that it gives in hot weather a day load of no mean importance to the central station and goes a long way toward equalizing the summer and winter receipts. The growth of its use has been gradual and few probably realize how large a proportion of the total current on distributing mains finally finds its way through these small motors. One of the most forcible indications, although an unfortunate one, of its magnitude is the serious lagging current which it often throws upon alternating current systems.

The problems involved in the design of the fan motor are not as small as its size, when compared with comparatively enormous power motors, would tend to indicate. The conditions under which it operates are peculiarly trying. As a rule it receives no attention from the beginning to the end of the season, or worse, what

Digitized by Google

attention it does receive is from unskilled or meddlesome hands. Its lubrication must, therefore, be provided automatically for a period as near perpetuity as possible. Its journals are never rebabbitted, its commutator is never turned, polished or even cleaned and its brushes are only renewed when it refuses to run longer.

Perhaps the most serious requirement that the designer must comply with is the question of cost; the number of parts in the motor must be worked down to the very minimum and each small casting, screw or nut made to fulfill as many functions as possible. The eager competition of many manufacturers and the unskilled criticism of most users occasions this limitation.

In the matter of efficiency the requirements are also much more severe than would appear from its small load. In most instances its use is a luxury and the power supplied to it is paid for at the rate of 15 or 20 cts. per k.w. hour. If the motor requires 100 watts and runs 10 hours per day, it costs for power $4 or $5 a month, making it to many a rather expensive luxury. The efficiency of the fan motor cannot, because of its size, compare with the 90 per cent. or more obtainable with large motors used on heavy loads, but ranges more near 50 per cent. If taken as the ratio between the power given to the air by setting it in motion, to the electrical input, the figure falls away below this, so there are opportunities to perhaps double or treble the efficiency by slight changes in design; whereas on large motors, the most carefully worked out improvements can only hope to gain 2 or 3 per cent. At least one fan motor is now made with a field commuting switch by which the speed can be adjusted without using wasteful dead resistance, but by varying the strength of the field.

The ideal simplicity so necessary in fan motors is most easily obtained with the alternating current machine, which requires no commutator nor even collector rings or brushes, but does require, as do large induction motors, a very narrow air gap and a low induction in the iron to keep down the lagging currents, which are at the best excessive in such small machines. The designer of the alternating current motor also encounters difficulties in obtaining low speeds at high frequencies. With a desk fan running at 1000 to 1500 r.p.m. the problem is not a difficult one, but with ceiling fans running at one-tenth this speeds it becomes serious. The reason for this is that to obtain anything like the efficiency desired the fan must run somewhere near synchronism with the current supplied to it. Assuming that the frequency is 16,000 alternations per minute and the fan runs at a speed of 150 r.p.m. and has a 25 per cent slip, it must have 80 poles, a number quite out of the question for motors of this small size, as they would become thin teeth with an absolutely prohibitory magnetic leakage. The production of a direct current motor to run satisfactorily at this slow speed without excessive weight and cost is a distinct achievement, although not as difficult as the problem of the alternating current type. The chief triumph of the direct current designer has been the construction of motors of this small size which can be run singly across circuits with as high a pressure as 500 volts.

The alternating current induction motor, pure and simple, when fed by single-phase currents is non-starting, that is, it has no tendency to turn until it gets in motion. This is overcome in fan motors as a rule by putting in what are known as shading coils, that is, short circuited copper strips around parts or corners of the poles. The currents induced in these give a magnetization out of phase with that of the main body of the poles, thus giving a rotating field which starts the motor in motion. Once up to speed the armature or secondary gives the necessary cross magnetization so that the starting coils are no longer necessary. As they cause a constant waste of energy they may be cut out, and in one motor at least they are connected with the switch in such a way that they are cut out in the running position and only closed while starting.

**Armature Reaction in Alternating Dynamos.**

Many engineers of alternating current plants, especially those transmitting power to distant motors, or feeding long-transmission lines with high-capacity or underground cables, have been puzzled by a rise of e.m.f. at the machine terminals with the throwing on of the load. It is well known that under certain conditions the voltage at the distant end of a transmission circuit or feeder may be higher than at the generating station supplying it, the current apparently rising in voltage along the line. The latter action is, of course, due to the effect of leading or condenser currents on the self-induction of the line and can often be made valuable for compounding or over-compounding systems without rectifiers or composite windings on the machines.

The rise of the machine voltage with the load is due to the same cause, namely, leading or condensing currents, which in this case affect the field strength of the machine. The action is best explained by reference to the familiar unitooth or pole wound dynamos, in which the armature coils are wound about large poles or teeth, equal in number to the poles of the field. In such a machine the e.m.f. is a maximum when the winding on the armature teeth is crossing from a position in front of one of the field poles to its next neighbor, and if the load is non-inductive the current in the armature will be in phase with this e.m.f., that is, will be at a maximum when the armature tooth is midway between the field poles. In this position the armature current will tend to weaken one pole as much as it tends to strengthen the other, the aggregate effect on the main field strength being nil.

If, however, there is a large capacity in the circuit or other synchronous machines giving a capacity effect, the current will rise in the armature windings before the tooth reaches mid-position between the poles and will tend to magnetize the fields more strongly. On the other hand, if there is considerable self-induction in the circuit making the current lag behind the impressed e.m.f. the current will not rise in the windings until the tooth has passed beyond the mid-position, and will tend to oppose the field by setting up lines of force against it. This is the reason that induction motors, arc lamps, reactive coils and other devices which take lagging current interfere so badly with the regulation of alternating current dynamos. The action is the same in multi-tooth machines, with distributed windings, and differs in polyphase machinery only by being more continuous and less pulsatory in character.

The same reasoning explains why two alternators may be safely connected in parallel with each other when giving quite different voltages. The one with the higher voltage immediately gives out a lagging current which pulls down its field strength. This current enters the machine with the weaker fields and is there a leading current which builds up the field strength, the effect on the two machines adjusting their voltages to the same value. So great is this effect in some dynamos that one generator may be run without any current in its field coils whatever, giving full voltage by a field excitation entirely set up by the armature reaction. Machines with a large ratio of armature to field ampere turns naturally exhibit this effect more strongly than do those with powerful fields and weak armatures or, as they are called, machines of close regulation.

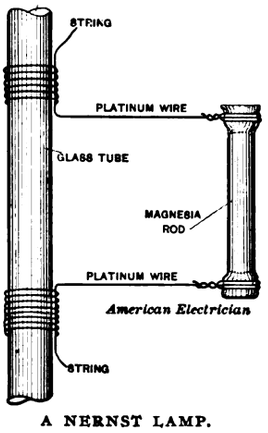
## THE NERNST LAMP.

This lamp, recently invented by the physicist, Nernst, of Göttingen, consists of a rod of dense magnesia with platinum terminals. This rod is connected in series with a dead resistance, and an e.m.f. (preferably alternating) of from 200 to 600 volts is applied to the arrangement. Upon heating the magnesia rod, by a blow pipe, for example, it becomes a conductor and passes sufficient current to raise its temperature to that of intense incandescence.

In the more recent types Nernst uses a large proportion of thoria in the rod.



An increase of current in the lamp causes a rise in its temperature and a drop in its resistance, and, at the temperature at which the lamp is used, this drop in resistance is so great that considerably less e.m.f. is required to push the increased current through the rod, so that the lamp is unstable, and without the dead resistance the lamp would be destroyed by the excessive current that would flow through it. The efficiency of the lamp, according to tests made abroad, is about 1.5 watts per c.p., including the watts lost in the dead resistance. The lamp gives a beautiful and pleasant white light and its life is claimed to be very great.

A number of these lamps have been constructed at the physical laboratory in Bethlehem, Pa., by Prof. W. S. Franklin and Mr. R. B. Williamson. After many trials the following procedure was found to give good results: A mixture of calcined magnesium oxide (composition of mixture given below) is tamped as compactly as possible into a smooth-bore brass tube lined with two or three thicknesses of stiff writing paper. This paper should be fixed in place with a little glue and baked dry. The tube full of magnesia is then slowly baked on a metal plate over a Bunsen burner until the paper is completely charred, when the magnesia rod may be pushed out. The rod is then calcined before a blow pipe, heating it slowly and uniformly to avoid cracking by unequal shrinkage. The rod is then broken to a length of about 2½ ins. and laid upon a bed of magnesia. Two ordinary arc carbons are brought up to the ends of the rod, one carbon being fixed by weights, the other being preferably held in the hand. Several hundred volts e.m.f. are applied to the carbons with dead resistance in circuit and the magnesia rod is heated by the blow pipe until the current starts. As the magnesia rod rises in temperature it shrinks greatly, and it must be subjected to very slight end pressure to prevent the formation of cross cracks; too much pressure will cause longitudinal cracks. The current is then increased until the magnesia rod becomes slightly soft, when it may be straightened if, as is likely, it has curled up in shrinking. The rod is then allowed to cool and ground on an emery wheel to the required shape, as described below.

The most convenient source of current for the purpose of this preliminary heating and for operating the finished lamp is a step-up transformer with a rheostat in the primary circuit; a secondary e.m.f. of 1000 volts is satisfactory. This e.m.f., of course, falls off greatly when the current starts, because of the action of the primary rheostat.

The magnesia mixture may be pure calcined magnesia with a slight amount of magnesium chloride ground up with it to serve as a bond. A slight amount of soluble silicate of soda is also a good bond. The mixture should be only moist enough to pack like flour; it is better to have it perfectly dry than too moist. A lamp made of pure magnesia or of magnesia with 1 per cent or less of powdered silica, has a very high resistance and can scarcely be started with less than 1000 volts, and then with difficulty. After it is once started, however, the resistance falls so that even a pure magnesia rod will operate with, say, 300 volts per inch of length. A lamp which is very much easier to start is made by mixing from 2 to 6 per cent of pounded glass with the powdered magnesia. Perhaps a lime glass would be best for this purpose.

The magnesia rod should be about 1 in. or 1½ ins. in length, and about ⅛ in. in diameter, with slightly enlarged grooved ends; platinum wire is wound two or three times around these ends and covered with

A NERNST LAMP.

a paste of magnesia, pounded glass, and water glass (or simply water). The lamp is conveniently mounted by binding the platinum wires to the side of a small glass tube. The figure above shows the finished lamp full size.

A lamp made as above described, with about 1 per cent of pounded glass and 1 per cent of powdered silica, the rod being about 1¼ ins. long and ⅛ in. in diameter, operated on 250 volts (between platinum terminals), takes 0.8 ampere, and gives fully 175 c.p., although the c.p. has not been measured at Bethlehem. It has been found that the silicates of sodium and potassium (or perhaps simply the sodium and potassium) are slowly expelled by the heat while the lamp is in use, causing the resistance to become slowly greater.

Commercial magnesia (calcined Grecian magnesite) makes good lamps without any admixture of silica, although its resistance is rather high unless it is mixed with powdered glass.

An attempt was made to fuse magnesia into a compact mass in an electric furnace (100 amperes at about 90 volts), but it was found that the boiling point of magnesia (at atmospheric pressure) is about the same as its melting point, so that the material vaporized about as rapidly as it was melted. The operation would, no doubt, succeed under pressure. During this work with the electric furnace it was necessary to keep a close watch of the action, and a small piece of heavily smoked glass was used to screen the eyes, leaving the forehead exposed, and a severe case of sunburn was produced, although the heat on the face was not excessive.

A most striking experiment is to mount a glass tube as a Nernst lamp. A large, thin walled tube gives the best effect. Wind copper wire terminals about 4 ins. apart on a thin walled glass tube ½ in. or ¾ in. in diameter. Connect to the secondary of a step-up transformer with a rheostat in the primary. Heat the tube along one side. The current starts along a narrow strip of the glass, heats it to bright redness, and this heated strip gradually widens until the whole tube is melted down. This experiment was tried in Bethlehem with a 1000-volt secondary, but it would certainly be possible to perform the experiment successfully with as low an e.m.f. as 100 volts, and direct current would answer as well as alternating. With low e.m.f. the distance between the copper terminals should be much less than 4 ins., and, of course, a rheostat should be included in the circuit.

## AMERICAN TELEPHONE PRACTICE.

### DISTRIBUTING BOARD.

BY KEMPSTER B. MILLER.

In every central office some means must be provided for distributing the various line wires which enter the exchange to their proper numbers on the switchboard and to enable changes to be made in this distribution as required. If such provision were not made, and the line cables were run directly to the switchboard, the wires in one one-hundred-pair cable, for instance, being led to the No. 1 section, and those of another to the No. 2 section of the switchboard, and so on, it would be necessary, at any time when a change in a subscriber's number was desired, to open the cable, take out the proper wire and fasten it alongside of one of the other cables leading to the proper section of the board. The changing about of wires from one part of a board to another is a very frequent occurrence, and to do it in the manner above suggested would be entirely impracticable. To do it without a proper regard to systematic arrangement would lead to endless trouble, by producing a tangle of wires, commonly and well termed "a rat's nest."

In order to provide means for the systematic arrangement of the wires what is called a distributing board or frame is used. These assume a great variety of forms, but the principle on which they are designed is as follows: On one side of the distributing board are placed clips, suitably

Digitized by Google

arranged, in which wires of the line cables may terminate. On the other side of the distributing board is arranged another set of clips or connectors, in which the separate wires of the switchboard cables may terminate. Supposing, for convenience, that the cables entering an exchange are twenty in number, each consisting of one hundred pairs of wires. These wires would pass through suitable office cables to the various terminals on the line side of the distributing board. Suppose further that the switchboard was arranged in twenty sections of one hundred drops each. Then twenty switchboard cables, of one hundred pairs each, would lead from the switchboard terminals to the terminals on the switchboard side of the distributing board. This brings connections from the line cables and also from the switchboard cables, in a permanent manner, to the various connectors on the respective sides of the distributing board.

The gap between the terminal of any line on the line side of the distributing board and that of the corresponding pair of wires leading from the switchboard is filled by means of "bridle" or "jumper wires." Suppose that the line circuit terminating in terminal No. 101 on the line side of the distributing board is to be connected with drop and jack No. 599 on the switchboard; then a bridle wire is run from terminal No. 101 on the line side to terminal No. 599 on the switchboard side, thus completing the circuit of that line between the switchboard drop and the subscriber.

One side of the distributing board often carries lightning arresters through which the various line circuits pass before entering the switchboard. These, however, are sometimes placed on a separate board between the line side of the distributing board and the cable heads. Test clips are also often provided on one side of the distributing board. These are usually simple forms of jacks, normally maintaining the continuity of the lines. They are, however, adapted to receive a test plug so that the testing operator may connect his testing apparatus with the line side of the circuit, leaving the switchboard side open, or with the switchboard side of the circuit, leaving the line side open, or he may merely bridge his testing apparatus between the two sides of the line without breaking its continuity.

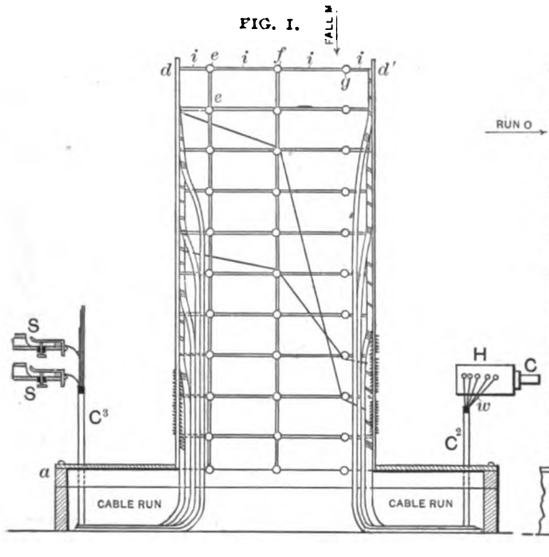
Inasmuch as there are in a large exchange several thousand of these bridle wires, means are provided for their systematic arrangement as far as possible. The chief object of distributing boards is to bring all of the confusion among the wires leading from the subscribers to the switchboard into one small place, and then to minimize that confusion as much as possible. This is well done in the Hibbard distributing board, modifications of which are used to a large extent in the Bell exchanges.

This was designed by Mr. Angus S. Hibbard and is illustrated somewhat in detail in the accompanying figures. The frame is built up entirely of iron pipes, extending in three directions and mounted upon a hollow platform a, shown in Figs. 1 and 2. These two figures represent respectively the end and side elevations of the complete framework, a plan view being shown in Fig. 4. Vertical pipes serve as supports for the structure, and are intersected at short intervals by transverse pipes i and longitudinal pipes e, f and g extending the entire length of the framework. As a result of this arrangement channels or horizontal runs are formed for the jumper wires between the vertical and the lateral bars, and vertical channels or falls between the sets of intersecting horizontal bars. On the ends of the lateral bars i are vertical strips d and d' of insulating material upon which are arranged the terminals for the various wires in the cables and the jumpers.

The general plan by which the wires are led from the cable heads to the switchboard is shown quite clearly in Fig. 1, where H represents the cable head carrying the terminals of the line cable C. The various wires w leading from the cable head are bunched into a cable $C^2$, which enters the cable run in the box beneath the frame, and after passing in a horizontal direction to the proper insulating strip d' is led upward and fanned out, the various pairs of wires being soldered to the outer ends of the terminals on the insulating strip. The method of fanning out is shown in Fig. 3. the covering of the cable being taken off and the various pairs of wires r r being led out at intervals corresponding to the distance apart of the terminals on the strip. After being properly formed the cable is laced and varnished, after which it is strapped into place and the wires soldered to the terminals on the strip.

The details of these strips and the method of attaching the wires of the cable are shown in Fig. 5, in which p and p' are the connectors screwed to the strip d. These connectors have outwardly bent lugs u, to

FIG. 1.



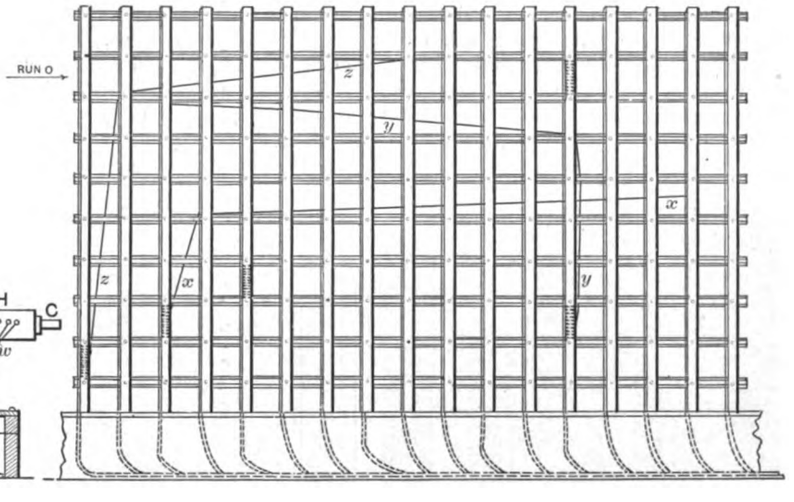


FIG. 2.

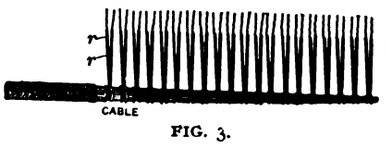

FIG. 3.

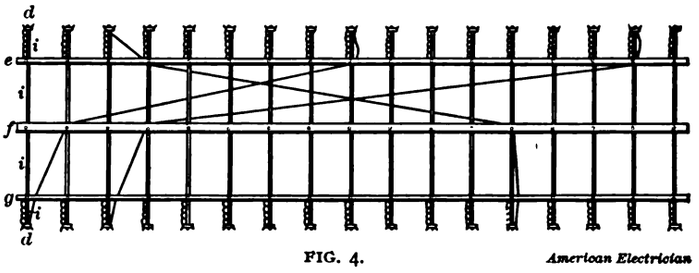

FIG. 4.

American Electrician

Digitized by Google

which the wires may be soldered. The ends of the jumper wires are shown at t t'. In a similar manner the wires leading from the switchboard jack are bunched into a cable $C^s$, which is then led through the cable run and to the proper strip d of the

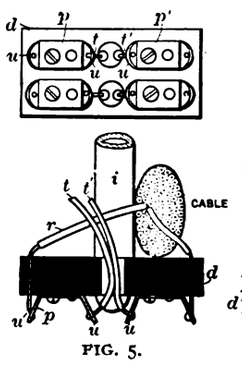

FIG. 5.

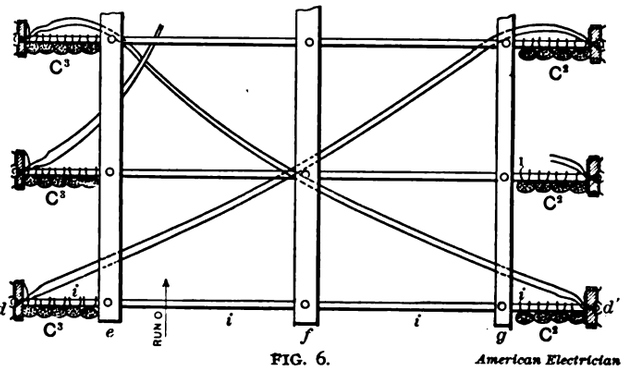

FIG. 6. American Electrician

distributing board, where it is fanned out and connected to similar terminals. The vertical portions of the cables, which are to be fanned out on the distributing board, are supported by the lateral horizontal rods i by being laced thereto, this being shown

through the proper channels in the framework to the desired terminals on the switchboard side, where they are secured in the same manner.

This arrangement serves to keep the wires fairly open and easy of access, but for very large exchanges it becomes cumbersome and has been supplanted by one designed by Messrs. Ford & Lenfest, some of the details of which are shown in Figs. 7, 8 and 9. This, like the Hibbard board, is in the form of an open framework built

carry upon one side of the frame horizontal strips 8 of hard wood upon which are secured the terminals for the wires of the street cables. A detail of these terminals is shown in Fig. 9, the metallic connectors m and n being secured in place in transverse saw-cuts in a thin strip of board by another strip bolted over them. A good idea of this general construction may also be had from Fig. 10, which shows a slightly modified construction. Supported upon the other end of the horizontal bars 6 are the vertical pieces 10 and 11 of hard wood and the flat bar 12, which is of iron. Upon this bar of iron are mounted the arresters X and Y, as shown in Fig. 8. These arresters, which are of the combined static and sneak-current type, will be recognized as the same as one of those shown in a previous article.*

In wiring this distributing frame, the street cables C are led in a horizontal direction under the strips 6, as shown in Figs. 7 and 9. These cables are then fanned out, the various pairs of wires passing through holes 14 in the underside of the horizontal wooden strip 8 and secured to the lower ends of the connectors m and n.

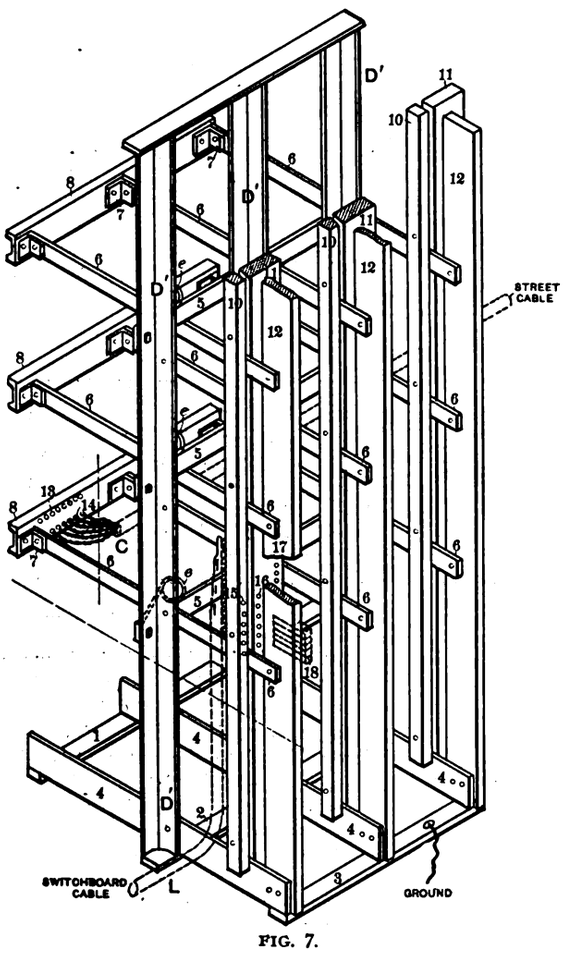

FIG. 7.

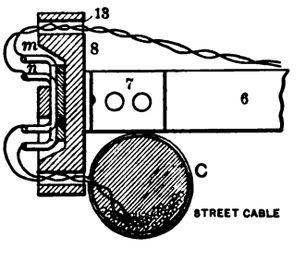

FIG. 9.

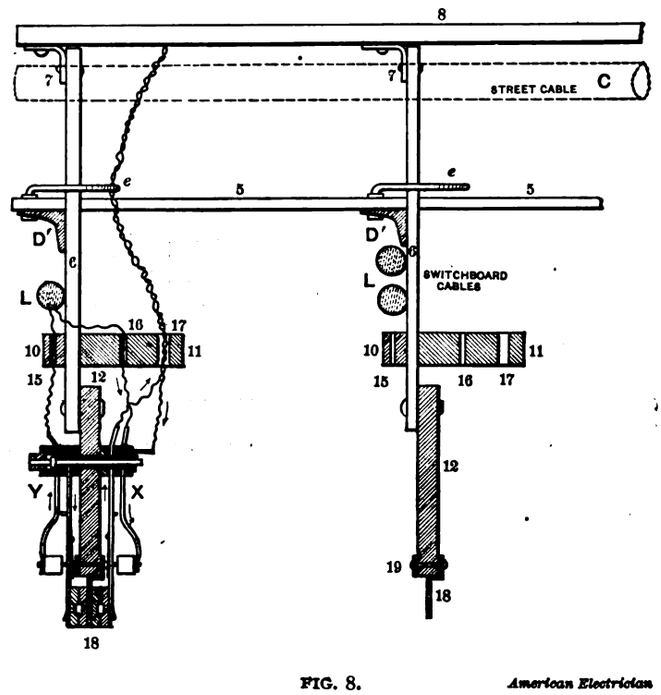

FIG. 8. American Electrician

quite clearly in the enlarged plan view of Fig. 6. The jumper wires which are usually formed of No. 22 B. & S. G. tinned rubber-covered wire in twisted pairs, are attached to the inner ends of the terminals on the line side of the distributing board and led through a hole in the strip and

chiefly of iron. Iron bars, 1, 2 and 3, to which are bolted plates 4, form the foundation of the frame. To the face of the plates 4 are bolted the supporting columns D' of angle iron, to which are secured all of the other portions of the frame. Horizontal bars 6 are bolted to the columns D' and

The switchboard cables L, shown in Figs. 7 and 9, are led from beneath up along the sides of the bars 6 between the supporting bars D', and the wooden strips 10 and 11. They are supported in this position by be-

*"American Electrician," November, 1898, Fig. 6, "American Telephone Practice."

Digitized by Google

ing laced to the horizontal bars themselves. These cables are fanned out, the various pairs passing through holes 15 and 16 in the wooden strips 10 and 11 and to their appropriate terminals on the arresters. The

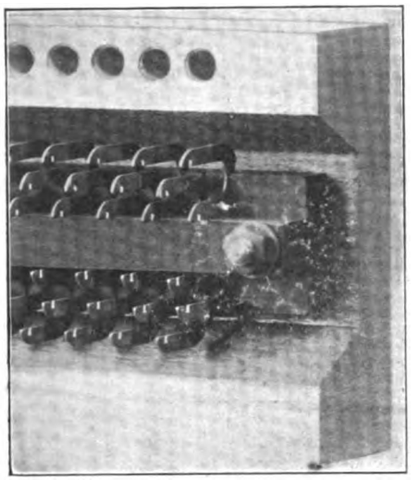

FIG. 10.

connections of the street and switchboard cables are thus as far as possible made permanent. The jumper wires are each led through a hole, 13, in the upper part of the horizontal wooden strip 8, its ends being secured to the upper portion of the connectors m and n, as shown in Fig. 9. The wire is then led in a horizontal direction along the top of the bars 6 on the line side of the frame until a point is reached opposite the vertical strip on which the desired switchboard terminal is located. It is then led through an eye or ring e and through a hole 17 in the vertical strip 11, and attached to the proper terminals on the arrester through which the connection is made with the switchboard wires.

A distributing frame built upon this general plan is shown in Figs. 11 and 12.

The line cables enter the exchange and are fanned out on the horizontal side of the distributing frame, as shown in Fig. 11. The terminals on the line side are numbered with respect to the wires in the cables to which they belong. On the vertical side of this board, which is shown in Fig. 12, are placed the arresters, to which lead the wires from the switchboard cables. The jumper wires connecting the horizontal with the vertical sides are arranged as already described.

In this exchange and in many others of the more modern Bell exchanges, the wires from the vertical side of the distributing frame do not pass directly to the switchboard, but to an intermediate distributing frame which is similar to the one shown, with the exception that the arresters are left off. After passing through this intermediate distributing frame the cables are again formed up and led to the switch board. At the main distributing board all of the changes are effected which are made necessary by the change in the location of the subscribers, by the addition of new subscribers and the loss of old ones. The function of the intermediate distributing board is to permit of the rearrangement of the lines upon the switchboard, in order that they may be grouped to the best advantage for quick service. By it the number of calls received per hour by the various operators may be practically equalized so that a part of the operators will not be overworked, due to having an undue proportion of busy lines.

The distributing board manufactured by the Western Telephone Construction Company for some of its larger exchanges is shown in Fig. 13. The side shown in this figure is the line side, to which the line wires from the cable heads are run. Each of the vertical strips seen in the lower sec-

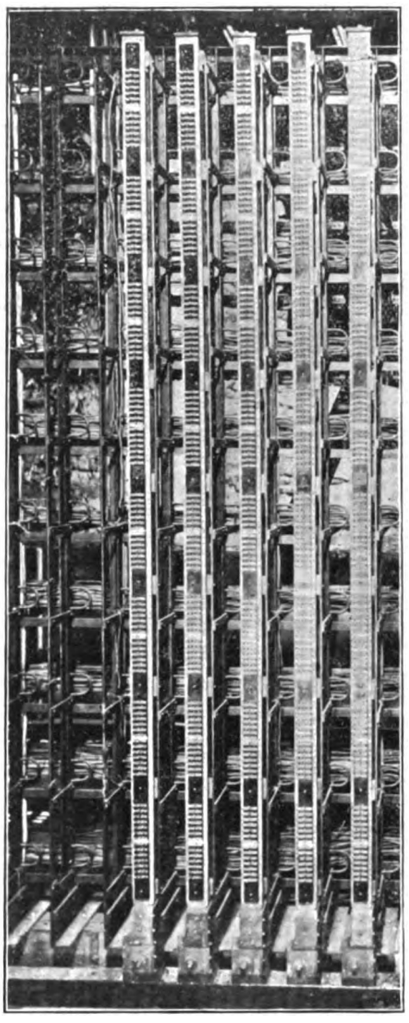

FIG. 12.

tion of the structure contains lightning arresters for twenty-five metallic circuits. These arresters consist merely of delicate fuses with suitable clips for holding them. Each strip is provided with a ground plate coming into close proximity with the various clips, so that a high tension charge may find passage to the ground. The cables leading from the cable heads of the outside lines are afforded room in the box or trough underneath this structure and each one is bent upward when opposite the proper pair of strips and then fanned out and permanently connected to the appropriate clips on the lightning arrester strips. All of these connections are made permanent.

In like manner the cables leading from the switchboard are brought into the same trough and bent upward through holes in the baseboard on the opposite side from the line cables, and are then fanned out and connected to the test clips, which are arranged on similar vertical strips to those containing the lightning arresters. These connections are also made permanent. Each jumper wire is run from the proper clips on the arrester side under the nearest one of the horizontal wooden rods shown on the interior of the lower part of the structure, and then bent upward so as to pass through a hole to a rack above. Inasmuch as the wire is to go to a certain terminal on the switchboard side it passes through a corresponding opening in the rack and thence in a horizontal channel, formed by the outwardly projecting pins, until it is opposite the terminal to which it belongs on the switchboard side of the board. Here the pair of jumper wires again passes through the vertical rack and down through a small opening and under one of the horizontal rods below, after which it is soldered to the proper pair of terminals. This com-

FIG. 11.

pletes the connection from the outside line to the switchboard line.

The test clips on the opposite side of the boards and lightning arrester clips are of heavy German silver springs arranged for

Digitized by Google

the insertion of a double plug in such manner that the testing apparatus may be connected in any desired manner to any line.

The best wire to use for jumpers is No. 20 or 22 B. & S. G. tinned, rubber covered, twisted in pairs. It is convenient to have the two wires forming a pair of different colors, so as to distinguish between the tip and sleeve sides of the line.

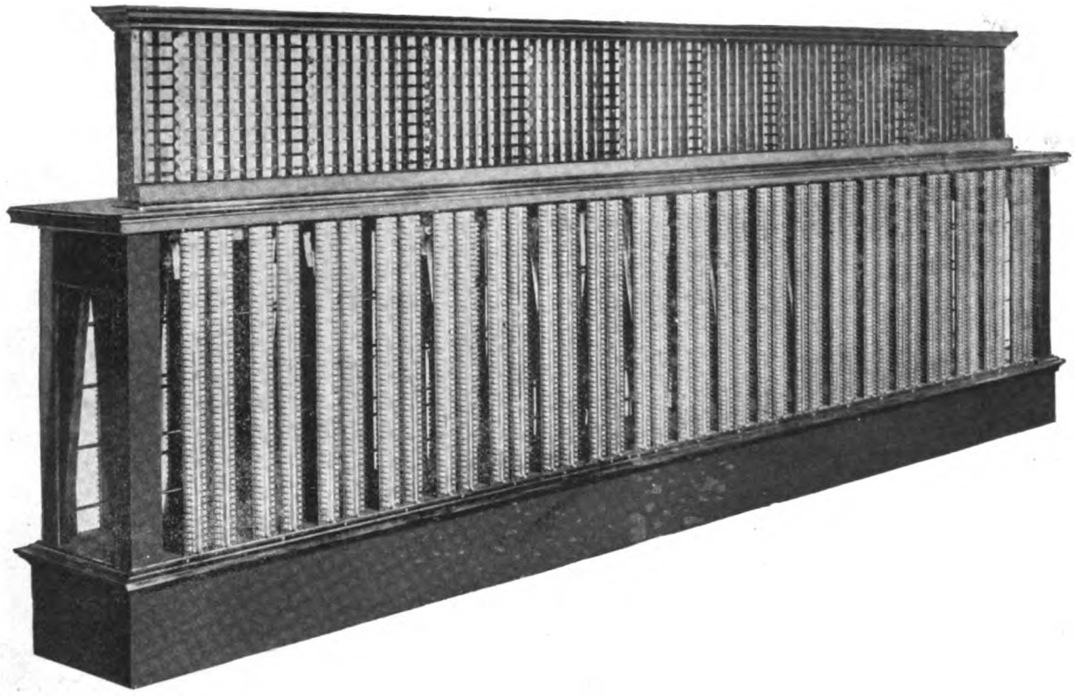

FIG. 13.—AMERICAN TELEPHONE PRACTICE.

## INTERIOR WIRING.

### STARTING THE INSTALLATION.

BY CHAS. E. KNOX.

In all the previous articles in this series, we have considered the subject of interior wiring from the standpoint of the person preparing the plans for the wiring installation. We have considered and discussed the various problems, which present themselves in "laying out" the outlets and lights and planning the circuit work. It now behooves us to change our point of view, and consider the subject from the standpoint of the contractor installing the work.

We will not stop to discuss methods of getting contracts, which, while interesting from the financial standpoint, are not equally so from an engineering view. We will suppose that he did get the contract by hook or crook, by merit or influence, and pass on to the trials and tribulations which he will meet in the performance thereof.

In taking up this portion of the subject we will introduce for consideration the various kinds or makes of conduits, insulators, wires, panel boards, switchboards, etc., and methods for their installation. In connection with these, cuts and drawings of the materials and appliances will be given as well as photographs of actual installations. Recent improvements and innovations will also be shown and their merits and defects pointed out. Examples of electric light installations in old buildings in which no provision for electric lighting was made at the time the building was put up, will also be given.

The first question which arises in regard to the installation of the work in a new building is, at what stage of the erection of the building should the electrical work be started? If the circuit work is to be exposed on insulators it can be commenced at any time after the building has reached the point when proper support for the insulators may be obtained. It is not well to commence putting up the wires too soon, however, as they are frequently used by other workmen as means of support. I know of an instance where large conductors on insulators were actually used in lieu of scaffolding by the steamfitters working on the same building, to the great indignation of the foreman in charge of the electric work.

If the circuit work is to be concealed, it must necessarily start before the flooring is laid and before the plastering is commenced or, in case of a frame building, before the lathing is put on. Experience has shown, however, that it is a mistake to start the conduit work before the partitions are set, for the reason that when this is done, it frequently happens that the partitions are shifted slightly from the location shown on the plans or there may be a discrepancy in scaling the plans by the different workmen. Again, if the work be started too soon, loss of the workmen's time ensues, owing to the lack of definite information as to exact location of outlets, distributing centers, allotment of space, etc. If, on the other hand, the work be started too late, the space provided for the electric work (particularly the "risers") is very apt to have been appropriated by some of the other trades. Also the amount of cutting and patching which must be done is greatly increased.

Sometimes the conduit work for the branch circuits is installed before the sleepers are laid. In this event the carpentry contractor has to notch the sleepers for the conduits, instead of the electric-wiring contractor. While this procedure has its advantages from the standpoint of the latter, it is objectionable from the standpoint of the owner, because if any changes have to be made afterward in the conduit work, the cost of the changes is increased, as the sleepers must be cut all the way through in order to raise the conduits (the latter being under instead of being laid on the sleepers) or else the conduits must be abandoned entirely and new ones run in the required direction.

A limited number of men (say two or three) should be put on the work at the start, in order to let the foreman get the "run of the work," for otherwise the men will be principally occupied in filling in time (and incidentally their time sheets) waiting for instructions. Before the work is actually commenced, information should be obtained on the following points: Height and exact location (as far as possible) of outlets, switches, distributing centers, etc., and, if the building is to be piped for gas, at what outlets combination fixtures are to be provided. If outlet boxes are used a sample of the gas "L" should be obtained to be used as a guide in ordering the outlet boxes for the side brackets so that the holes for the screws fastening the "L" to the box will be drilled in the right manner and the proper distance apart; also, it should be determined if any modifications have been made in the building which will affect the electric work, since the plans for the structure were made; conferences should be held with the representa-

Digitized by Google

tives of the other trades in order to anticipate any trouble which might otherwise arise from the work of one trade interfering with another.

Of course there are numerous other questions which occur peculiar to each case which should be settled before the work is started. While all the above points are minor details and may not seem worthy of the attention given them, it is just such trivial things which cause trouble. A little foresight at this stage of the work will save a great deal of trouble, annoyance and expense later on in the work.

Now as to what part of the work should be started first, it will be found that this is generally settled by the circumstances of the case. Where this is not so and the contractor may choose, it would probably be better in the majority of cases to commence with the feeders and mains. It is harder to find suitable space for the large conduits, and even if a particular space be set aside for them, this space is always liable to be seized for the overflow of the steamfitting, plumbing or other work requiring similar space. But if the feeders and mains are put in first, the other trades will be forced to accommodate their work more or less to the electric work, instead of putting all the burden on the electrical contractor.

It should always be borne in mind that the architect's cardinal idea of electrical work is embodied in a "flexible cord." He seems to think that while the plumbing and steam pipes, ventilating ducts, etc., require actual space, the electric work may be "tucked" in anywhere and sometimes has a poor idea of the electrician's ability because the latter has to give up a problem which is as impossible of solution as getting an "elephant in a cigar box." This idea is, however, gradually disappearing and the electric work will soon be treated in this respect in the same manner as the rest of the equipment of a building.

In the next issue the installation of the feeders and mains will be taken up.

## THE THAWING OF FROZEN WATER PIPES BY THE ELECTRIC CURRENT.

The use of electric current for thawing frozen water pipes, especially service branches in inaccessible locations, was brought to the attention of the public through the newspaper accounts of some experiences of this kind carried out about March 1st by Professors Jackson and Wood, of the University of Wisconsin. Since then the subject has excited widespread attention and considerable data has been given as to the voltage and current necessary in individual cases, a general resumé of which may be of interest.

In the first place the current required is far greater than that of arc light circuits, so that there is little hope of accomplishing anything with the 10 amperes that can be derived from them. On the other hand the voltage needed is so low that if street railway power is used an enormous amount of it is necessary, fully nine-tenths or more of which is not only thrown away but requires cumbersome apparatus for its absorption. With 110 volt isolated plants of sufficient dynamo capacity good work can be accomplished and the application of the current is of such short duration that no fear need be felt of electrolysis. Where such plants are available and are not in constant use, being shut down through the day, the current strength can be very simply adjusted by varying the field strength of the dynamo, and no water rheostat or other resistance need be used. With Edison 220-volt systems attention must be paid to the grounding of the circuit at other points. Many such systems have their neutrals permanently and heavily grounded so that any currents drawn into underground water pipes must be taken from one side of the system. The unbalancing effect of the heavy current necessary for thawing water pipes is so great that an equal load should be applied to the other side of the system at the same time.

The best source of current is an alternating system, especially as the temporary wiring for this purpose can be put in the primary circuits, the transformers being located close to the frozen pipes, and comparatively small wires can therefore be used. A secondary pressure of 50 volts will be sufficient for all ordinary cases. One odd result of the use of alternating currents in this way has been reported from a town with a ground return telephone system, where the alternating potential difference applied to the water mains promptly called

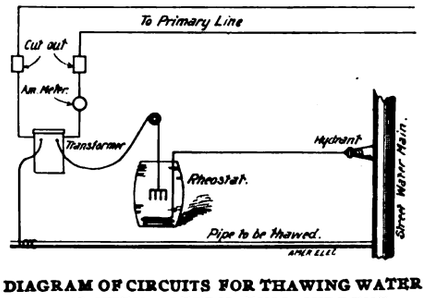

DIAGRAM OF CIRCUITS FOR THAWING WATER PIPES WITH ALTERNATING CURRENT.

up every subscriber in town and caused quite a flurry at the central exchange.

The general arrangement of the circuits is best shown in the accompanying drawing representing a frozen service from a street main. One lead from the secondary of the transformer is connected to the piping inside the dwelling house or other structure to which the service leads, and the other terminal of the transformer secondary is connected through a water rheostat with the street main, either via a convenient hydrant or a service branch to neighboring premises or any other point of access. Care should be taken that the water piping within the house affected is not crossed with other pipes such as gas pipes, etc., which might give another outlet to the street mains. If the piping of the premises is elaborate and heavily grounded, it would generally prove best to cut it off from the service.

The following reports give some idea of the amount of current necessary for different cases: Messrs. E. A. Britton, A. R. Welch and G. Lighthall, of Chelsea, Mich., thawed a house connection of 80 ft. of 1-in. pipe with 180 amperes applied for 14 minutes. Current was taken from a 100-k.w. 220-volt direct-current generator and controlled by a water rheostat made of an ordinary barrel filled with salt water, a coil of bare copper wire in its bottom, forming one terminal, and a bundle of seven common arc lamp carbons hung from a piece of line wire forming the upper and adjustable terminal. The same gentlemen thawed out two house connections at once, the houses being on opposite sides of the street and connections made to the respective sill-cocks of the two houses. One hundred and sixty amperes were used in this case.

F. H. Soden, of Chicago, thawed a 1-in. pipe, the circuit containing 110 ft. of lead pipe of this size and 45 ft. of 6-in. iron pipe. The current used was 155 amperes at 25 volts. Water began to flow in seven minutes. Alternating current was used in this case and controlled by a reactive coil in the primary circuit. In another case a ¾-in. lead pipe required 190 amperes, the voltage necessary to force this through 85 ft. of the lead pipe, and 22 ft. of 6-in. iron pipe being 30 volts.

Mains have been thawed in some cases; in one instance a 6-in. main required 350 amperes, the length in circuit was 320 ft. and 100 volts alternating current were used. Professors Frederick Bedell and G. S. Moler report the thawing of a 4-in. cast iron main on the campus of Cornell University, Ithaca, N. Y. A current of 160 amperes was maintained for 5 hours and 40 minutes in this case and was supplied by a 220-volt low pressure alternator. This was run with only 12 volts across the terminals, of which 9 volts were delivered to the water pipe.

## UNIQUE USES OF THE ELECTRIC CURRENT.

One of our English contemporaries cites the uses of electricity to liven up a dancing bear. This peculiar adaptation of the principle that "electricity is life" was made public by the claim of an electrician for work done in fitting up an electrical table on which the bear was to dance, the owner refusing to pay on the ground that the current was not sufficient to have the intended effect. There is obviously an opportunity here for a special course of instruction in the institutions of electrical education.

A physician of Wiesbaden has discovered that the application of electricity will cure the bites of insects, such as the Jersey mosquito and the elusive flea, as well as the more serious wasp and hornet. According to accounts, a direct current should be used and the negative pole put in contact with the place stung.

Still another application, somewhat out of the ordinary, has been proposed by the Board of Health of Newport News, Va., the suggestion being to surround the local pest-house with a barbed wire fence, the wires to be charged with a sufficiently high pressure to discourage attempts at escape, but insufficient to do serious physical damage.

## STEAM AND WATER STOP VALVES.

MISCELLANEOUS.

There are many valves in use that are neither gate, globe nor plug, yet they are well adapted for the duty they are called upon to perform. A very good form of the improved plug valve is shown by Fig. 1. The valve carries a double cap and

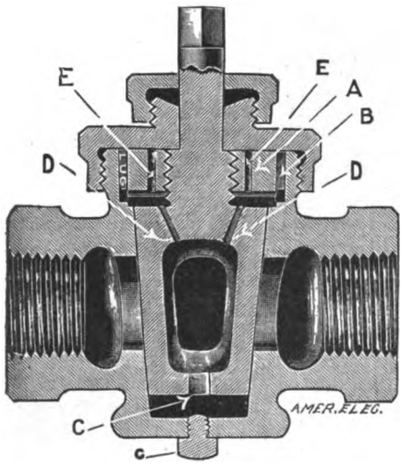

FIG. 1.—HOMESTEAD STRAIGHTWAY PLUG VALVE.

also contains a traveling nut, marked A in the engraving, which raises the plug from the seat when the valve is opened and also carries lugs which limit the travel of the plug to one-quarter turn, this being sufficient to give full opening or full closing of the valve.

This valve is made by the Homestead Manufacturing Company, and is constructed in either brass or iron. The plug is made with ports C D D E E for the purpose

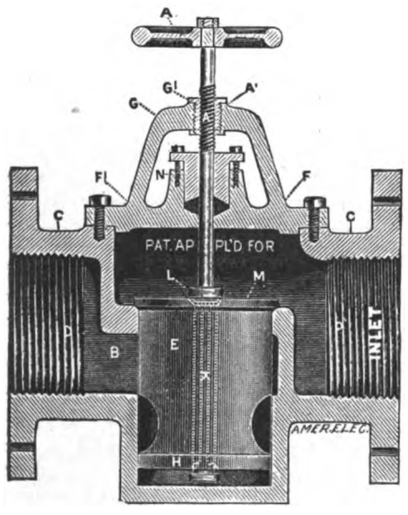

FIG. 2.—HENNEBOHLE'S BALANCED VALVE.

of equalizing the pressure on the two ends of the plug, thereby allowing it to move easily when opened or closed without the possibility of sticking to its seat. There is a screw plug in the bottom of the valve casting which may be removed whenever it is desired to drain the valve or to remove any sediment that may have collected. This valve is such an advance upon the crude constructions that have and still do duty as plug valves, that many of the prejudices against that ancient form of valve must be removed as soon as this form becomes familiar to engineers. For the engraving and description of this and several other valves in this article, we are indebted to "Power," from the pages of which the items in question were reproduced.

Another outgrowth of the old-fashioned plug valve is presented by Fig. 2, in the shape of Hennebohle's balanced valve. The engraving shows the construction so plainly that but little description is necessary except to state that when the valve is to be opened the hand wheel is turned just enough to allow steam to pass through the center of the valve until the pressure is equalized, then the valve may be easily opened to its full extent.

The stuffing box under the yoke, together with the bearing in cap and yoke air well form ample bearing surface for the valve stem, while the body of the valve sup-

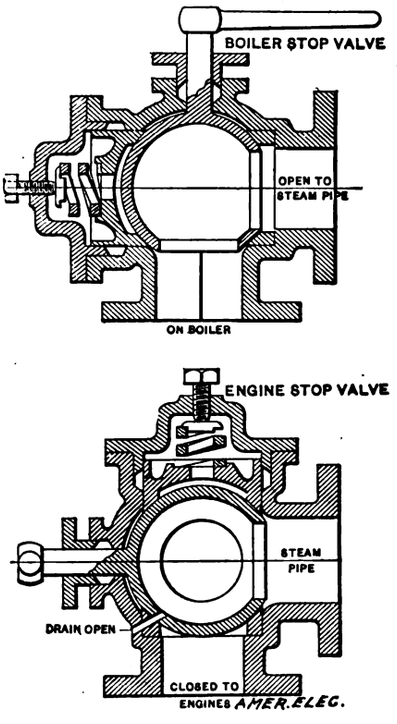

FIG. 3.—SPHERICAL BALANCED VALVE.

ports the cylinder or disc in a very thorough manner. This valve was patented by F. Hennebohle.

A valve, which is designed to withstand any pressure which the material will admit, is illustrated by the two engravings comprising Fig. 3. This is not a globe valve, neither is it a gate nor a plug; yet it is a modification of the latter with about all the poor points eliminated therefrom. The valve is balanced by the application of the balance plate shown in the engraving, in which openings are provided suitable to correspond with those in the globe.

When the valve is closed all the steam and water of condensation from the body and passages in the valve run to the condenser or to the drip, thereby preventing all possibility of explosion from confined steam or water. This valve may be made applicable to any degree of pressure when applied to hydraulic machinery, by adjusting, through the coiled spring as shown, the pressure screw which bears against the balancing valve or plate. This valve is the

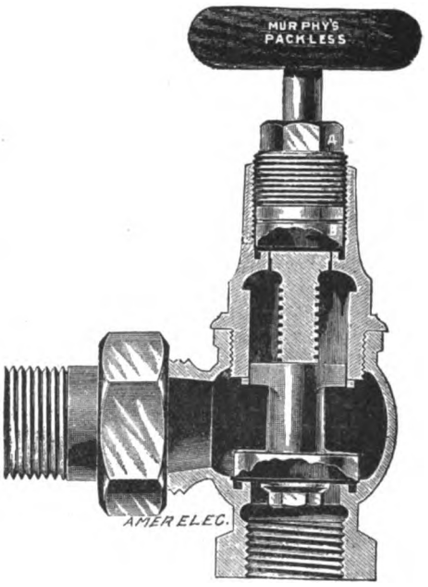

FIG. 4.—MURPHY'S PACKINGLESS VALVE.

invention of an English engineer, Mr. James Casey.

A type of valve known as "Packingless" is on the market, placed by several makers. The Murphy Packingless Valve, illustrated by Fig. 4, is one of this kind. It is not to be understood that there is no packing between the disc and seat of these valves, but between the stem and the gland this paint is made tight by the disc B in the

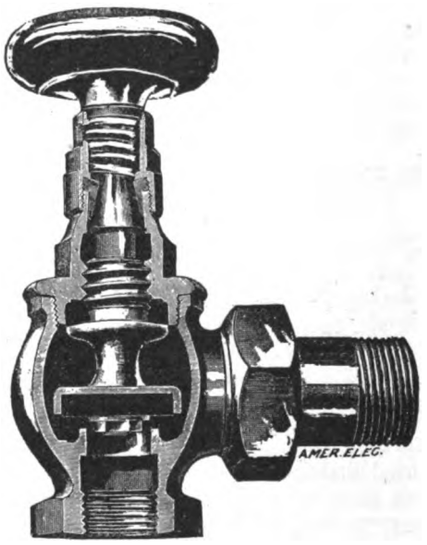

FIG 5.—MORIN PACKINGLESS VALVE.

neck of the valve, the nut A being used for adjusting the disc B.

The peculiarity of this valve is, therefore, that the loose neck packing usually placed around the stem of a valve is replaced by the disc on the stem which carries a ground surface against which an ordinary packing ring bears, in a manner similar to the reg-

Digitized by Google

ular disc packing in ordinary valves. The nut under hand wheel need only be adjusted just right and the valve is packed tight or loose as desired. This valve is made by the Van Auken Steam Specialty Co.

Another so-called "packingless valve" is illustrated by Fig. 5. It effects the same results as described above, but in a slightly different manner. This valve is known as the Morin Packingless Valve and was placed on the market by the McNab & Harlin Company. It is understood that two styles of this valve are made, one with a double core disc which may be reversed when one side is worn out; the other style, which is the one shown in the engraving, carries the regular Jenkins seat.

That portion of the disc which carries the thread is loose in the valve, and is only attached and guided by the thread in question. The stem is square in section, and enters a square hole in the disc, which slides up or down upon the stem when the latter is turned one way or the other. Just above the square portion of the stem may be seen a core which forms part of the stem, and is kept pressed into the cap or gland by the force of the coiled spring, shown above it.

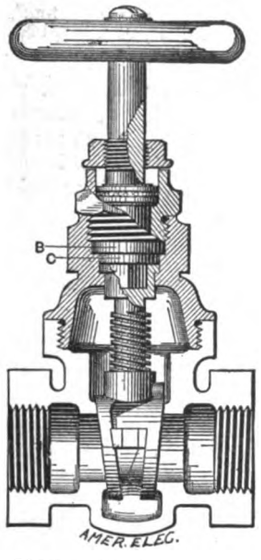

FIG. 6.—COOK PACKLESS BALL BEARING VALVE.

The pressure of the spring keeps the stem core at all times tight against a conical seat in the cap so that there is no leakage whatever. As the steam or water pressure increases, the pressure against the conical seat also increases. This is caused by the area of pressure against the lower end of the valve stem.

There is also a projecting ring to be seen on the upper portion of the disc, which engages the bonnet when the valve is fully open. This allows the cap or gland to be removed when the valve is fully open, taking with the cap the stem, spring and conical seat, without leaking steam in the least. The valve may also, of course, be opened, as above, when fully closed.

Still another form of "packless" valve is shown by Fig. 6. It is known as the "Cook Packless Ball Bearing Valve," and was invented by J. J. Cook. This is a gate valve with a packed disc B, which is reversible and works against the disc C, attached to the valve stem and held in place by a jamb nut, in the upper portion of which is a circle of steel balls caged between two steel plates, thus eliminating all friction, except that of the packless joint.

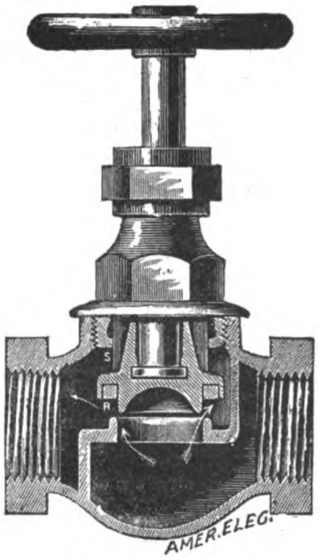

FIG. 8.—THE LOCKE VALVE.

This gate valve is of the "loose wedge" variety, whereby there is little or no scraping of the gate and seat surfaces over each other. The packless joint is kept tight by means of the nut on the upper part of the valve stem, which can be tightened without fear of working loose, as the collar on top of the upper plate has a lug on its interior surface which fits into a slot in the valve stem and must therefore revolve with it. By drawing the disc on the lower part of the stem firmly against the disc B, steam is prevented from leaking around the valve stem.

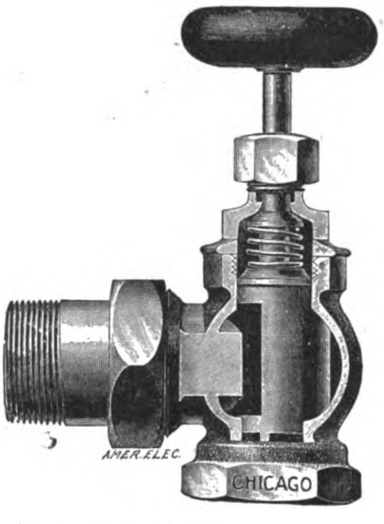

FIG. 9.—CHICAGO HOT WATER RADIATOR VALVE.

A form of valve is shown by Fig. 7, which is of the globe variety, and is so designed that the seat may be easily turned up with a file by simply removing the bonnet. As seen in the sectional view A, and the plan C, this valve is provided with a cylindrical seat which projects above the body of the valve when the bonnet is removed. It is also claimed that the annular construction of this valve seat makes it impossible for heat to distort or spring the seat so as to cause leakage.

The course of the fluid through this valve is not very direct, but it is claimed that for a majority of purposes this disadvantage is more theoretical than practical. Another good point in this valve is the lug shown in cuts A and B, through which a bolt is placed to hold together the bonnet, which is split through the thread at this point. It is very hard to remove the bonnet from a valve which has been exposed to the heat for a long time, but by loosening the bolt, the split bonnet opens a trifle, permitting it to be readily unscrewed. This valve is the invention of C. M. Callanan.

A valve, which has been designed to protect its soft metal packing, is illustrated by Fig. 8, and is known as the Locke Valve, being manufactured by the Locke Regulator Company. In this valve the disc is readily removable, and is fitted with an annular channel into which some soft metal is cast at R. A projection of the disc passes inside the opening in valve seat and takes the wear of the fluid away from the soft metal ring, especially when the valve is nearly closed or is just opening. The upper part of the disc is fitted with lugs and extends up into the bonnet, thereby forming all the guidance that is necessary for entering the disc into the seat.

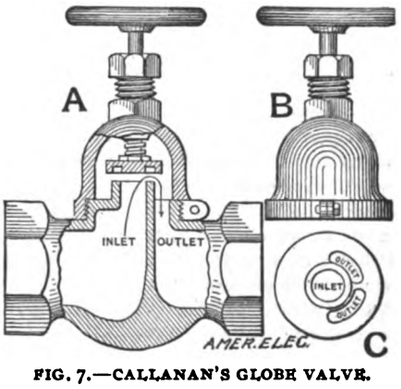

FIG. 7.—CALLANAN'S GLOBE VALVE.

A valve, which is in considerable use upon radiators, is illustrated by Fig. 9. This valve has some characteristics which are very useful. Among them is that of being packable without shutting off the water.

The disc of this valve is cast of brass, and has a by-pass which assures perfect circulation at all times. The construction of the valve is so plainly shown by the engraving that no further description is necessary. This valve is made by The Roe Stephens Manufacturing Company.

Two valves made by The Crane Company are illustrated herewith by Figs. 10 and 11. The first is a quick opening steam radiator valve which opens with a quarter turn of the lever. The stem of this valve simply rotates instead of rising, which goes

Digitized by Google

far toward preventing a leaky stuffing box. The vulcanized rubber with which this valve is packed, and also the material which is used in other valves for a similar purpose, will expand in a different ratio from the metal of which the body of the valves is composed. This, as many people have found to their sorrow, permits the valve to leak after it has cooled down to normal temperature. To prevent this leakage a spring has been placed in this

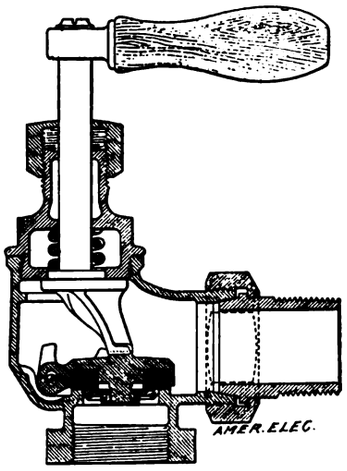

FIG. 10.—QUICK OPENING STEAM RADIATOR VALVE.

valve of sufficient strength to close the valve against the pressure it is likely to have to stand. Thus when the valve is closed the spring is compressed more than enough to allow for all possible contraction of the packing washer. In this manner the valve must remain tight, no matter how much the packing may shrink.

Again, with the ordinary form of valve, it may not be quite closed when a person

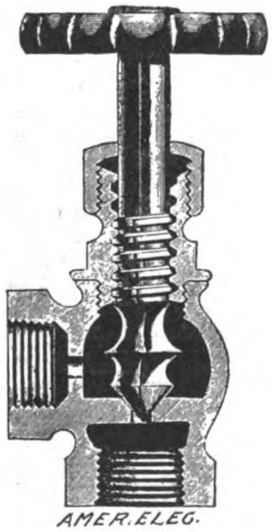

FIG. 13.—NEEDLE POINT ANGLE VALVE.

turns down the hand wheel, and then the radiator fills with water and thumps badly when steam is turned on again. With the valve here described it must be either fully open or fully closed, so that the kind of leakage above described cannot occur. The spring will close the valve tight if the lever is depressed enough to close it at all, otherwise the spring will keep the valve fully open.

The other valve alluded to in a preceding paragraph is a quick opening valve for a hose connection. This valve also is fully opened or closed by a quarter turn of the lever. The construction is virtually the same as that of the preceding valve, with the exception that the valve is made positive by removing the spring. This valve gives practically a full opening of the pipe, and is virtually a straightway. There is the smallest possible surface to corrode in this valve, a point which is of value in hose connections which must necessarily be exposed to the weather all the time.

A form of globe valve is illustrated by Fig. 12, which is in use considerably for controlling the flow of oil to an oil-burning furnace or burner. Outwardly the valve has the appearance of an ordinary globe, but the seat casting extends entirely across the interior of the valve and is pierced by the small hole as shown. This

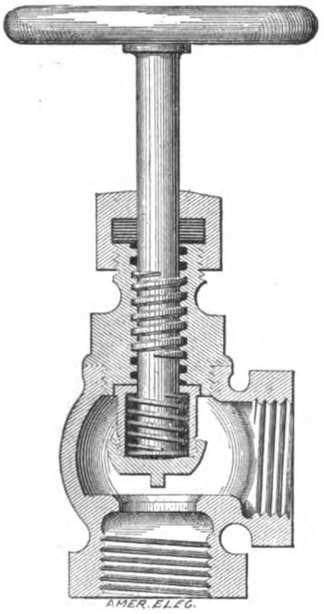

FIG. 14.—DODGE'S AUTOMATIC VALVE.

valve is made by the Haydensville Manufacturing Company, and is tested up to 100 pounds. The seat is reamed out a little when the valve gets to leaking, and the needle point may be put in a lathe and trued up whenever necessary.

Another form of needle valve is illustrated by Fig. 13, and is of the angle form. It is a product of The Crane Company. A feature of this valve is the placing of a second web in the end of the tapping hole leading to the horizontal opening. This strengthens the valve a great deal and admits of its being made somewhat thinner than otherwise would be permissible. The metal around the valve seat can also be relieved a great deal of the cutting action of the stream of oil by making the hole through the vertical diaphragm smaller than the hole where the needle works. Thus the needle seat will keep in shape for a much longer time than where there is only a single hole as in the globe needle valve.

A peculiar and very convenient form of valve, which, though not strictly a stop valve, may well be considered as such, is shown by Fig. 14. This valve is intended for an automatic cylinder cock which will work while the engine is running, and which may also be used at will as an ordi-

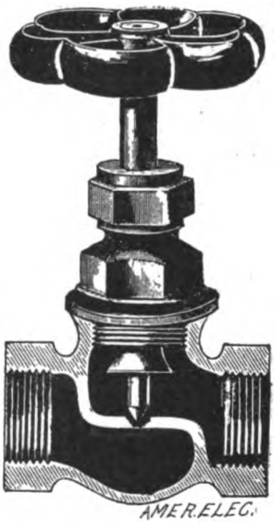

FIG. 12.—NEEDLE POINT GLOBE VALVE.

nary globe valve. The engraving shows the disc held up by a spring. When steam pressure is put into the cylinder the spring is compressed and the valve closes. This happens when an engine takes steam at the beginning of the stroke. When the engine exhausts the spring opens the valve again and any water of condensation that may be in the cylinder can run out. The spring can be so delicately adjusted that a very slight increase of pressure in the cylinder

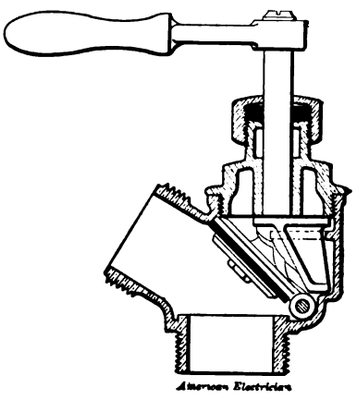

FIG. 11.—QUICK OPENING HOSE VALVE.

will close the valve. It is claimed that many accidents resulting from water in the cylinder would be obviated by the use of this valve, which does not require that the water shall be under great pressure in order to be forced out of the cylinder, as is the case when the ordinary relief valves are used. This valve was invented by John S. Dodge.

## ECONOMY OF STEAM PRODUCTION.

BY A. L. HARRISON.

When one notes the improvements made in the engine room and the way in which every detail is made in accord with the most advanced knowledge of the principles involved and of the most intelligent practical utility, and then looks in the boiler room there is a contrast which is astonishing.

It is true there has been improvement, but there still remains so much evident room for further improvement, especially in details, that one necessarily wonders why this important factor in the production of heat, light and power has not received its share of attention. That it has not is painfully evident in the majority of boiler rooms. The boilers in use at the present time are, for the most part, of good general design, but there is an evident lack of attention to special practical requirements.

This lack of intelligent adaptation is, I think, due in a large measure to the practice in making specifications for and in the purchase of boilers. There are some notably commendable exceptions, but the great majority of architects, even at this late day in designing a large building for business purposes, are lame in respect to the steam plant. If an architect, when proudly showing his plan for an important hotel, office or other business structure, is asked where he is going to put the plant (upon which, in a large measure, the economy and comfort, if not the success and usefulness of the building depend) the usual reply is, "Oh! that goes in the basement," and in consequence great difficulty is experienced in placing the necessary equipment because no intelligent provision has been made for space to place the various appliances required.

This is true not only of the older buildings into which a modern equipment has been introduced, but of many of the most modern and pretentious buildings in the various cities. There is one firm of world-wide reputation as designers of modern large office structures who cannot point to a single one of the fine, large buildings designed and built under their supervision where the steam plant is not a disgrace to the profession. This firm, like many others, never "points with pride" to the intelligent knowledge displayed in the arrangement of the basement. Their pride is that part above the ground.

Boiler manufacturers are behind in a similar manner in respect to the furnace, which is a basic factor in the successful operation of the boilers. They design the heating surface with a view to strength, durability, circulation, separation and advantageous application of heat, but take no such pains as to arrangement and adaptation of a furnace. As a consequence there are not a few large modern boiler plants from which full capacity cannot be practically realized, because no adequate grate surface can be arranged or placed so as to burn the necessary amount of "steam coal." I know one very large boiler plant in a Western city where oil is now being used for fuel at a cost which would ruin any concern not having a monopolistic profit, because the furnaces are so arranged that getting "full duty" with coal is a practical impossibility. The boiler company's design provided a furnace nine feet deep and with four fire doors across the front. Think of a fireman trying to clean or to keep that grate surface well covered, the rear end of which is twelve feet or more from where he must stand to do his work! Think of his trying to "hold" steam with one of those doors necessarily open nearly all the time, admitting almost constantly a great volume of cold air into the fire chamber!

There is also a large plant in New York where "double deck" boilers of 500 h. p. rated capacity have been installed and more of the same form and size are to be added. These boilers are 10 feet 10 inches wide between walls. If there is 5,000 feet of heating surface in each boiler (no such boiler should be rated on less than 10 square feet of heating surface to each horse power) and as economizers are placed in connection with these boilers, there should be a ratio of 1 square foot of grate to each fifty of heating surface. This grate, therefore, should be not less than 9 feet deep to work the boiler strong and secure suitable benefit from the economizers. Surely such engineering can hardly be termed an embodiment of wisdom.

Consulting engineers and architects who make specifications for and the purchasers who buy large boiler plants often leave so important a feature entirely to the contractor. They simply specify that proposals must state the evaporating efficiency that will be guaranteed. Then, when in practical operation, the owner is disappointed he wonders how it is that he has been fooled. The fact is he has not been fooled. He has fooled himself. His specifications and guarantees are a farce. Guarantees as to capacity which do not include restrictions as to temperature of escaping gases practically only guarantee that if the boiler be crowded hard enough a certain maximum horse power can be developed. The usual guarantee of a certain economic evaporation only guarantees that, with the best of fuel and while operating under the most favorable conditions, a certain economy can be shown. When it comes to everyday work with ordinary "steam coal," neither such capacity nor such evaporation per pound of fuel is realized. The boilers, however, have fulfilled the guarantee.

If any of the standard make of boilers have the requisite water heating surface with a suitable ratio of grate surface of suitable design to properly burn the requisite amount of "steam coal," satisfactory economical and capacity results can both be realized.

When the requirements of purchasers are made definite and embody the proper practical details, guarantees of economy and of capacity can be dispensed with and satisfactory results will follow as naturally and as surely as water unobstructed will run down hill. If you want capacity secure the proper heating surface accompanied with the necessary ratio of grate of suitable form. If you want to use cheap or soft "steam coal" without committing a "smoke nuisance," buy a form of furnace that can burn such coal in suitable quantity without making smoke.

In a future issue I shall try to give a description, accompanied with illustrations, of one of the best examples of intelligent selection and arrangement of an "up-to-date" boiler plant.

## ELECTRICITY AT HIGH PRESSURES.

A discourse on this subject was given by Prof. Elihu Thomson before the New York Electrical Society on March 29th. While the treatment of the subject was as a rule elementary and popular in character, some new ideas were advanced and one new machine was described and exhibited in public for the first time. The object of this machine is to obtain very high electrical pressures, unidirectional in character, that is not alternating, and with calculable voltages. Several scientists, among them Prof. Trowbridge of Harvard University, have utilized several thousand primary cells in series with each other, giving steady direct potentials which can be multiplied in various ways.

Professor Thomson's machine is based on a combination of the selector device designed by Mr. Hermann Lemp for giving unidirectional currents to Crookes tubes and the historical Planté rheostatic machine. The new combination consists primarily of a rotary converter driven by direct current at perhaps 110 volts and giving alternating current at some 70 volts, which is then transformed up by an ordinary transformer to a high pressure—15,000 volts in the case of the machine exhibited. The rotary converter also drives a large revolving frame of wood, carrying contacts, which, from time to time, connect a battery of eleven condensers in multiple with each other and across the high tension side of the transformer. The gearing is so arranged that this connection is made and immediately broken at the instant when the alternating e.m.f. is at a maximum, which is about 20,000 volts if the effective pressure is 15,000. The connection is only made when the current tends to flow in one direction, there being no contact at the peak of the opposing wave, but at the time of this peak the frame makes contacts which connect the eleven condensers in series with each other, giving a total difference of potential of over 200,000 volts.

The action is of course intermittent, the charging connections in parallel alternating with discharging connections in series. Another contact can be mounted on the same frame which will at the instant of discharge connect the eleven condensers in series across another condenser. This condenser will then receive at every revolution a cumulative charge until it becomes charged up with the full potential difference of the eleven condensers in series.

# Lessons in Practical Electricity

CALCULATION OF ALTERNATING CURRENTS.

In the preceding article it was shown that if we lay down in the form of curves the inductive and resistance e.m.f.'s of an inductive circuit, such as of a coil, then the impressed e.m.f., or that which would be measured by a voltmeter at the terminals of that circuit, may be determined by simple algebraic addition, as in the case of direct e.m.f.'s.

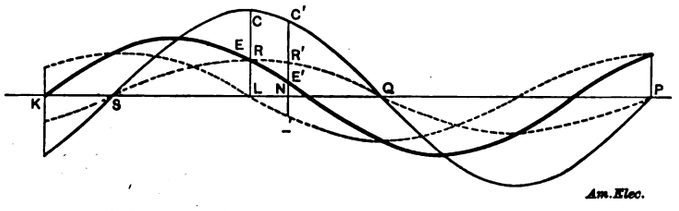

FIG. 1.—DETERMINATION OF IMPRESSED E.M.F.

As we pointed out, however, it would be impracticable to use this method where alternating-current calculations are actually to be made, and therefore an artifice is used, based upon the fact that commercial alternating currents follow a sine curve law of variation.

Fig. 1 is the illustration used in the preceding number, in which C is the current curve, from which is derived by means of the formula, $E = C R$, the resistance curve R; and also the inductive curve from the formula,

$$E = \frac{2 \pi N L C}{1000}$$

The resultant of these, or the curve in heavy line, E, was determined by adding together algebraically at each point, the sum of the inductive and resistance e.m.f.'s.

In the same article it was shown how a sine curve may be constructed. Referring now to Fig. 2, the right hand part is a duplicate of Fig. 1, and the left hand part is a construction showing how the curves given may be laid down independently of any physical considerations; that is, relying alone upon the geometrical properties of the sine curve.

For example, the current curve C may be plotted from different angular positions of the radius O C, as explained in the preceding articles. Since the resistance e.m.f. must be in phase with the current, for the reason that it increases and decreases as the current increases and decreases, O R will represent the radius from which the resistance curve R will be obtained in the sine curve construction. As the inductance curve has its zero value when the current curve has its maximum value, the relative position of the radius of that curve will be 90 degs. away from the current radius, or at O L. If now, we follow the construction given in the preceding lesson, it will be found that by revolving simultaneously the lines O C, O R and O N, the curves C, R and L will be obtained.

As the curve E of impressed e.m.f. is, at any point, the algebraic sum of the resistance e.m.f. and the inductive e.m.f., and since when the former is a maximum the latter is zero, E L in the left of the diagram will represent the impressed e.m.f. when the current has its maximum value; and drawing O E will give us the length of the radius for the sine curve construction of the curve of impressed e.m.f. Another way of looking at the matter is that since O R and O L are two forces, their resultant is the diagonal O E of the parallelogram O R E L.

The dotted lines in the circles are the positions when the heavy lines have been revolved through 90 degs.; then, it will be seen, the resistance e.m.f. and current become zero as at N, since R is now lieing on the horizontal base line. E will have moved to e and L will have moved to l, the corresponding points on the right hand diagram being e and l.

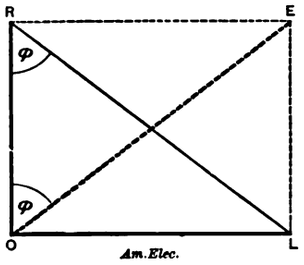

FIG. 3.—TRIANGLE OF E.M.F'S.

While this method of determining the values is less cumbersome than that involved in actually laying down the curves, it is nevertheless a process too complicated for practical use, and we will, therefore, proceed a step further in simplification, though in doing so we get further away from the physical aspect of the phenomena.

We have seen in Fig. 2 that O E, representing the impressed e.m.f., is the diagonal of a rectangle, of which the resistance e.m.f. O R, and the inductive e.m.f. O L are two sides. Suppose now that in Fig. 3, we lay down O R, the resistance e.m.f. to scale, and also O L, the inductive e.m.f. to scale, and complete the rectangle. Then O E will be the impressed e.m.f. But since the figure is a rectangle, the length of O E will be the same as the length of R L.

Therefore the problem resolves itself into laying down a right-angled triangle, one side of which—for example, the perpendicular—represents the value of the resistance e.m.f. in the circuit; and another side—the base, for example—represents the value of the inductive e.m.f. in the circuit; when the hypothenuse, R N, will represent the maximum value of the impressed e.m.f.

A very large class of calculations in alternating currents can be made with respect to such a right-angled triangle, and by a further extension, which will be treated later on, and introducing the general solution of a triangle of which three parts are known, practically all calculations in alternating currents may be very simply made.

As an example, suppose we wish to know the inductance of a given coil. First, pass through the coil a known direct-current and by means of a voltmeter determine the e.m.f. between the terminals of the coil when the current is flowing; this will give the drop in the coil for the given current, and dividing by the current will give the resistance drop in the coil for 1 ampere. Next, send through the coil an alternating current of known value and frequency, and by means of a voltmeter determine the resulting e.m.f. between the terminals of the coil; this will give the e.m.f. for the given current, and dividing by that current will give the impressed e.m.f. for 1 ampere. The latter quantity will correspond to the hypothenuse of the right-angled triangle and the former quantity to the perpendicular. It is then merely necessary to solve the triangle; that is, the square of the base is equal to the difference between the square of the hypothenuse and the square of the perpendicular; extracting the square root of this difference will give the desired inductive e.m.f. It may be added, that the resistance can be measured directly instead of by the drop method; and since we have assumed 1 ampere, the value of the resistance will be the length of the perpendicular.

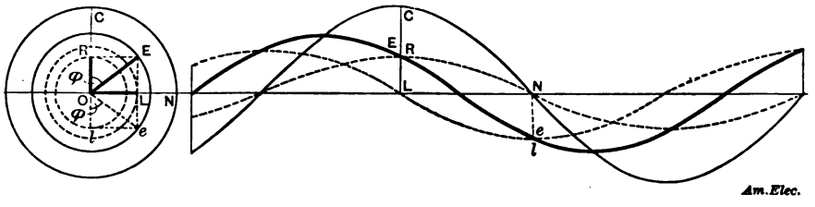

FIG. 2.—GEOMETRICAL DETERMINATION OF INDUCTANCE CURVE.

Suppose that we know the inductance in millihenrys of a coil, and also its resistance, and wish further to know how much e.m.f. must be applied to the terminals of that coil to send through it a given current. First, start out with the assumption that the current is 1 ampere. Then the resistance drop will be $I \times R$, which gives the length

Digitized by Google

of the perpendicular of the triangle. The inductive e.m.f. will be

$$\frac{2\pi N L.}{1000}$$

and the value of this will be the base of the triangle. As the impressed e.m.f. is represented by the hypothenuse of the triangle, its square will be the sum of the squares of the other two sides. Suppose this gives, say, 10 volts for the impressed e.m.f. which corresponds to 1 ampere; if we desire 10 amperes to flow through the coil, then the impressed e.m.f. for this current will be 10 x 10, or 100 volts.

In the preceding article, the maximum values of current and e.m.f. were partly used, and in this no qualification has been made. When we actually construct the sine curves, the radii of the several circles represent the maximum values of the current, or e.m.f. All commercial instruments indicate, not the maximum, but the mean square current or e.m.f., which is the value representing the energy value. In using the triangle, however, the relation established holds for both maximum and mean square values, and in practice the latter are the only ones that will ever have to be considered. Should it be desired to lay down the sine curve geometrically, the maximum may be determined by multiplying the mean square values by the square root of 2, or 1.41. In the preceding article, the value of this square root was erroneously given as 1.7.

## Letters to the Editor

### A New Type of Generator.

*To the Editor of American Electrician:*

Sir—It is with surprise that I notice that as yet no one has publicly criticised the remarkable claim for a so-called new type of generator, a description of which appeared in the American Electrician (page 101) and in other electrical journals of recent issue.

We all remember Pennock and his "Voltage Distributor," by which he proposed to get 1000 from 1 h.p., and many other things incidentally. The principle embodied in his apparatus and in that referred to appear to be identical.

In the report of the test accompanying the description of the machine, the most glaring discrepancy is in the number of watts produced. Two 55-watt lamps were tested, one on an ordinary machine and the other on this "New Invention." The lamp on the latter appears, however, to have been the only one submitted to photometric test.

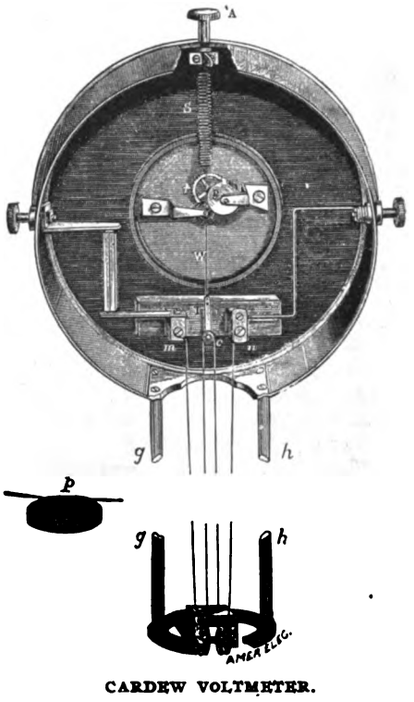
Presuming that the same style of lamp was used, 15.56 16-c.p. lamps (which it is claimed were operated by each h.p.) would, at 55 watts each, give 855.8 watts per h.p., which would be a performance so novel as to be suggestive of either Keely or Pennock.

Now, a watt is a watt, and represents a definite amount of power, and when a concern offers to furnish a machine that will maintain more lights per h.p. than the most efficient generator yet constructed, based on the supposition that the heat-retaining qualities of a filament will enable them to accomplish it, I should say look out for "sparks."

LOUIS D. BLISS.

Washington, D. C.

[The description was printed in that department of the American Electrician in which the claims of the manufacturers of the apparatus described form part of the article. Owing to the wide range of apparatus covered, and the limited data usually at hand, it would be impracticable—often impossible—for the editor to express an opinion as to the merits in each case. Besides, it is not only fair to the manufacturer, but desirable for obvious reasons, that the reader should know upon what grounds the maker believes a new piece of apparatus merits consideration; and in the department referred to, the source of the claims made is either specifically stated or clearly shown by the context. As to the machine criticised, we agree with our correspondent that the claims made for remarkable efficiency rest upon a false basis. On the other hand, the manufacturers of the machine are an old and reputable firm, and evidently thoroughly believe that the claims are well founded. The apparent violation of the fundamental law of conservation of energy has probably crept in through errors in the engine tests. The friction load was excessive due to the fact that the engine, when tested, was running also a line of shafting. The power given to the lamps is thus determined as the difference between two quantities, the determination of both of which was subject to all the inaccuracies of commercial indicator work.—Ed.]



## Electrical Catechism

*284. In what way may the heating effect of the current be used for measuring?*

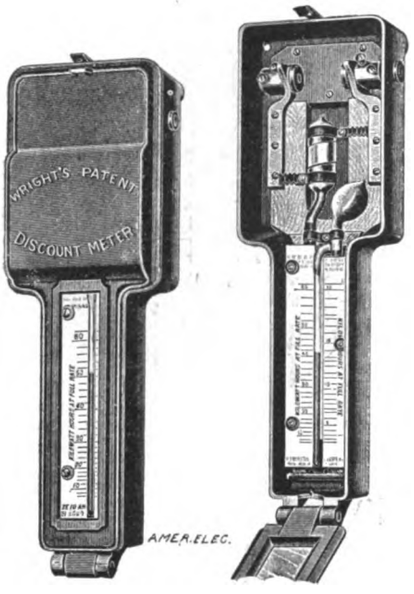
The energy absorbed by the resistance of the wire raises the temperature of the conductor above that of the surrounding objects. The rate at which heat is interchanged between objects varies directly as the difference of temperature between them; therefore heat is given off to surrounding objects more and more rapidly as the temperature of the wire increases. A point will be reached where the heat is given off as fast as it is developed in the conductor, and then the temperature becomes constant. At this point the conductor and the surrounding objects have expanded a definite ratio larger than their original size. The expansion of either the conductor or the surrounding objects may be used to indicate the temperature and therefore, indirectly, the current which caused it.

*285. How is the expansion of the conductor used to measure current?*

This has been found suitable only for measuring small currents. As the conductor expands, its increasing length may move a pointer through some form of lever or other multiplying device. The most common instrument based on this principle is the Cardew voltmeter, which was formerly used quite extensively, as it is suitable for either direct or alternating current. This instrument contains a fine wire about 4 yds. long and having so high resistance that it will take only a small current when connected across a circuit of 20 to 120 volts. The current through it is proportional to the pressure at its terminals, so that the motion of its pointer may be taken to measure volts. As current passes through the fine wire it becomes hot and lengthens, thus turning a multiplying gear, to which the pointer is attached. The instrument requires considerable current (0.28 amps. at 100 volts) and is not so much used as formerly.

CARDEW VOLTMETER.

*286. How is the expansion of objects near a conductor used for measuring the current?*



Several plans have been proposed, although only one seems to be a commercial success. One plan proposed by Forbes is to arrange a conductor as a coil below a small windmill, which will be rotated by the air put in circulation by the heating of the conductor. The speed of the windmill or the number of turns it makes in a given time registers the amount of the current. Others have tried placing the conductor around a thermometer, whose rise of temperature would thus measure indirectly the

Digitized by Google

current in the conductor. One form of this is coming into extensive use for determining the largest current used at any time by a consumer, known as the Wright maximum demand meter.

*287. Explain the Wright demand meter.*

It consists of a glass tube with two bulbs, around one of which the conductor is wrapped, the tube being partly filled with a liquid, as shown in the accompanying illustrations. The passage of current heats the air in the left bulb and the expansion of the air inside forces more or less of the liquid into the bulb at the right, and into the graduated overflow tube, from which it cannot be removed except by tipping up

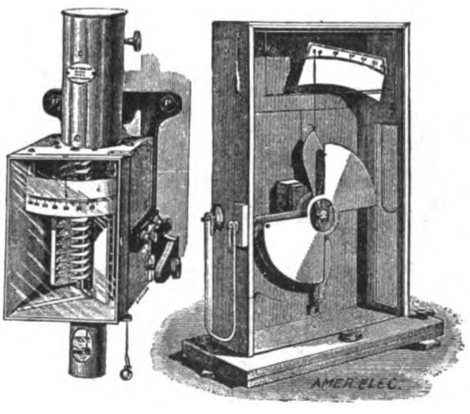
A WRIGHT DEMAND METER.

the meter. The amount of liquid that flows over depends upon the amount of expansion of the air, which depends upon the strength of the current. Any larger current will send more liquid into the overflow or indicating tube, but a smaller current will not. The instrument thus indicates the largest amount of current used at any time, which gives the station manager a basis for estimating the discount to be allowed from the bill as calculated from the regular meter.

*288. Is any other heating effect used for measuring the current?*

The fact that the resistance of a conductor changes with the temperature has been used for purposes of measurement, notably in the Howell lamp indicator or voltmeter, formerly made by the Edison Company.

*289. Upon what principle is the Howell lamp indicator made?*



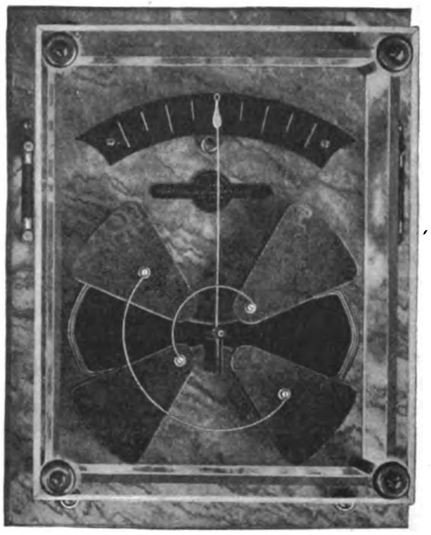
It depends upon the fact that the resistance of most metals increases with rise of temperature, while that of carbon decreases. Two circuits are arranged so that when equal or proportional currents flow in each, one neutralizes the effect of the other upon a galvanometer or other current indicator. One circuit contains a carbon resistance consisting of a special incandescent lamp; the other contains a long fine wire of iron or some other such metal whose resistance increases rapidly as its temperature increases. These two circuits are coupled in multiple and are connected across the circuit, whose voltage is to be kept constant. If the pressure increases, more current flows through each circuit and thus raises the temperature of each; this increases the resistance of one and decreases that of the other, so that the two currents are no longer equal or proportional as before, so that one affects the galvanometer and deflects the pointer in one direction. If the voltage becomes lower than the standard for which the instrument was set, the resistances change in the opposite direction and the pointer is moved accordingly. This instrument does not measure the voltage, but simply shows whether it is above or below the standard. It is not made now.

*290. How is the electro-static effect used for electrical measurement?*

A number of instruments are based upon the fact that two conductors attract one another when any difference of potential or electric pressure exists between them. If one is delicately suspended so as to be free to move, it will approach the other. This is developed in the electro-static voltmeters of Lord Kelvin (Sir William Thomson) and others, also in the electro-static ground detectors of the Stanley and the General Electric companies.

*291. Describe and explain the Kelvin electro-static voltmeter.*

This is made in a number of forms, one of the simplest being shown in the figure. It consists of a metal case containing a pair of highly insulated plates, between which a delicately mounted paddle-shaped needle is free to move. When the needle is con-



THE KELVIN ELECTRO-STATIC VOLTMETER.

nected to one side of a circuit, to the other side of which the stationary plates are connected, the needle is attracted and moves between them a certain distance indicated by the pointer. Adjusting screws at the lower end of the needle allow it to be balanced so that its center of gravity is the least bit below the center of suspension. The motion of the needle is then opposed by gravity. Different weights may be hung upon the needle to change the range of the instrument. The form having only two stationary blades, and one movable blade is suitable for measuring from 200 to 20,000 volts. By increasing the number of blades, the sensitiveness may be increased so that it will measure as low as 30 volts. The sensitive laboratory form known as the quadrant electrometer will measure a small part of 1 volt.

*292. Describe and explain the electro-static ground detector.*

One simple form is shown in the figure. It is a sort of differential static voltmeter having one movable vane and two stationary pairs of vanes. The movable vane is electrically connected with the ground, one

AN ELECTRO-STATIC GROUND DETECTOR.

pair is connected to the side of the circuit to be tested and the second pair to the other side. When both sides of the circuit are highly insulated so as to be free from "grounds," the needle is attracted equally by both pairs of vanes and so remains in the neutral position. Now, suppose that the insulation of one side becomes impaired so that it is more or less grounded; the pair of vanes connected with that side now attracts the needle less strongly than before, because the difference of pressure between them is less than before; the attraction between the needle and the other pair of vanes is not less but rather more than before, because the opposite wire has approached more nearly the potential of the ground and of the grounded needle. The needle therefore moves away from the pair of vanes connected with the wire that is grounded. The instrument shown is that of the Stanley Company, that of the General Electric Company being in principle the same. For use on circuits of more than 10,000 volts, the stationary vanes are not connected directly with the wires, but are charged inductively by auxiliary vanes which are insulated from the instrument and are connected with the circuit.

# Queries and Answers

**What kind of a storage battery is best for experimental work?** R. E. B.

Any kind.

**How much iron wire and what size is needed to reduce a voltage from 110 to 10, and give a current of ½ ampere?** G. E. N.

Use a 110-volt lamp.

**At what temperature does a storage battery solution freeze?** G. L.

Diluted sulphuric acid freezes at about 0 degs. F.

**Is an ampere-hour meter as accurate on a 110-volt secondary circuit of 16,000 alternations as a wattmeter would be?** W. S. S.

Yes, except in the case of varying potential or lagging currents.

**Will high and low voltage have equal effect on a magnet if the amperes remain the same?** F. W.

But the amperes will not remain the same.

**If a voltmeter registers an alternating current voltage of 1000, what is the maximum voltage?** C. A. K.

The maximum voltage will be 1410 when the mean square voltage is 1000.

**What h.p. is required to run a 2000-c.p. arc lamp?** C. J. M.

For street lighting it is usual to estimate 1 h.p. per full arc. At 45 volts and 10 amperes, 3-5 of a h.p. is used in the arc.

**Why is the positive pole of a dynamo connected with the trolley in street car working?** J. J. F.

To reduce electrolysis on neighboring pipes, or to confine its action to the district nearest the station.

**What size of aluminum wire is equivalent to 3-0 copper wire?** H. L. C.

The aluminum wire will have a larger section in the ratio of 100 to 63. Its weight, however, would be less in the ratio of about 1 to 2.

**What loss is there in a transformer on an open circuit?** C. J. M.

The iron loss, principally due to hysteresis; that is, the energy required to magnetize and demagnetize the core. There is also an eddy current loss and a negligible copper loss.

**Would it not be beneficial to use smaller than No. 36 wire on the secondary of an induction coil?** F. E. G.

As the inductance drop in the secondary due to the number of turns enormously exceeds the resistance drop, nothing would be gained practically by decreasing the latter.

**How is a Ries regulating socket wound?** H. S. K.

With sixty turns of stranded wire on a soft iron ring, connections being made to a desirable number of regulating points. This will give a maximum reduction in the light of 70 per cent.

**What is the equivalent on the meter system of a charge of 35 cents per month for a 16-c.p. incandescent lamp used on an average of four hours per day?** D. H. D.

At New York City meter rates, the cost would be $1.20. Thirty-five cents per month is undoubtedly far below cost of generation and delivery.

**I wish to construct an electromagnet for use in a grinding machine that will hold pieces of iron as large as a ⅝-in. bolt at a distance of 8 ins. What should be the winding?** A. R. M.

What you desire to do is practically impossible. It will be best to cause all the material to pass over magnet poles, so that any iron present will come into contact and be held by the same.

**How can I transform an alternating current of 52 volts down to 3 or 4?** S. A.

Wind wire on a soft iron core and connect between the turns, the ratio of the turns between connections being to the entire number of turns as the desired voltage is to 52. The simplest method would be to make connections to the turns of the secondary of an old transformer.

**How much wire will I need to boil coffee in about 30 minutes on a 550-volt railway circuit with three or four 110-volt lamps as resistance?** F. B.

To raise one quart of water from 60 to 212 degs. in 30 minutes will require about 1-5 h.p., or the heat equivalent of about three incandescent lamps. Therefore, the resistance of the heating wire should be three times the resistance of an incandescent lamp in such a circuit as that indicated.

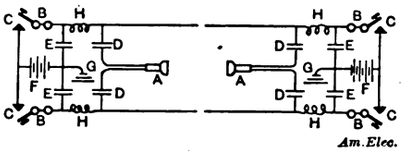
**How many k.w.-hours will a 25-h.p. motor consume in one hour loaded to full capacity, and what amount of coal will it take to furnish this power?** A. W. A.

With a motor of 80 per cent efficiency, the input will be about 30 h.p., which is equivalent to about 22.5 k.w. A k.w.-hour may take on the average anywhere from 3 to 20 lbs. of coal. The fuel, however, is but a small part of the cost of electrical energy delivered.

**One of several 600-amp. machines runs with cool fields and armature, but the commutator becomes hot with both copper and carbon brushes, and sparks badly with the former. The other machines run cool. What is the probable trouble?** C. T.

The brushes may not be set on the proper line of communication, or they may not be ground down to a good fit. If the other machines run well the trouble is probably in the brushes themselves or their position.

**What should be the winding of the 1-h.p. bipolar motor described in the December number, for electroplating?** P. M. R.



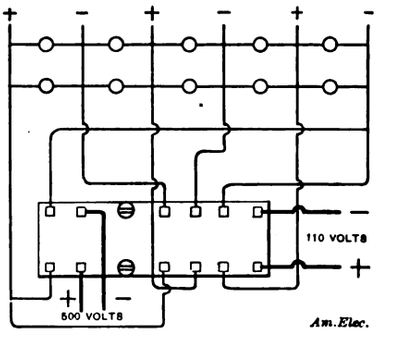
Armature coils of No. 8 wire, two in parallel, each coil having two turns of the double wire. Each slot will contain eight wires, two wide and four deep. Field coils of No. 12 wire 2¼ ins. deep and as long as can be gotten between poles in putting coils on cores. The commutator should be long enough to give ¾ sq. in. brush contact without lapping more than two segments.

**How may a choking coil be used on a 2000-volt series line to obtain a voltage of 200 between its terminals?** E. W. C.

Experiment with a small transformer by cutting out primary turns and testing with the station secondary voltage. The voltage between the terminals with the line current flowing will be to the secondary voltage used, as the series to the latter current. Not having a low-reading ammeter, the current for a few turns may be determined, and the number of turns necessary for 200 volts very simply calculated by means of a proportion.

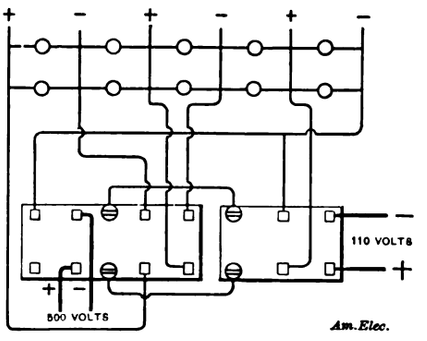
**How can telephone and telegraph currents be sent simultaneously over the same wires?** D. I. T.

Referring to the accompanying sketch, B, B, are telegraphic instruments; C, C, telegraph keys, and A, A, telephones, there being two grounded telegraph lines and one metallic telephone line to a two-wire circuit. H, H are choke coils, which prevent the high frequency telephone currents



Am. Elec.

from passing out of the telephone circuit, and D, D are condensers, which prevent the telegraph current from the batteries F, F from affecting the telephones. E, E are condensers across the telegraph instruments, in order to round off the telegraphic current so that it will not affect the telephone diaphragms, the choke coils, H, H, having also a similar effect. Telephone lines may thus be used for telegraphy without the knowledge of the telephone user.



**How can lamps be wired so that they may be supplied from either 110 volt or 500 volt circuits?** E. M. H.

The accompanying diagrams show two

Am. Elec.

ways. The first involves the use of one special double-throw switch with long blades which will enter four clips in the

Am. Elec.

right-hand position. The second uses one double-pole double-throw switch such may be found on the market.

## ALUMINUM, ITS HISTORY, MANUFACTURE AND USE.

The name aluminum is derived from *alum* a Latin word, which applies to all bodies having an astringent taste. Its basis is that of an argillaceous earth, and with the exception of oxygen and silicon, with which it is usually combined, it is the most widely distributed element in nature, forming, it is claimed, about one-twelfth of the earth's crust. It is a tin-white metal, but gray when powdered. It is odorless and tasteless, and is about as hard as silver after fusion, but when hammered about as hard as soft iron. It is malleable, ductile, very sonorous, and may be highly polished, but is only slightly magnetic. The melting point of aluminum is about 1200 deg. F. Its specific gravity as a casting is 2.56, being the lightest of the commercial metals, and bulk for bulk is only one-third as heavy as iron.

The electrical conductivity of pure aluminum wire having the same cross section as silver wire is about 63, as compared with silver at 100, and compared with copper, it is as 60 to 100, but the weight for weight aluminum wire will have a conductivity of 200, copper being taken at 100.

Aluminum unites readily with nearly all the common metals, and forms many useful alloys, in some of which its tensile strength is greatly increased. It is difficult to solder aluminum, however, due to its high heat conductivity, as it causes molten solder to harden before flowing sufficiently. The wires and bars are easily spliced by inserting the ends in a thin tube of the same material, then twisting the section.

As an ore aluminum usually occurs as irregular, pebble-like concretions. A few foreign deposits are more or less stratified. The minerals from which aluminum is principally prepared are known as bauxite, cryolite, native sulphate of aluminum, alum salts, and from the clays. The value of the clays, however, especially those like kaolin, which carry a large amount of aluminum, is small in comparison with bauxite, which is double and triple hydrated oxide, and has only a small amount of iron and silica to be removed in preparation for the reducing operations.

The principal deposit of bauxite, which is the ore most extensively used, so far found in this country are in several counties in the northwest of Georgia, and in the northeast of Alabama, where the supply seems to be very large.

The ore is found in a belt 30 miles wide and 75 miles long, not found in continuous beds or in veins, but in pockets having well defined outlines ,and containing compact masses of ore. Useful varieties of the ore are also found in Arkansas, Colorado, New Mexico and Greenland, and in southern France, Asia Minor and South America.

The Pittsburgh Reduction Company, which is the principal producer of aluminum in this country, and, in fact, has only one competitor in the old country, controls the Alabama and Georgia deposits, and here mines its principal supplies. One branch of the works of this company is located at New Kensington, 18 miles from Pittsburgh, and the other at Niagara Falls, where electric energy is employed in the process of reduction. The ores are first delivered to the Pennsylvania Salt Manufacturing Company, whose works are in the neighborhood of the Kensington plant of the Pittsburgh Reduction Company. Here the ore undergoes a certain chemical process of purification from the natural impurities of silica and oxide of iron. It is then delivered to the Kensington plant of the reduction company in bags, in the form of a perfectly white, fine powder. The first proces sis to remove the water of hydration, of which the ores contain about 30 per cent, and this is done by heating the material in peculiarly designed furnaces in which natural gas is employed as fuel.

When properly prepared, it is shipped to the Niagara Falls plant, where the pure metal is extracted and molded into pigs, when it is shipped back to the Kensington plant, where it is cast into billets, or smaller pigs, or any desirable form. The casting is done in crucibles in furnaces of the type usually employed in brass foundries. The billets are next rolled into plates, bars or rods, and afterward the rods are drawn into wire of various sizes.

The electrical separation of aluminum at the Niagara Falls works is done by what is known as the Hall process, consisting in the electroylsis of aluminum dissolved in a molten bath of the fluoride of aluminum, and the fluoride of one or more metals which are more electrically positive than aluminum, which quality is generally found in sodium or potassium and calcium.

The process is carried on in iron pots placed in series. The pots, as well as the reduced metal lying in them, serve to form the negative electrodes, or cathodes, while the anodes are of carbon usually, and dip into each kettle of the metal. The negative connections are made by having copper bars riveted to the iron pots, and which are in circuit with the positive poles of the next pot, the current going thus in series from one pot to the other, and back to the negative side of the dynamo.

A large continuous current having a low voltage is passed through the mass, melting it, when the deposition of aluminum in a molten condition is brought about.

The bath is maintained in a constant condition by frequent fresh supplies of alumina. The molten aluminum that collects at the bottom of the pots is dipped or siphoned out as water would be removed from under a layer of oil, due precaution being taken to prevent the molten electrolyte from being taken up with the metal, and this is done without interrupting the current passing through the bath. It is estimated that the amount of energy required to reduce one pound of aluminum from its oxide is about 5 h.p. hours.

The Pittsburgh Reduction Company has recently increased the capacity of the Niagara Falls plant by 75 per cent, and now the works have a capacity for producing nearly a million pounds per month. The company has also added fourteen trains of rolls, including continuous rolls, and several complete wire-drawing benches to the equipment of the new Kensington plant; for operating the same, a number of new engines aggregating about 1700 h.p. have been installed. The original buildings have been extended, and two neighboring glass plants purchased, which have been converted into suitable shape for the aluminum processes. The new Kensington plant covers a tract of 17 acres in extent on the bank of the Allegheny River, which is navigable to Kensington.

The enlargement of the works has been undertaken to meet the increased demand for aluminum conductors for the electric transmission of power, and for use in the manufacture of dynamos and motors, as well as for an increased demand for use in the mechanical arts.

The company has been making extensive tests during the winter on long sections of wire of different metals, which are mounted side by side near the works. Daily records of the temperature, and the records of sag as well as relative expansion and contraction of the different wires have been made, so that the relative merit of aluminum wire for withstanding the climatic changes has been fully established. A corps of chemists and electricians are constantly employed by the company for testing and determining facts with reference to the economical production of the metal, and for determining its value for different industrial purposes. The processes are now so thorough that the company is prepared to furnish the metal in ingots guaranteed to be over 99.75 per cent pure. It also furnishes several other grades, as well as a number of alloys and sheets are furnished in varying grades of stiffness from soft to hard.

## PUMPING HOT WATER.

It is to be inferred from the fact that feedwater heaters of the "open" type are coming into more general use, that the hot water delivered by them (which will have a temperature very close to 212 deg. F., or even higher, if there is any back pressure on the heater) can be handled (that is, pumped), without much difficulty. This is the case, for it is only a question of a proper location and equipment in order to satisfactorily perform this work.

The real secret of pumping hot water is in keeping at all times a solid body of water against the water piston, so that no opportunity will be given for the water to flash into steam. If the atmospheric pressure be reduced on water near 212 deg. F. by the partial vacuum of the suction of a pump owing to small piping or other causes the water will vaporize as the boiling point or the pressure goes down. Hot water cannot be lifted by a pump, because the instant the pressure is reduced by the water piston moving away from the inlet end of the pump, steam is formed, and this cushions the pump, prevents it from doing work, and causes it to race. It is only necessary to deliver the water to the pump in a solid mass, having some head; if the piping is short and free, a head of one foot will an-

Digitized by Google

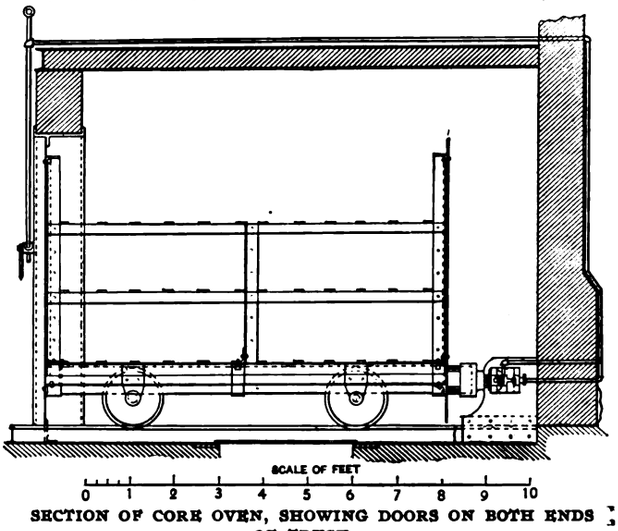
swer in some cases, though a greater head is better. With a high head, water can be pumped at a temperature considerably above 212 deg. F.

In arranging to take the supply from an open heater, the pump should be set close to the heater, and if the pump is raised up to bring it to a convenient height for the engineer to examine or regulate packing, etc., then the heater should be raised the same height. The piping should be kept free and of large size right from the heater up to the pump, where it can be bushed down if necessary.

This eliminates, to a large extent, the friction from long lengths of pipe, and from short bends, which can also be offset in many cases by erecting a loosely capped stand pipe in the pump suction, close to the pump, which gives a reservoir of water at the same height as that carried in the heater, directly at the pump.

It should not be forgotten that the pump suction valves and their springs must be lifted by the head of water before the water can enter the pump. In many cases where trouble is experienced in pumping hot water, the cure is to be found in lightening these suction valve springs, which are too strong; that is, they offer too much resistance for the available head or pressure of the water.

Brass fitted pumps, having metal valves, are to be preferred, as rubber or composition valves are affected at the temperature of water near the boiling point. Probably the best pump for handling hot water is an outside packed piston pump.



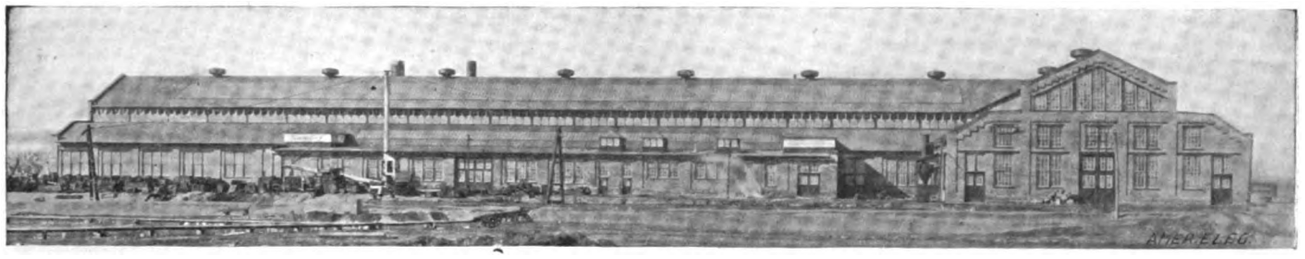
With a little attention to the details as suggested above there need be no more trouble in pumping water even at 230 deg. to 240 deg. than in handling it at 150 deg.

## THE GENERAL ELECTRIC COMPANY'S NEW IRON FOUNDRY.

The latest extensive addition to the manufacturing facilities at Schenectady of the General Electric Company is a large foundry which was first put into operation on January 5, 1899. The building, which stands to the east of the other works of the company, was carefully designed after a study of other similar plants, and contains some novelties in foundry construction.

The main structure is over 500 ft. in length and 140 ft. wide, and down its center runs the main bay, 65 ft. wide. At one end is an L, about 100 by 12 ft. in size, where all the castings are cleaned. The estimated capacity of the foundry is about 100 tons per 24 hours, 80 tons having already been poured in one day with 325 men working.

The crane equipment is unusually elaborate. Two 40-ton Morgan cranes with main and auxiliary hoists span the main bay. One 10-ton Morgan crane serves the cleaning room and 4 smaller two-motor Box cranes span one of the galleries where considerable heavy work is done. These latter cranes are conveniently controlled by chains reaching down to the floor from the switches and controllers above. Besides these, three 5-ton jib cranes will be installed later to relieve the 40-ton cranes of considerable local work. These jib cranes will be portable and can be lifted and placed in any position in the main bay by the bridge cranes overhead.



SECTION OF CORE OVEN, SHOWING DOORS ON BOTH ENDS OF TRUCK.

One of the most striking features of the foundry is its cleanness, the perfection of its lighting and the purity of its atmosphere, three qualities generally conspicuous for their absence in iron foundries. The interior walls are painted white, the roof of the main bay is almost entirely one vast skylight of woven-wire glass, and a large number of arc lights are in place for night work. Two large ventilating and heating blowers are in use, and the windows in the monitor of the main bay may be opened or shut in groups of eighty by chains brought down to the floor. By properly manipulating the windows according to the direction of the wind, and setting the dampers in the blower ducts, the structure may be cleaned of dust, smoke and steam even when metal is being poured or castings shaken out.

There are at present two Paxson Colliau cupolas in service, one of 17 and the other of 7 tons capacity per hour. A third cupola of 11 tons will be brought over from the old foundry. Around the cupolas is grouped all the small work to which metal is carried by hand, the heavy work supplied by ladles carried by the cranes being at a greater distance. One of the most interesting features of the foundry is the arrangement of the core ovens. There are six of these, two having very large doors about 10 by 12½ ft. in size. The hinges of these doors are mounted on ball bearings so that, in spite of their great weight, the doors can be moved by the pressure of the little finger. The four smaller core ovens are ingeniously fitted for continuous heat. Each is equipped with a truck or car, pushed out from or pulled into the oven by compressed air, and on each end of the truck is a door so that whether the truck is in or out the oven is always closed and under heat. The general arrangement is shown in the accompanying figure. The longer gentle heat that can be given in an oven so constructed apparently gives stronger cores.

The cranes, blowers and all other power absorbing apparatus in the foundry are, of course, motor driven, there being some twenty-seven motors scattered through the structure. The wires and steam piping are brought in through a conduit crossing the two main crane spans, this conduit being fitted with cast covers grooved to give tracks for both the 36-in. gage cars running around the works in general and the 21½-in. cars which run only inside the foundry.

The foreman's office is at the middle and to one side of the main bay, so as to give a view over the whole operating floor. Elaborate lavatories, shower baths and private lockers for the men have been provided. The old foundry which this modern structure has replaced will be turned into a machine shop, in addition to which the General Electric Co. is building a very large new machine shop.

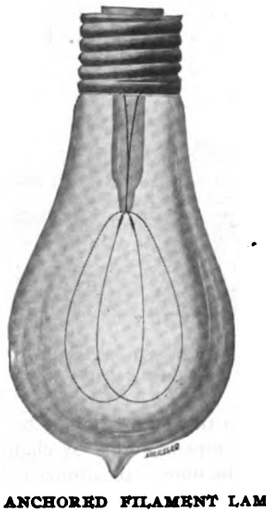
# New Apparatus and Appliances.

### THE JANTZ & LEIST GENERATOR.

The engraving below illustrates the line of generators built by the Jantz & Leist Electric Co., of Cincinnati, O. As the illustration shows, the machine embodies the principles and proportions of modern design. It is of the four pole spherical type, with laminated soft wrought iron pole pieces, cast in. The field coils are, as usual, machine wound and shunt and series coils are separately insulated. Carbon brushes are used firmly held in position by heavy bronze holders fitted with adjustable automatic tension feed. The bearings are of phosphor bronze, self-oiling and self-aligning, and the sub-base is cast with sliding rails and belt tightening attachments. The machines are made in sizes from 3 k.w. to 65 k.w. and of the standard voltages, 110, 220 and 500 volts.

A 4-POLE BELT-DRIVEN GENERATOR.

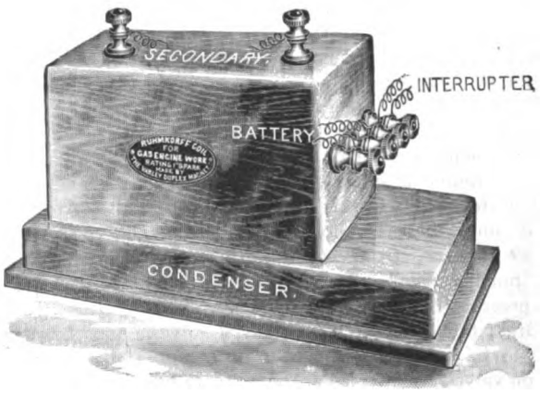
### AN INSULATED ARC LAMP HANGER.



The combination of a bell-shaped insulating hanger, similar to those used on over-head trolley lines, with a wooden break-arm makes a remarkably neat and simple insulating support for arc lamps. The accompanying figure illustrates such a hanger made by the Ohio Brass Co., of Mansfield, Ohio. The two metal parts of the hanger are made of malleable iron, insulated from each other by the well known Dirigo insulation which is widely used in the trolley wire appliances made by the same company. The iron parts are so shaped that even should the insulation become shattered, the lamp could not fall unless the castings also were broken. The hook to which the lamp is attached is made deep and narrow to prevent accidental detachment. The break-arm is of seasoned hard wood, covered with a preservative paint and fitted with porcelain insulators. The hangers are tested at the factory with 6,000 volts alternating current and are built to support a weight of 2,000 pounds.

AN ARC LAMP HANGER AND BREAK-ARM.

### THE "NEW LYNN" LAMP.



The accompanying illustration shows a new lamp put on the market by the Lynn Incandescent Lamp Company, of Lynn, Mass. The filament is oval in shape, designed to fill the bulb evenly with light and to obtain the maximum resistance against jars, vibrations or sagging. It is anchored to a glass stem direct without wires. The company has recently been granted a patent for this anchorage. The works of this company are fortunately located in an electrical center where the skilled workmen and workwomen, so necessary for the production of high-grade incandescent lamps, are easily obtainable. This is one reason for the high grade of lamps that the company can turn out at a reasonable price.

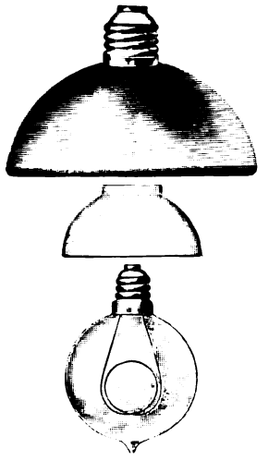
AN ANCHORED FILAMENT LAMP.

### AN INDUCTION COIL FOR GAS ENGINE IGNITERS.

Electrical ignition is for many reasons preferable to other methods in use on gas and gasoline engines. The earlier igniters consisted of contacts within the cylinder in which the gas was ignited and supplied with current through inductive coils which gave a considerable spark when the circuit was broken. A method far preferable is the use of a contact outside of the hot chamber, accessible for cleaning and not exposed to the destructive action of the burning fuel. This can be simply obtained by means of an induction coil with a make and break device operated by the engine at the proper point of the cycle and a secondary coil connected with two terminals within the cylinder. Such a coil, as shown in the accompanying illustration, is made by the Varley Duplex Manufacturing Company, of Jersey City, N. J. It is fitted complete with a condenser to increase the discharge in the well-known way.

A GAS ENGINE IGNITION COIL.

### A NOVEL REFLECTING SHADE.

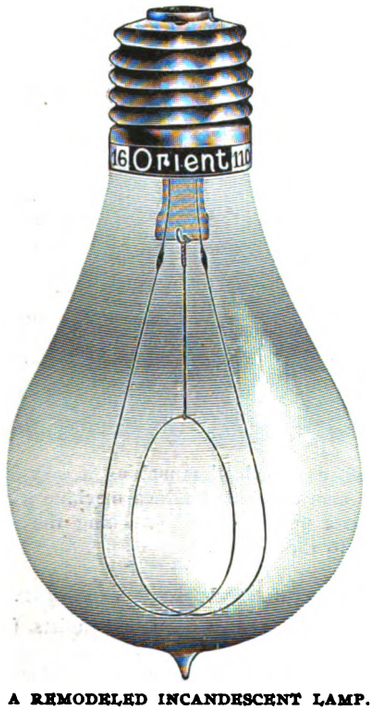


A simple and neat reflector for incandescent lamps is shown in the accompanying illustration, and is made by Schiff, Jordan & Co., of 232 and 234 Greenwich Street,

A REFLECTING SHADE WITHOUT A SHADE HOLDER.

Digitized by Google

New York City. The device, which is known as the "S. J." reflector, consists of an outer shade of silvered glass fitted with a base that screws into the lamp socket and an inner reflector of porcelain that fits snugly over the lamp. The base of the



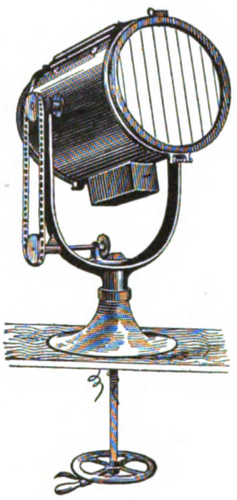
REFLECTING SHADE AND LAMP TAKEN APART.

lamp screws into a socket in the outer shade; this intermediate receptacle thus doing away with the necessity of a shade holder.

### THE REMODELED ORIENT LAMP.

Some time ago The Orient Electrical Company of Youngstown, Ohio, decided to modernize its factory equipment and processes by the adoption of the very latest machinery, devices and instruments known to the lamp business. The plant was overhauled completely, old-time appliances and

A REMODELED INCANDESCENT LAMP.



instruments were thrown out and old processes abandoned, so that to-day the company has a modern lamp factory and employs the most approved processes in the manufacture of its incandescent lamps.

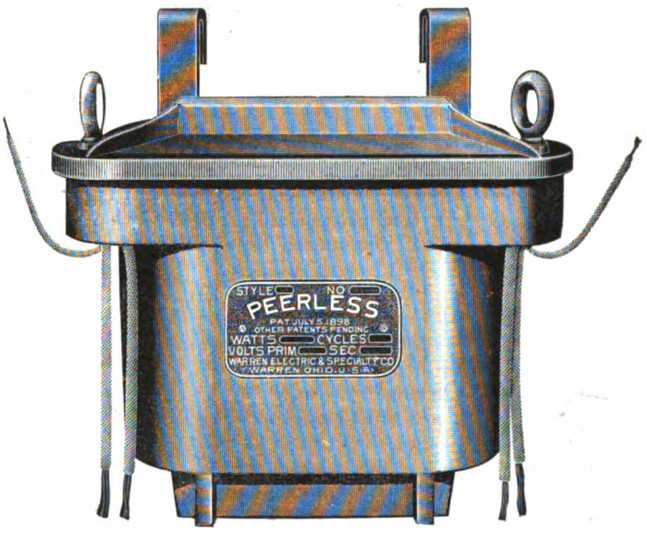
The new lamp has been thoroughly tested and is claimed to be a decided success in every sense of the word. It contains the oblong loop, coiled filament, which is anchored from the mount by a process which is used exclusively by this company. That its new lamps are meeting the requirements of the most critical purchasers is attested by the fact that it is now selling to some of the largest consumers of incandescent lamps in this country, both in central stations and isolated plants. It also manufactures a special street railway lamp which is giving general satisfaction.

The company has recently opened offices in the Havemeyer Building, 26 Cortlandt St., New York City, where Mr. Francis Granger is in charge, with a complete stock of standard lamps for immediate delivery to the Eastern trade.

### AN EASILY MANIPULATED SEARCH LIGHT.

The accompanying cut illustrates one of the many types of marine projectors and

A HAND-CONTROLLED SEARCHLIGHT.



search lights manufactured by Chas. J. Bogue, 213-215 Centre street, New York.

This apparatus is designed for use on the roof of the pilot house, the light projected from it being entirely under the control of the pilot. The mechanism is simple and easy to handle and consists of a hollow tube running to the standard of the projector through the roof of the pilot house. A wheel is attached to the end of this tube, through which runs a rod extending through the contacts, and engaging with bevel gears and a sprocket carrying a chain over a second sprocket on the bearings of the cylinder. A lever handle at the end of the rod engages with a ratchet on the under side of the hand wheel; thus, by turning the wheel, the light sweeps the horizon, and by moving the lever the gears are set in motion and the light beam is given an up-and-down motion.

These projectors are made in various sizes, from an 8-in. size taking 10 amperes, giving a beam effective at one-half a mile up to a 32-in. throwing the light over six miles.

### THE PEERLESS OIL TRANSFORMER.

A line of transformers, embodying the various improvements which have been developed in transformer designs of the last few years, is illustrated in the accompanying figure. The features apparent on the exterior of this type are the over-hanging eaves under which the terminals are brought out vertically downward, and the handy method of support. Four lugs cast on the transformer case hang over two cross pieces, bolted to inverted L-shaped bars which may be conveniently hung over cross-arms, joists, &c. The four terminals of the two coils of the secondary are brought out so that the connection can be changed from parallel to series, or vice versa, on the outside of the case. The case is either japanned or painted with aluminum paint like the up-to-date U. S. mail boxes. The performance of the transformers as given by the makers is another indication of modern progress in transformer construction. The one kilowatt size is listed with a core loss of 2.2% and a regulation of

THE PEERLESS OIL TRANSFORMER.

2.5%, while in the 10 kilowatt size the core loss comes down to 0.8 of 1% and the regulation to 1.9%.

### THE TRIUMPH EXHAUST FAN.

The exhaust fan shown in the accompanying illustration is built with a flat square back, owing to which fact it can be easily and cheaply placed in position. After being simply lagged or bolted up

A BELT-DRIVEN EXHAUST FAN.

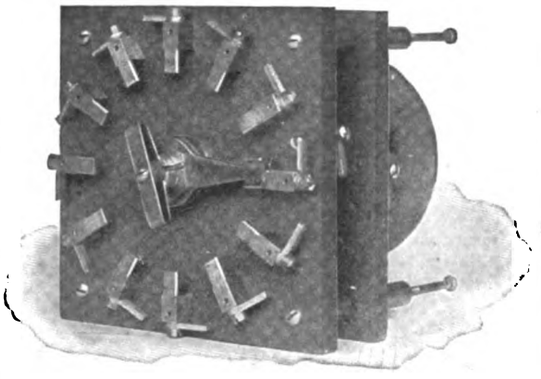
with the flat back to the opening, the fan is ready to run, no other frame work or support being required. Another great advantage of the Triumph exhaust fan is its adjustable self-oiling boxes which are pro-

Digitized by Google

vided with phosphor bronze bearings, not babbitt, cast iron or other cheap bearings, thus securing the best and most durable bearing known to the trade. As the life of a fan depends entirely on the bearings, it follows that the quality of the latter largely determines the value of the fan.

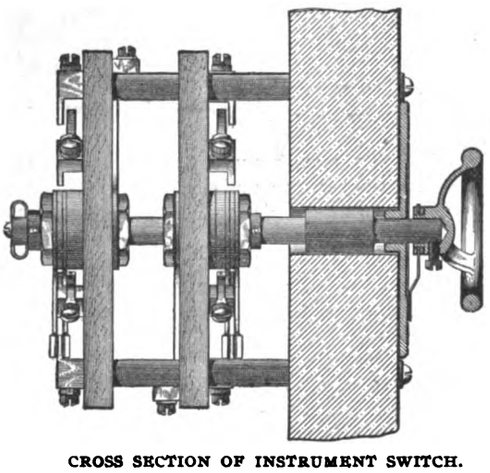
The Triumph fan has a smaller number of blades than is usual in fans of this class, but the manufacturers claim this to be a great advantage as the ingress and egress of air is effected with greater ease than when a greater number of blades is used.

A WATER BLOW FAN.



The makers are so sure of this fact that they warrant the Triumph fan with five or six blades to show a better efficiency than any other fan equipped with ten or twelve blades, or in other words to use less power.

These fans are made for belt service only, as almost all users have power at hand, but if it should be necessary to purchase a separate electric motor, the manufacturers of the Triumph fan state that a first-class electric motor and one of their fans can be bought for fifty per cent. less money than any direct connected fan and motor. The belted combination is also advantageous where extreme heat, acids, steam, etc., will pass through the fan, as in such places it is often inexpedient to use direct connected fans. The Triumph exhaust fan is made by the Specialty Manufacturing Company, Indianapolis, Ind., which is also placing on the market a water blow fan, known as the "Junior," to meet the demand for a good and serviceable fan of this type at a low price. This fan has a ground tool steel shaft and a hard brass bush or bearing, and is guaranteed by the manufacturers to be one of the most efficient and durable water fans ever offered to the trade. The motor and base are enameled in black. It has 13-in. blades of spring brass, nickel plated, and protected with a wire guard, and the motor is equipped with a jet 1-16 in. in diameter, thus insuring economical water consumption. The inlet or jet holder is provided with a thread which fits an ordinary ¼-in. hose coupling, enabling it to be easily and cheaply fitted with rubber hose for service and waste. The fan operates on any pressure from 30 lbs. upward, and weighs 9 lbs. complete.

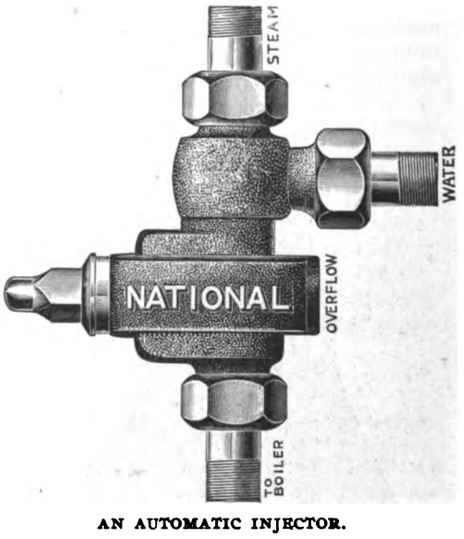


### VOLTMETER AND AMMETER SWITCHES.

The convenience of a voltmeter switch by which one instrument can be connected with any one of a large number of machines or centers of distribution is well recognized, but similar switches are comparatively rarely used with ammeters. Where the full current to be measured passes through the ammeter it is, of course, impossible to equip the instrument in this way, but with ammeters of the low resistance shunt type any number of shunts can be connected with the switch and through it to one instrument. This requires, however, switch contacts of very low resistance, as the e.m.f. across the shunt is extremely small.

Such a switch is that built by the Western Electric Company and known as "Type F," illustrations of which are shown herewith. The high conductivity is obtained by the knife contacts, which are capable of carrying 15 amperes without heating. The positive and negative poles are in two different planes on white marble slabs, both fitted behind the switchboard as the cross section

FRONT AND END VIEWS OF VOLTMETER AND AMMETER SWITCH.



CROSS SECTION OF INSTRUMENT SWITCH.

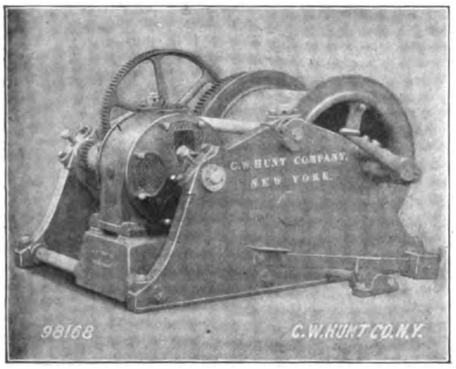
clearly shows, the contacts being rotated by a hand wheel on the front of the board, and the position indicated by an index finger working on a graduated circle. These switches are built for any number of circuits from two up to twelve, and are readily applied to marble or slate switchboards from 1 to 2 ins. in thickness. The space occupied at the back of the board is only 6½ ins. square, projecting 6 ins. from the surface.

### THE NATIONAL AUTOMATIC INJECTOR.

An injector, the starting of which is automatic, requiring only the turning on of the steam, is illustrated in the accompanying figure and is made by the National Injector Co., of 98 Woodland Ave., Cleveland, O. The other strong features claimed for this injector are equally good starting or working when taking water with a pressure or from long lifts or lifting through hot suction pipe and working at unusually high temperatures.

The National injector has no sliding tubes and lime cannot deposit so as to interfere with the range or the perfect working of the injector or prevent the tubes from coming out. As the tubes are not screwed in, they can be put in or taken out without a wrench, thus making it easy for every man to repair his own machine with duplicate parts without returning the injector to the factory.

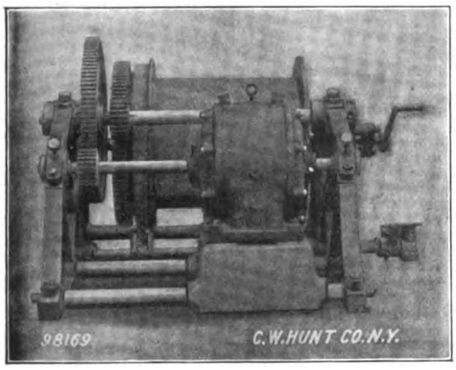
AN AUTOMATIC INJECTOR.



### THE HUNT ELECTRIC HOISTING ENGINE.

The disadvantages of steam hoists for many purposes are only apparent when their performance is compared with that of hoists driven by electric motors. In the large cities on the temporary work of new buildings the cumbersome, noisy and smoky steam hoist with its extremely low fuel economy gives a good opportunity for the introduction of electric hoisting en-

Digitized by Google



gines. Central stations may well look into the matter, as this sort of work would give them quite a profitable load were they to encourage the use of electric hoists among contractors and others now using the older types.

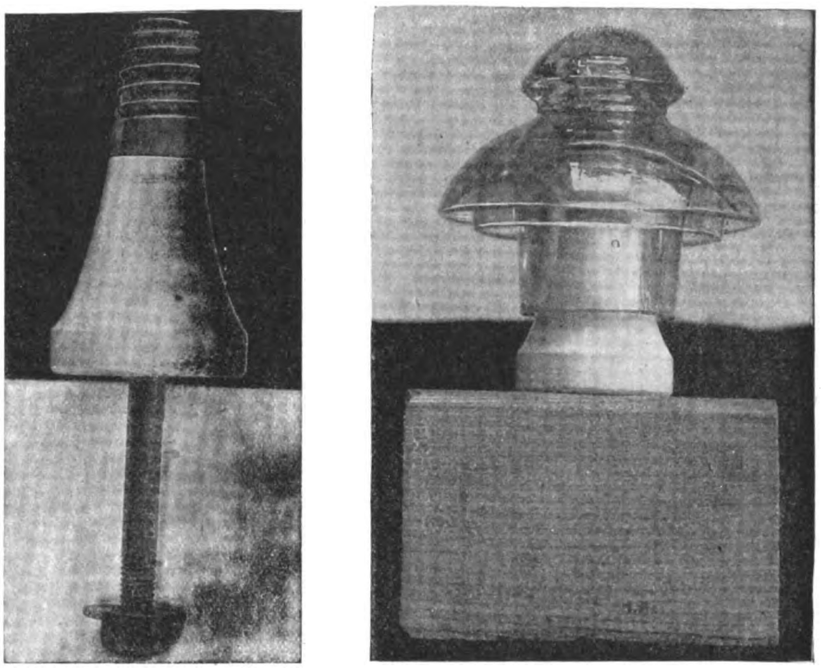
An equipment of this type of remarkably neat design is illustrated in the accompanying engravings. The motor drives the hoisting drum through a double reduction spur gear and a friction clutch which is operated by the upper handle. A band brake is set or released by a toggle joint of the differential type operated by a foot lever. These two controlling mechanisms give a perfect man-

AN ELECTRIC HOISTING ENGINE—SIDE VIEW.

ipulation of the load, the motor running at constant speed whether the load is rising, falling or standing still. The structure of the hoist consists of two solid side frames held together by distance bars. The bearings of the three shafts are let into these side frames and bushed with replaceable phosphor-bronze bushings. The gears are entirely under-hung between the two side frames, and the friction clutch is built so that it introduces no tendency to spread

AN ELECTRIC HOISTING ENGINE—END VIEW.

the frames. The machine shown in the illustration is equipped with the Westinghouse "type C" induction motor for alternating currents, but direct current motors may be fitted, the convenient support on the lower distance bars allowing for the ready fitting of any standard type.



### HIGH TENSION INSULATORS.

The merits and defects of the porcelain insulator have been well shown up by the experience obtained with it during the last two or three years. The most recent designs show great improvements in overcoming the disadvantages of the earlier types.

The accompanying illustrations show the meritorious details of the insulators manufactured by Fred M. Locke, of Victor, N. Y. In order to avoid the strains brought about while cooling through unequal shrinkage of parts of different thickness these insulators are made up of two or three shells, one for each petticoat.

The cut shows the pin on which the insulator is mounted. It consists of a ½ in. galvanized steel bolt with a screw threaded top of wood boiled in paraffine, and a base of porcelain, which extends well up within the inner petticoat of the insulator and increases greatly the arcing distance between the rim of the insulator and the pin, preventing the destructive arcing and consequent burning off of pins, cross-arms, etc., and increasing greatly the voltage which may be carried on the lines.

There is also shown a glass insulator with eaves to carry the water away from the cross arm and a long inner petticoat coming well down over the porcelain base just described. This is designed for 25,000 volts, its diameter being 5½ ins. and weight 3 pounds. Another glass insulator 7 ins. in diameter weighing 5 pounds is put out for potentials from 22,000 to 50,000 volts.

AN IRON PIN WITH WOODEN TOP, PORCELAIN BASE AND GLASS INSULATOR.

### THE ROYAL ELECTRIC COMPANY'S INDUCTOR ALTERNATOR.

The design of machinery in general, and of electrical apparatus in particular, constantly tends toward greater solidity, simplicity, and the elimination of small detail attachments. The alternating-current dynamo is an improvement in this respect over the direct-current, and of the alternating-current types the revolving armature is inferior in this regard to the revolving field, and that in turn is inferior to the inductor type. There are now quite a number of different classes of the latter type, which, simple as it is, gives considerable scope for the ingenuity of the designer, a fact which will be evident from the improvements in the design of the machine of this type built by the Royal Electric Company, of Peoria, Ill.

Of the accompanying illustrations, Fig. 1 shows a 150-k.w. generator assembled. It exhibits the usual features of the inductor type, namely, the absence of all collector rings, brushes or exposed connections of any kind, and the concealment and protection of all parts of the machine, the pulleys and bearings excepted, within the yoke ring, and the end plates fitted to it. Fig. 2 shows the frame of the external stationary armature without coils. From this it is evident that the machine is of that class of inductor dynamos in which both polarities of the rotor are fitted with poles opposed by wound armature teeth, as distinguished from that class in which there is but one ring of armature teeth, the other polarity being a continuous ring, untoothed on the armature side and without poles on the rotor side.

The slots are approximately the same width as the teeth, giving ample room for the armature coils. The external ring is of cast iron, and the laminated teeth are attached to it by means of cast steel end plates of a toothed contour. There are two armature teeth for each pole of the rotor, and the dimensions are so chosen that the reluctance of the magnetic circuit is the same for all positions of the poles.

The space between the two rings of teeth is occupied by the field exciting coil, shown removed in Fig. 3. This has an external diameter smaller than the internal diameter of the armature teeth and fits down between the two rings of poles of the rotor, thus giving it a minimum ohmic resistance and waste of energy per ampere turn. The coil is short and deep—that is, of many layers and few turns per layer. It is

Digitized by Google

wound upon a spool, the cylinder of which is of heavy copper to cut down the inductive rise of pressure on opening the field circuit, the sides of the spool being perforated to allow the ventilation of the field winding by the currents of air set in motion by the poles of the rotor. Fig. 4 shows the frame with both the field and armature windings in place, and the rotor removed. The armature coils are at their outboard ends joined by connectors, and may readily be connected up in series or parallel to give one or more of many different voltages.

Fig. 5 represents the inductor mounted between the bearings on the base of the machine. This rotating element is divided into three parts, one the central cylindrical core and the other two the rings carrying the laminated poles. These three parts are bolted together securely, and by simply loosening the bolts either ring may be removed to get at the corresponding armature windings or to remove the field-exciting coil. The poles are laminated to prevent the foucault currents which would otherwise be set up by the armature teeth.

The division of the armature coils into two separate rings allows the machine to be very simply transformed from a single to a two phase generator. This is accomplished by simply shifting one of the pole rings relatively to the other, so that the poles have a staggered relation, and dividing the circuits of the two rings of armature teeth. One of these then generates an electromotive force displaced in phase from that of the other. The necessary holes are provided in the center core of all machines, so that this change can be quickly made.

The magnetic density throughout the whole circuit is low, no point running above the bend of the magnetization curve. The air gap between the rotating and stationary elements is comparatively large, and although this condition increases considerably the cost of manufacture it has been adopted for mechanical reasons, as well as to reduce the armature reaction and give close automatic regulation without the complication of a rectifier and compound winding. The regulation obtained is within 2 to 7 per cent., depending on the size of the machine.

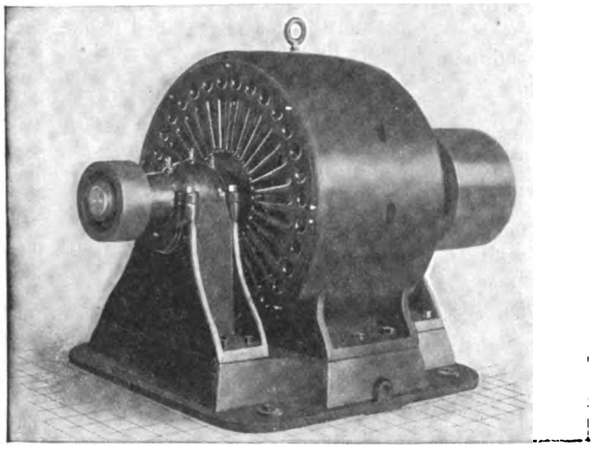


FIG. 1.—A 150 K. W. INDUCTOR GENERATOR.

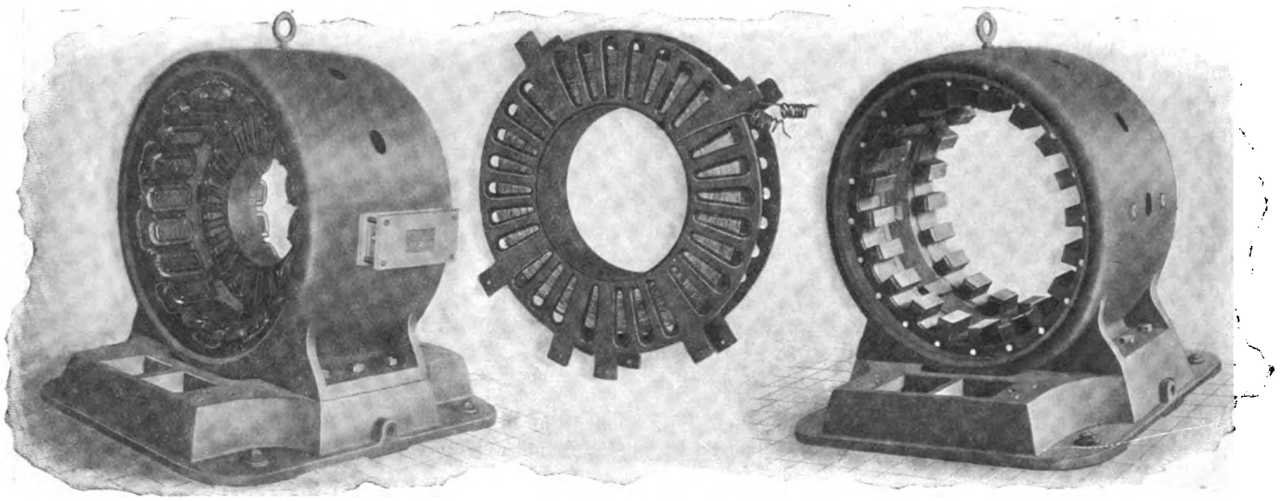

FIG. 4.—FRAME WITH WINDINGS IN PLACE. FIG. 3.—EXCITING FIELD SPOOL. FIG. 2.—FRAME OF EXTERNAL STATIONARY ARMATURE.

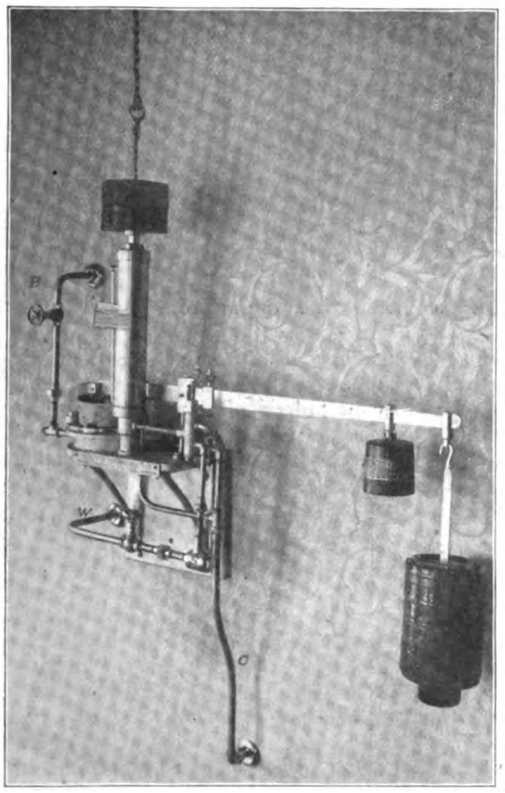
## AN UP-TO-DATE HYDRAULIC DAMPER REGULATOR.



The automatic control of the draft of steam boilers is now recognized to be superior to the comparatively careless control given by the average fireman. A damper regulator that will respond to the slightest variation in the steam pressure is just as essential an adjunct for controlling the work of a boiler, as is the governor for controlling a variable load on an engine. The uniformity in steam pressure and in the temperature of the furnace, which is attained by close regulation through an improved automatic damper regulator, is necessary to the highest efficiency for the boiler. To attempt to economize in fuel consumption or to maintain a uniform steam pressure by manipulating the dampers by hand is as difficult as trying to get a uniform engine speed with the old-style plain throttle valve. The large saving constantly effected in fuel by the use of hydraulic damper regulators is so well established that now it is universal custom among consulting engineers and architects in this country to specify hydraulic damper regulators in boiler plant specifications.

The accompanying illustration shows a Patterson's improved hydraulic damper regulator, an up-to-date machine for handling from one to twenty boilers. All of the parts of the apparatus have been carefully designed from a scientific and engineering standpoint, and it is claimed that for simplicity of construction, compactness, neatness in finish and sensitiveness in operation, it is superior to any yet put upon the market. It is guaranteed that a change of one-half pound in the boiler pressure will open or close the heaviest dampers. It will also give a partial movement to the damper, moving it from time to time in sympathy with the slightest change in the steam pressure.

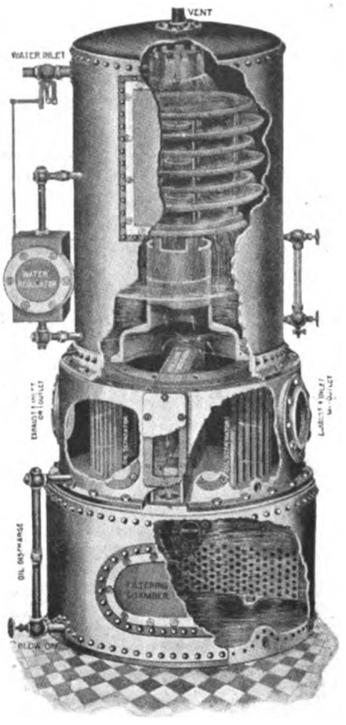
In the Fig. B is the steam pressure con-

Digitized by Google

nection taken from the boiler which acts on the diaphragm and causes the diaphragm lever to move upward or downward less than one-sixteenth of an inch. W is the water supply for motor, S is a strainer to prevent floating matter from getting to the damper water valves. By unscrewing the cap at the end of this strainer foreign matter can be removed without breaking

HYDRAULIC DAMPER REGULATOR.

pipe connection. The overflow pipe for carrying off the discharge water from motor is shown at O.



The apparatus is made by The Patterson Damper Regulator Company, of Baltimore, Md., and was designed by Mr. George F. Patterson, the President of the company, who has had wide experience with damper regulators.

### THE COOKSON IMPROVED FEED-WATER HEATER, PURIFIER, FILTER AND OIL SEPARATOR.

Unfortunately for steam users, the steam boiler is a mammoth still. Every pound of water that enters it comes in in liquid form and goes out as a vapor, leaving behind all impurities, oil, lime or whatever else may have been in the feed-water. Any impurities which are in the feed-water thus accumulate and eventually result in the destruction of the boiler. The purification of the feed-water is therefore a matter of most vital importance.

A feed-water purifier, which is also a heater as well as an exhaust steam oil separator, is manufactured by the Bates Machine Co., of Joliet, Ill., the latest improved type having many interesting details. One of these heaters rated at 500 h.p. is shown in the accompanying illustration, parts being indicated broken away to show the internal construction.

The structure is built up of cast iron and steel plates, with parts interchangeable for easy duplication and assembled in such a manner that it can be taken entirely apart with a monkey wrench. The top section is of steel plate, the centre section of cast iron in a single piece including the shell, top and bottom heads and internal parts, while the bottom section or filtering chamber is made with

THE COOKSON FEED WATER HEATER.

a heavy cast iron bottom and a cast ring at the top, to both of which the steel shell is riveted. In heaters of smaller sizes than 300 h.p., this lower chamber is built of cast iron. The three sections are securely bolted together with special gaskets.

The operation of the heaters is as follows: Exhaust steam may be introduced from either side and discharged from the other. Steam entering from the right side, as shown, strikes the V-shaped oil separating plates, which purify it, the ribs on these plates separating the water and oil from the steam. The latter then flows over the central hollow partition and down through the V-shaped plates on the other side and out through the exhaust outlet to the atmosphere or the heating system. Thus all steam passing through the heater is purified of oil, but only that needed for heating feed-water is taken off from the main flow, the balance passing straight through without being cooled, so that its heat may be available for other purposes.

At the top of the heater is a vent pipe for carrying off the air and gases relieved from the water in heating. The cold water supply from the city main or tank enters in a spray and condenses the steam, forming a partial vacuum, which draws the required amount of steam to heat the water up the large tube in the centre. But only that amount of steam necessary to heat the water comes in contact with it, the balance passing on in its dry purified state to the heating system or atmosphere.

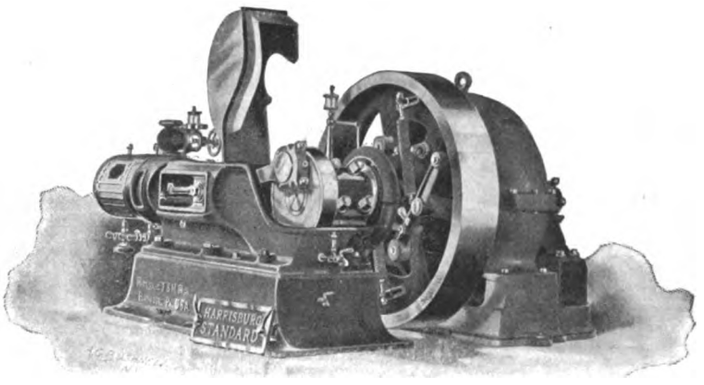
The water supply is connected to the water inlet valve which is opened and closed by the water regulator, maintaining at all times a uniform water level in the heater. The water entering the spray box at the top of the heater overflows in a spray to the pan below, and the overflow from this pan sprays into the next. The water passes from this second pan through its centre to the next pan below, and so on down. The last pan is bolted to the top of the exhaust tube. The spray falls from this pan to the water level below. All pans, with the exception of the bottom one, are loose, made in halves, and are readily removable from the manhole. The object of these pans is to catch the lime deposit.

The water, having been heated in direct contact with the steam, enters the hollow partition across the exhaust tube and discharges into the filtering chamber below, where the remaining impurities in suspension are removed by filtration. It is obvious that the water in the hollow partition is kept at the boiling point by having steam on both sides of it all the time. The filtering chamber is filled with coke or excelsior and at the back of this chamber is a perforated plate preventing the filtering material from passing through to the pump. A strainer plate is also placed at the blow-off connections. The two oil separating chambers are connected by a small opening through the hollow partition at the bottom, through which the oil and condensed water drain from one chamber to the other. All chambers are provided with large manholes and handholes for cleaning. The manhole in the upper chamber is hinged, making it an easy job to open the heater for examination and the removal of the lime catching pans. Exhaust flanges, suction and return flanges are also removable, and a heater will be furnished with any sized flanges desired up to the capacity of the heater. The water inlet valve is balanced, having a double valve, and is made entirely of brass. The water regulator contains a seamless copper float, and all connections, stuffing boxes, etc., are of brass, to prevent corrosion.

The Bates Co. has just issued a large lithograph of this improved Cookson Heater, which will be mailed to any address on application.

### THE HARRISBURG STANDARD SELF-OILING ENGINE.

The name of the Harrisburg Foundry & Machine Works, of Harrisburg, Pa., has long been a familiar one to steam users, through their engines, known as the "Ide" and "Ideal." More recently a new type known as the "Harrisburg Standard" has been evolved from the experience had with the other engines, and these three engines may now be known in their order as good, better, best, the standard embracing all the good points of the others, as well as some of its own.



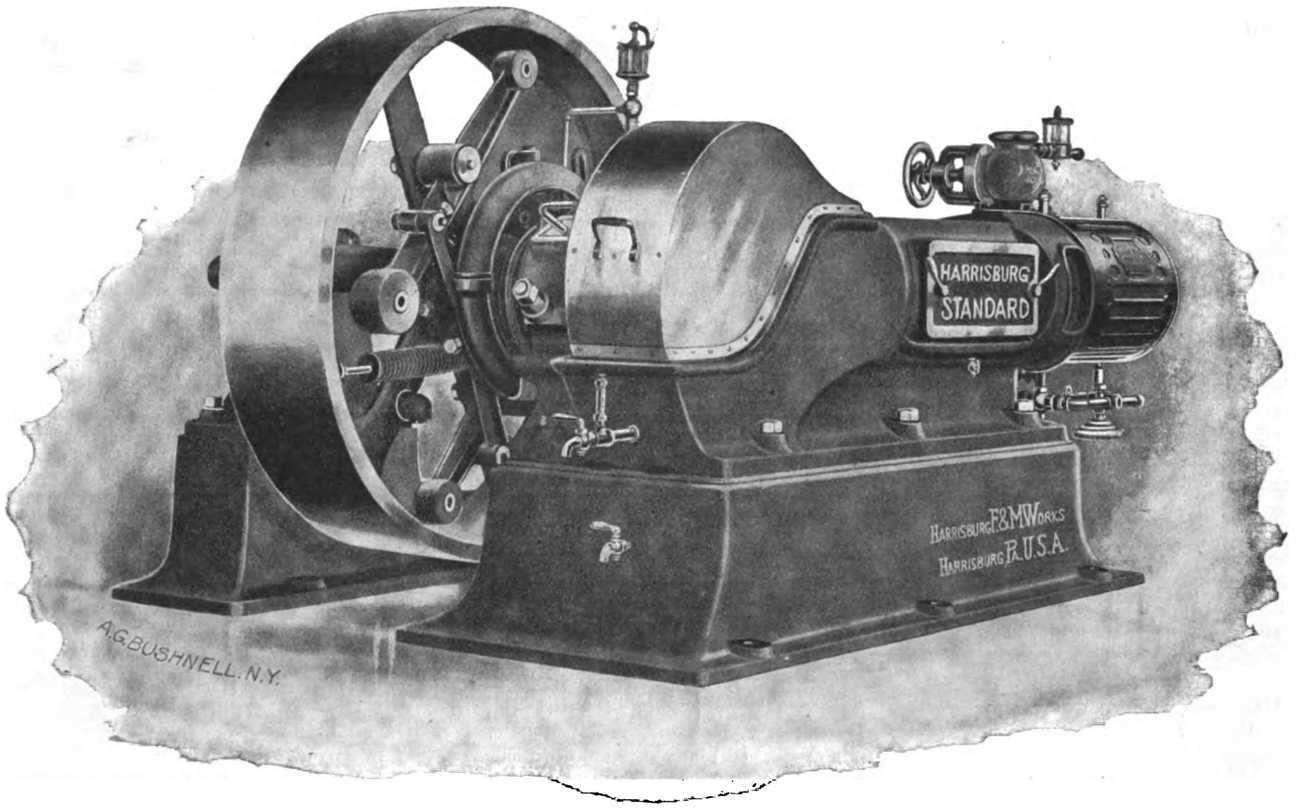
The "Harrisburg Standard System" of

Digitized by Google

engines includes simple engines, tandem compounds with single valves, and simple, tandem and cross-compound engines with four valves, medium and slow speed, the latter of the Corliss rocker type.

A peculiar feature of these engines is that they are all constructed with side cranks, requiring only two main bearings, whether designed for direct coupled or belted service, and thus many of the disturbing elements (excessive friction and bad alignment) that attend the operation of three or four bearing engines are removed, the friction in these machines being in many cases as low as 2 per cent.

The simple engine, which is made in sizes up to 36 ins. in diameter and stroke, is compact and graceful in design, as will be noted by the accompanying illustrations. Its salient features include an automatic oiling chamber, by which the crank disc, connecting rod and cross head are enclosed, being provided with a hinged hood which may be turned back, and a plate on the side which may be easily removed for inspection and adjustment of the reciprocating parts. By the revolution of the disc in oil, the rim of the disc touching its surface, it is splashed over the wearing parts including the cross head, and by means of a lateral internal trough across the inside of the cover, a large portion of the oil is led out through a pipe and directed in a stream upon the main bearing adjoining the crank disc. The lubrication of the crank pin is accomplished in a very ingeniuos manner, by means of an annular chamber, recessed in the face of the disc around the main shaft next to the main bearing, from which a diagonal hole is drilled through the disc, coming out about the middle of the surface of the crank pin, so that by centrifugal force a constant volume of oil is provided for its lubrication, completing the circulation from the reservoir to cross head, main bearing, crank pin, and finally draining to reservoir again.



THE HARRISBURG ENGINE COUPLED TO A GENERATOR.

The patented governing mechanism is also a special feature of these engines, and is of the fly wheel, technically termed centrally balanced, centrifugal-inertia type; it is sufficiently sensitive to regulate to one-half of one per cent. in load variations from zero to 125 per cent. Rollers are provided in the governor bearings.

The pillow blocks of the crank shaft have the covers fitted in a diagonal position, and the shell is provided with an oil chamber with recesses for the oiling chains. The engine frame is extended with a stuffing box exposed in such position as to provide for constant and easy access, its purpose being to prevent the water of condensation from getting into the oil supply should a leak occur. The oil is prevented by a guard from getting on the piston rod.

In the process of manufacture, the pistons, piston valves, pins and other special parts are all ground to an accurate fit, and micrometer records made of each piece, so that any part of an engine can be duplicated at any time after it leaves the works. The crank disc, including the pin, is cast in one solid piece of steel, the mould being placed in a horizontal position, with the pin down, producing a dense metal in the pin. This is afterwards turned and properly fitted, when the disc is shrunk on the shaft and keyed in position.

Every engine is thoroughly tested be-

THE HARRISBURG ENGINE, SHOWING GOVERNOR AND OILING CHAMBER.

Digitized by Google

fore it is shipped, and for this purpose metal bed plates on heavy masonry are provided, with suitable channels for clamping the engines in place. When in position for testing, the engine bed is supportetd on metallic points, and the machine is first run for adjusting the governing and valve mechanism. Next, the fiy wheel is accurately corrected to a running balance, and finally each engine is so perfected that it is run upon the metallic points without any fastening.

Although the "Harrisburg Standard Engine" was designed but a year ago, there are already in operation nearly one hundred of these machines with orders for thirty more in the shop.

The Harrisburg Foundry and Machine Works also manufacture road rollers to a considerable extent, as well as tubular boilers, and in order to meet the growing demands of their trade, are erecting extensive new shops at West Harrisburg, for which the walls and stacks are nearly up. The ground dimensions of the main building are 300 ft. x 140 ft., and it is intended that all departments, including the foundry, shall be under one roof. The designs show that this is to be an up-to-date establishment in every particular, and the equipment will embrace the latest improved machinery suited to this class of work.

The power equipment will consist of two "Standard" four-valve engines, direct coupled to two direct-current generators, each of about 75 kw. capacity. The different sections of shafting are to be driven by electric motors, and there will be electric cranes and hoists, together with a trolley shifting locomotive, which will communicate with the different departments outside of the building.

The affairs of the company are under the management of Mr. W. R. Fleming, who was induced to give up his engineering business in New York for this purpose and who has had much to dó with the designing of the "Standard' engine. Mr. Fleming took charge of the company's affairs January 1st, 1898, since which time the output of the establishment has shown an increase of 45 per cent. over the previous year.

## OBITUARY.

CAPTAIN SAMUEL TROTT, a well known inventor and expert in the laying and repairing of submarine cables, died of heart disease in Florida, March 11th, at the age of sixty-seven years. Captain Trott was born in England and took to the sea at the age of seventeen, becoming a master at twenty-seven. He had command of the cable laying steamer Faraday from 1874 to 1880, during which time he laid several trans-Atlantic cables and made many remarkable repairs in mid-ocean.

Captain Trott assumed command of the cable repairing steamer Minia in 1880, and retained the command until his death. He was the joint inventor of a new type of deep sea cable, and was the sole originator of an electric grapnel, which is now in very general use, the electric mechanism being such that a bell is rung on the cable steamer whenever the prongs of the grapnel come in contact with the cable. Just previous to the outbreak of the Spanish war he laid the cable connecting Key West and the Dry Tortugas for the United States government.

EDWARD SMITH TABER, president and treasurer of the Morse Twist Drill and Machine Company since 1868, passed away at his home, in New Bedford, Mass., on the tenth day of March, 1899, aged 73 years.

Called to the position of president when the company was in its infancy, he filled it long and faithfully. While adverse to taking upon himself the credit for this success, his associates are most glad to attribute a large measure of the general prosperity of the company to his untiring efforts, his faithful activity and his skill as a director.

His services were in demand by other business interests of New Bedford, and for many years he served as a trustee and member of the board of investment of the Institution for Savings, and for the past eighteen years was a director of the First National Bank, in addition to serving for the past nine years as its president.

A type of the older school of business men, whose very presence inspired confidence, Mr. Taber was held in the highest respect and esteem not only by those associated with him, but by the community at large, and he made himself a power in New Bedford's general business circles and exercised that power with conservative judgment.

## PERSONALS.

MR. EDWARD L. COOLEY has been appointed manager of the Boston office of the C. & C. Electric Co., 19 High Street, Boston, Mass., the position formerly held by Mr. William F. Palmer. Mr. Cooley was formerly located in Boston, but has been for a number of years in Philadelphia with the General Electric Co. He has made a large number of friends, who regret to see him leave.

MR. GEORGE W. BROWN has retired from the general management of the Belknap Motor Company, Portland, Me., to give his whole attention to the management of the Cumberland Illuminating Company, of North Gorham, Me. Mr. Brown will be succeeded by Mr. E. E. Furnald, who has been so long connected with the Belknap Company as superintendent.

MR. F. D. KILLION, for the past twelve years connected with Messrs. Walker & Kepler, of Philadelphia, in the capacity of a traveling salesman, has accepted a similar position with the Franklin Electric Supply House, of Philadelphia, and has already entered upon his new duties. Mr. Killion's territory will be the States of New York, Pennsylvania, New Jersey, Delaware, District of Columbia and eastern Ohio. As Mr. Killion has been in the electrical business since 1881 he naturally has a great many friends in the business who will be glad to see him in his new position, and will undoubtedly favor him with a fair share of their business.

## TRADE PUBLICATIONS.

THE "PAN-AMERICAN" is a new weekly journal, published in Buffalo, N. Y., that will be devoted to the affairs of the Pan-American Exposition to be held in Buffalo in 1901.

THE ROBBINS & MYERS COMPANY, of Springfield, Ohio, has issued, besides its regular catalogues of its Standard ceiling and "Search-Light" fans, a book of testimonials reproduced by the photo-engraving process from the actual letters of users of the Standard fans.

THE WESTERN ELECTRIC COMPANY, Chicago, in addition to its forty-page fan motor catalogue, is issuing a series of four-page bulletins descriptive of the different styles of fans. Bulletins 16 F, on W. E. standard ceiling fans and 17 F, descriptive of desk and bracket fans for direct currents, have just been issued.

"THE HORSELESS AGE," the journal representing the automobile industry, will hereafter appear as a weekly instead of, as formerly, a monthly paper, the growing importance of the business it represents having warranted this change. The offices of the paper have also been moved to the American Tract Society Building, of New York City. The "Horseless Age" is a publication of no little value and interest to those electrical engineers who are interested in electric vehicles.

## BUSINESS NEWS.

G. W. HOFFMAN, of 295 East Washington Street, Indianapolis, reports an order for a carload of the U. S. infallible metal polish paste for export.

THE SMITH & HEMENWAY COMPANY, of 20 Warren Street, New York, has bought the hardware branch of the business of the Maltby-Henley Co.

THE WARD LEONARD ELECTRIC COMPANY, Bronxville, N. Y., profiting by its experience in the construction of enamel rheostats, has engaged in the manufacture of enameled iron signs.

THE KEYSTONE ELECTRICAL INSTRUMENT COMPANY, of Philadelphia, has recently opened a New England office at 170 Summer street, Boston, which will be in charge of Mr. F. B. Smith.

MESSRS. BRYAN & HUMPHREY, the well known consulting mechanical and electrical engineers of St. Louis, Mo., have moved their offices from the Turner building to the Lincoln Trust building in that city.

PROFESSOR J. W. TROTTER has placed with Messrs. Goldmark & Wallace, of New York, the exclusive right to handle his commutator compound. They will mail samples free of charge to any address and all orders will receive prompt attention at their hands.

THE WESTERN ELECTRIC COMPANY, Chicago, prior to the recent rise in copper, greatly increased its stock of rubber-covered wire, and is prepared to meet the demand of the spring trade with reasonable prices and prompt shipments.

THE CUTLER HAMMER MANUFACTURING COMPANY., of Chicago, has opened an eastern office at 136 Liberty Street, New York City, where it will carry a large stock of rheostats. The office will be in charge of Mr. W. H. McGregor.

THE KNAPP ELECTRIC & NOVELTY CO. has moved from its former address of 47 Warren Street to a new building at 125 White Street, New York City. The facilities for turning out work in the new location are practically double those in the old.

A NEW MICA FACTORY.—Eugene Munsell & Company, of New York and Chicago, have recently determined to establish a mica factory in Ottawa, Ontario. The plan is to forward the mica direct from the mines to the new factory, where it will be treated, sorted and prepared for shipment to New York.

CREOSOTED WOOD PIPES make good conduits for drawing in underground cables. They are not brittle, and their deterioration is astonishingly slow. The Michigan Pipe Company, Bay City, Michigan, makes such ducts in convenient 8-foot lengths, treated by the Bethel process.

JAMES G. BIDDLE, formerly of 910 Drexel Building, Philadelphia, Pa., has moved his office to Room No. 1088 of the same building. Fortunately for all interested in electrical instruments, the new location is so near the old one that there will be no difficulty or delay in finding Mr. Biddle or reaching him by mail.

DISSOLUTION OF PARTNERSHIP.—The partnership heretofore existing between Messrs. John Y. Parke and Thomas J. Allen, under the firm name of John Y. Parke & Co., of Philadelphia, was dissolved on March 10 by mutual consent. The business will be continued by Mr. John Y. Parke under the old title.

THE DAYTON GLOBE IRON WORKS COMPANY, Dayton, Ohio, is meeting with exceptional success with its gas engine for electric lighting purposes. Many testimonial letters have been received from users of its engines and they all unite in agreeing that

Digitized by Google

the engine is giving wonderful regulation and efficiency, and general satisfaction is universally expressed.

CHAPMAN VOLTAGE REGULATOR.—Among the recent sales by the Belknap Motor Company of Portland, Me., are a No. 1 regulator for a General Electric alternator in the plant of the Montmorency Electric Power Co., Quebec; a No. 2 alternating regulator for the Fort Wayne Bamp Co., Ft. Wayne, Ind., and a No. 1 alternating regulator to J. S. Viles, Middlesex, Vt.

THE WIRT DYNAMO BRUSH has been reduced in price, as is shown by a new list of the manufacturer, Mr. Charles Wirt, 1028 Filbert Street, Philadelphia, giving a general reduction in the prices of all brushes. These changes, at a time when the cost of metals is moving in the other direction, are warranted by the reduced cost of manufacture consequent upon the increased scale of operations.

MESSRS. EYANSON & ARMPRIESTER of Philadelphia have shipped three large switchboards to London, England. These boards are a part of the equipment furnished by Messrs. Eyanson & Armpriester for the large electric fountain being built for the Crystal Palace Park Co. from designs by F. W. Darlington. The same firm is at work on switches to be shipped in a few weeks to Milan, Italy.

THE PITTSBURG TRANSFORMER CO. reports a very rapid increase in the demand for its transformers, its business during the first seventeen days of March being double that during the months of January and February combined. The popularity of this transformer is not local, as is shown by shipments during one week to California, the Dakotas, Illinois, New York and Maine, besides those to nearby territory.

THE STANDARD THERMOMETER AND ELECTRIC COMPANY, Peabody, Mass., has opened an office in the Washington Life Building, Broadway and Liberty Street, New York, under the management of Mr. Wm. J. Bramhall. The company has also opened a Chicago office at 313 S. Canal Street, Chicago, which will be in charge of Mr. Geo. H. Stout, who has been for many years identified with the arc lamp business of the West.

AN ELECTRIC GAS IGNITER for Welsbach burners is the latest thing put on the market by the Electric Appliance Company, of Chicago. The convenience of the electrical igniter is even greater on the Welsbach flame than on the ordinary fish tail gas jet, as the Welsbach must be lighted from above, a position often difficult to reach, and when lighted with a match starts with a small explosion. The new electrical igniter is fitted with a key extending downward, making it a more handy device than even the usual chains.

THE CENTRAL ENERGY INDEPENDENT TELEPHONE APPARATUS, made by the Stromberg-Carlson Telephone Mfg. Co. of Chicago, is in such great demand that the company will soon enlarge its factory to more than double the present capacity. Some switches under construction by this company, which compare favorably in magnitude as well as other features with the largest and best Bell boards, are two with a capacity of 5000 subscribers in St. Paul and Minneapolis, and one with a capacity of 1500 subscribers for Waco, Texas.

THE FEEDER AND HIGH TENSION CABLES for the mammoth system of the Third Avenue Traction Company of New York City have been ordered in part, contracts aggregating $400,000 having been placed. These include 300,000 feet of one million c. m. paper insulated Roebling cable and 80,000 feet of rubber covered 0000 three conductor cable for the high tension three-phase system. The orders for the high tension cable were divided among the General Electric Co., the Safety Insulated Wire & Cable Co. and the John Roebling's Sons Co.

A REMARKABLE ENGINE RECORD.—The Murray Iron Works of Burlington, Iowa, had one of their 24x48 Sioux Corliss engines at the Omaha Exposition that made a run probably without precedent in stationary engine practice. It was operated 24 hours per day for 50 days, or 1200 consecutive hours, with only one stop of 30 minutes. For 80 days it ran 23 and 24 hours per day, as the authorities desired, and its total run was 2983 hours in 155 days, an average of more than 19 hours per day, from the dull days at the start to the rush at the finish.

THE "CRITERION" ACETYLENE GAS GENERATORS are meeting with a constantly growing demand, according to J. B. Colt & Co., 3-7 West Twenty-ninth Street, New York City. They report a recent order for sixty of these machines to be shipped abroad and an increasing demand generally throughout this country. The "Criterion" meets the approval of every prominent fire insurance board of underwriters in the United States, and embodies in its design and construction features that insure the most desirable results in the use of acetylene gas for household and commercial purposes.

JAMES LEFFEL & COMPANY, of Springfield, Ohio, manufacturers of water wheels and automatic engines for electrical purposes, state that they have been compelled recently to double their foundry capacity to enable them to meet their largely increased trade. They have recently installed a new three-motor traveling crane of 50 tons capacity and a new G. E. generator for power and lighting purposes. Leffel water wheels are now known and used all over the world and enjoy a reputation second to none. The increased trade of this company will be noted with satisfaction by its many friends.

MR. W. G. AMOS, Chicago representative of the Murphy Iron Works, of Detroit, Mich., has recently closed an order for four Murphy automatic smokeless furnaces to be installed in the Western Electric Company's plant in Chicago. It is stated that these furnaces are to supersede another type of furnace manufactured by another company. The company claims that the superiority of the Murphy furnace has been repeatedly demonstrated many times in competition with other makes and that the purchasers of the Murphy furnace are always assured that they have obtained a most complete, modern and economical furnace.

THE OUTPUT OF WESTINGHOUSE OIL INSULATED TRANSFORMERS.—The growth of the demand for the Westinghouse Company's transformers of the oil insulated type has been something phenomenal. During the year 1895 there were installed transformers with a capacity aggregating 560 h. p., 1896 17,000, 1897 30,633 and 1898 90,000 h. p. The total output up to January 1st, 1899, aggregated 146,540 h. p. It is expected that the present year will show a record for which the previous years will present no parallel, as one single order has already been placed for 17,500 h. p. in seven transformers rated at 2500 h. p. each, larger than anything heretofore ever constructed.

THE HOPPES MANUFACTURING COMPANY, 67 Larch St., Springfield, Ohio., is building two live steam purifiers, each of 250 h. p., for the Deering Harvester Company, Chicago, and has sold in addition three 1000 h. p. purifiers, to be installed in the Kings County Light and Power Company's plant and three 625 h. p. to the Louisville Street Railway Company, Louisville, Ky. The orders from the Deering Harvester Company and the Louisville Street Railway Company are both repeat orders. The Hoppes Manufacturing Company has recently, through its London agent, Robert W. Blackwell, 39 Victoria St., Westminster, London, sold a 625 h. p. purifier and two six-inch vertical separators.

THE GARTON-DANIELS ELECTRIC COMPANY, Keokuk, Iowa, has issued an illustrated catalogue of various types of Garton-Daniels lightning arresters and the auxiliary devices, such as kicking coils, etc., to be used with them. The Garton-Daniels Co. claims that the usual winter dullness has been conspicuous for its absence during the season just closed, owing to the receipt of many large orders for export. In January nearly 80 per cent. of the company's shipments have gone abroad.

The company has also doubled its force in order to keep pace with the spring demand for its goods, but still finds that it is shipping faster than it is manufacturing, and this in spite of the fact that it had on hand at the beginning of the season twice as large a stock as ever before. Additional force will be employed, however, so that all orders will be filled with the usual promptness.

# A COMMUTATOR NECESSITY.

**The Only Article that will Prevent Sparking.**
**Will keep the commutator in good condition and Prevent Cutting.**
**Absolutely will not gum the brushes.**
**It will put that high gloss on the Commutator you have so long sought for.**

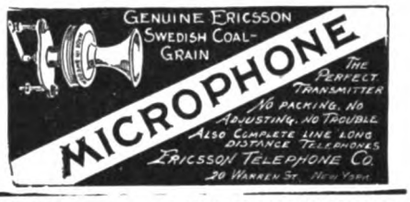
THE CLING-SURFACE MANUFACTURING COMPANY, Buffalo, N. Y., is to be congratulated on the results of tests recently made by Prof. R. C. Carpenter on belts treated with Cling-Surface. The tests were made on the belt-testing machine of Sibley College to determine the horse power which a given belt would transmit without excessive slip with different initial tensions. One 4-in. belt was tested before and after treatment with Cling-Surface. The results showed that with Cling-Surface the horse power which could be transmitted was greater with the lower values of initial tension than with the higher, showing that initial tension, with its resulting strain on journals, wear and tear of belts, etc., is absolutely unnecessary in belts treated with this compound.

THE AMERICAN DISTRICT STEAM COMPANY, of Lockport, N. Y., has contracted for a large extension of the steam mains of the Danville, Ill., Gas, Electric Light and Street Railway Co. The experience of the latter company in the sale of exhaust steam for the past four years has been very satisfactory, so that it is ready to respond to the demands of people for an extension of its heating district to parts of the city not now reached. The Wilkinsburg Electric Co., near Pittsburg, Pa., has also contracted with the American District Steam Co. to lay more than two miles of steam mains for heating the town with exhaust steam. The district to be heated consists mostly of fine residences, which are now being heated with natural gas. The company expects to compete successfully with the natural gas supply.

THE SIXTH ANNUAL REPORT of the Board of Electrical Commissioners of South Norwalk, Conn., has just been issued. It will prove of special interest to towns considering the question of establishing their own particular lighting system. It gives in detail the complete cost of the installation, together with detailed statement of the running expenses. So many indefinite and vague statements are made in regard to the cost of running municipal plants that the clear, detailed and reliable report of South Norwalk will be particularly valuable. A good word is said for the Watertown engines and boilers, manufactured by the Watertown Engine Company, of Watertown, N. Y., and the Siemens & Haske electrical apparatus, which form important features in the new plant.

A GOOD INDICATION OF PROSPEROUS TIMES.—The Bullock Electric Manufacturing Company moved into its Norwood plant in December, and at present, although increased facilities have more than trebled its output, it has so much work ahead that it has recently begun working night and day. When this firm had its factory at Hunt and Broadway, Cincinnati, it was recognized as one of the large electrical establishments of the country. The Bullock Company states that its new plant at East Norwood, Ohio, is, next to those of the General Electric Company and the Westinghouse Electric and Manufacturing Company, the largest electrical establishment in America, and that no plant is as well equipped with facilities for turning out work and modern conveniences in machine shop practce. All the machine tools are driven with individual motors, and the entire absence of belts and shafts makes it a novel factory, which is well worth a visitor's time to inspect, even if he is not especially interested in machine shops.

THE "NEW STANDARD" DRY BATTERIES.—The United States navy has a way of getting the best there is on the market, or if this does not meet its requirements, of getting manufacturers to make something that will, unless it is a physical impossibility. Just one year ago the navy asked Mr. William Roche, 259 Greenwich Street, New York City, for quotations on a special primary cell for gun firing, etc. The requirements were an e. m. f. of 1.40 volts and an internal resistance less than 3 ohms. The cell designed to fill these specifications has since become known as the "Navy Special." The require-



THE CROSS OIL FILTER

actually reduces oil bills 50 per cent. or more. Sent on approval. Capacities ranging from 3 to 120 gals. per day. Used in 18 countries. It is specially adapted to Electric Light and Power Plants. Established 8 successful years.

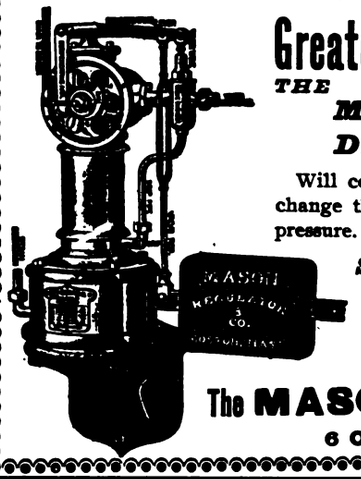
BAKER & CO., NEWARK, N. J.
New York Office, 120 Liberty Street.

FLICKERING of lights usually occurs when the station is being crowded. It is self-evident that this flickering is caused by the slipping of belts, and as a belt full of CLING-SURFACE runs steadily and positively beyond all possibility of slipping, the importance of this fact can be readily seen.

CLING-SURFACE MF'G CO., 188-194 Virginia St., Buffalo, N. Y.



Digitized by Google

ments have since been raised to a pressure of 1.47 volts, with an internal resistance not more than 0.3 ohm. Mr. Roche claims, however, that the cell as now made will give 1.53 volts and has an internal resistance less than 0.12 ohm. The value of such a cell for telephone and other purposes is obvious. On May 1st Mr. Roche's place of business will be moved to 42 Vesey Street, New York City.

THE INTERNATIONAL CORRESPONDENCE SCHOOLS, of Scranton, Pa., are doing a work the magnitude of which is quite astonishing. Instruction is now given in 52 engineering trades and professions, as well as in the elementary branches of business college work. Seventy-five thousand students have been enrolled, over 40,000 of whom are now studying. These students represent over 250 trades and professions, and reside in 65 different countries. There are 14 schools, among which are those of mechanical engineering, steam engineering, electricity, mines, architecture, etc., known collectively as "The International Correspondence Schools." They are owned by "The Colliery Engineering Company," proprietors of "The Colliery Engineering and Metal Miner," a publication from the educational department of which the schools sprang. Over 1,000 persons are employed in the instruction and business departments of the institution, whose success marks one of the most remarkable educational advances of the nineteenth century.

THE LIBERTY LAMP COMPANY, which has removed from its old location in Boston, to Malden, Mass., has now largely increased facilities for manufacturing incandescent lamps. The company, which was then a partnership composed of Mr. E. McOuat and Mr. W. W. Scott, started in business in the Fall of 1897 in Boston, but owing to the increased demand for Liberty lamps found its facilities inadequate to supply the trade. In November, 1898, it moved to Malden, Mass., where it is at present located, and has facilities for an output of 5,000 lamps per day. Its success in business can be largely attributed to the long and varied experience of both the gentlemen mentioned in the manufacture of incandescent lamps. Mr. McOuat first started in with the old United States Co. in 1880 with Edward Weston, afterwards being connected with the Sawyer Mann Co. in New York, and also the Westinghouse Co. in Pittsburg and the Beacon Lamp Co. of Boston. Mr. Scott started with the Westinghouse Electric Co. of Pittsburg in 1885, and after seven years severed his connection with that company and came to the Beacon Lamp Co. of Boston, Mass.

THE DEMAND FOR FILER & STOWELL ENGINES has become so great that arrangements are now being made to double the capacity of the Filer & Stowell Company's foundry at Milwaukee, so as to get out the necessary castings to keep all of the tools in the machine shop running day and night. The engine orders now on this company's books are sufficient to supply its engine departments with work for the next six months. Among the most prominent engines ordered may be mentioned: A 2000 h. p. cross compound, to be shipped to the home of the Corliss engine, Providence, R. I., for the Union Railroad Company of that city. The fly wheel of this engine is to weigh 100,000 lbs., and to have a cast steel ring 6 inches thick shrunk on the rim. This ring will be 24 feet in diameter, made in one piece, and must be shrunk on after the wheel is in position. Another 2000 h. p. cross compound is now under erection for the Armour Elevator Company of Chicago. Of cross compound engines rated at 1000 h. p., one has been ordered by the Edison Electric Light & Power Company of Erie, Pa., and two, which are to furnish the power for the generators at the central station of Armour & Co., are now under construction. These last two make in all ten engines which Armour & Co. have ordered from this company within the last two years. Besides the above the Filer & Stowell Company has received within the past sixty days orders for 26 large engines, two of which are to go to Huntsville, Ont., one to the city of Vera Cruz, and eight to Mexico.

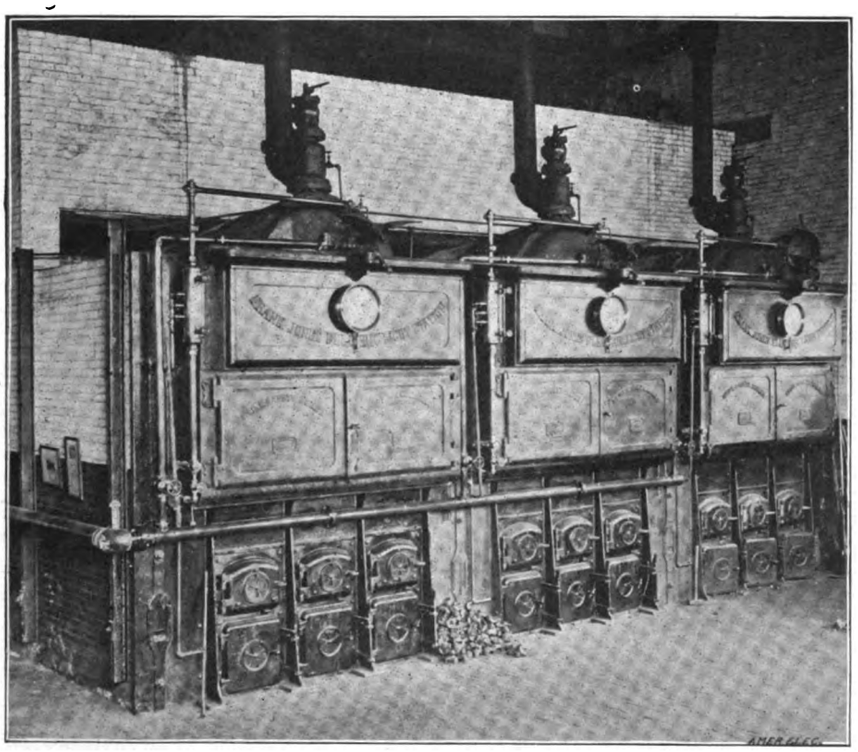
# American Electrician.

Vol. XI. New York, May, 1899. No. 5.

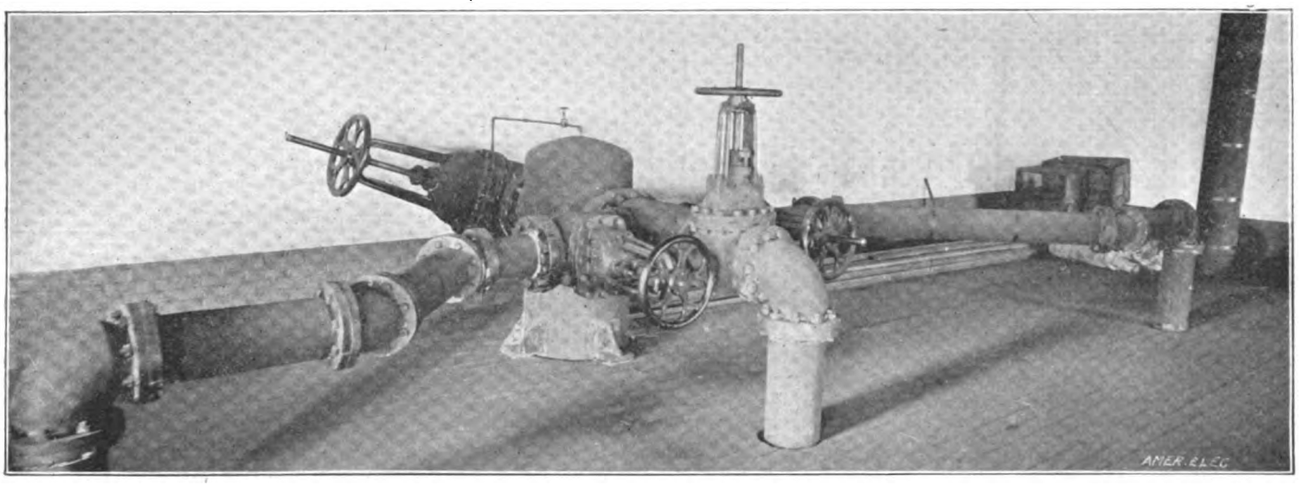


## A PRIVATE CENTRAL STATION.

### A MONOCYCLIC ISOLATED PLANT.

There are in this country, notably in the large steel works of Western Pennsylvania, several isolated plants supplying considerable districts and therefore necessarily running on central station lines, that is, with high tension alternating and series arc apparatus. There is, however, one isolated plant in the country which is even more nearly identical with the typical central station. It stands alone entirely removed from its loads, which are scattered and distant from it several miles in various different directions. Its distribution is over pole lines following the public streets, just as do the pole lines of any quasi-public central station. The plant referred to is the Frank Jones Electric Light Station of Portsmouth, N. H. Its load consists in the main of two large hotels—one a seaside summer resort—a brewery and the home and stock farm of the owner of all the property, whose name is incorporated in that of the plant. The station, while it is not new, has several very interesting peculiarities, which make a description of its general design and an account of its operation of interest, as does also the fact, well known throughout that part of New England, that nothing is too good for the Hon. Frank Jones.

THE THREE MAIN ENGINES.



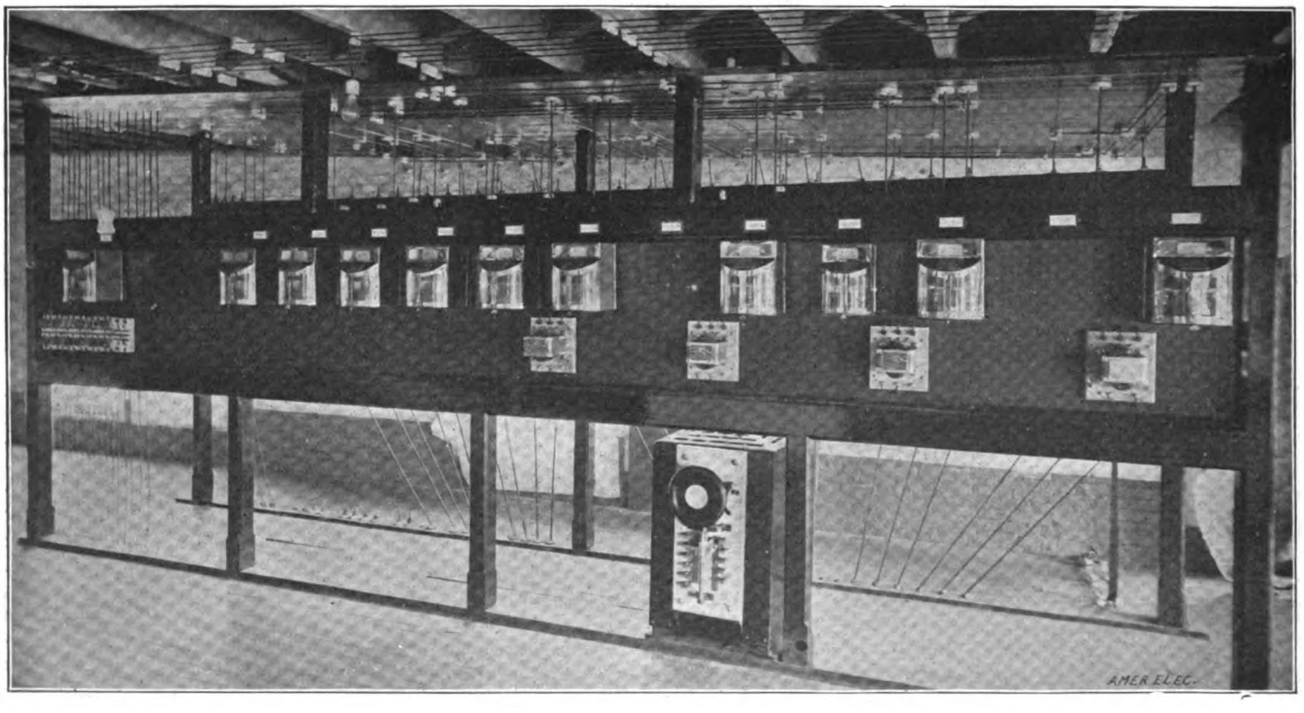
THE BOILER EQUIPMENT.

Structurally the generating plant consists of a brick building about 60x105 feet in size, as the plan on page 205 shows, standing beside the railroad track about one mile south of the center of the city. A spur runs in over the coal pocket, which has a capacity of 600 tons below the rails.

The boiler equipment consists of three Heine safety water-tube boilers, rated at 200 h.p. each, standing in a row, as the adjacent illustration shows. The products of combustion are taken by a brick flue resting on the top of the boilers to the steel stack, which is 6 feet in diameter and 150 feet high. This stack, a good view of which appears in the illustration of the station exterior, is encircled at its top with a crown of sixty-eight 16 c.p. incandescent lights. The powerful draft given by this stack, with its great size and height for the load it carries, is controlled by a Spencer automatic damper regulator.

The feed water comes to the station

Digitized by Google

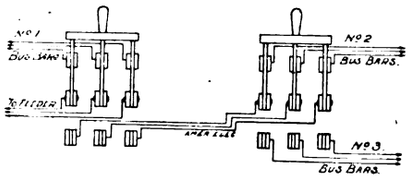


[illegible] ABOVE THE ENGINE ROOM CEILING, SHOWING SEPARATOR AND ARRANGEMENT OF VALVES.

from the Frank Jones pumping station, a complete water plant for private property resembling, as does the electric light plant, a public institution. The incoming feed water is passed through a Webster vacuum heater, where the engine exhaust heats the water up to within two or three degrees of the boiling point. The hot water is then taken by a Deane pump, placed well below the heater in order to give a solid body of water to prevent vaporization under pump suction, and is delivered to the feed line. All the feed water piping, as well as the water columns, is of brass. A Hancock inspirator gives a reserve means of feeding the boilers. All feed water is measured by passing it through a Crown water meter, which is calibrated once a month by weighing on scales the amount of water registering a certain number of cubic feet. The coal is also weighed in wheelbarrows on its way from the coal pocket to the boilers,

so that with the records of the integrating wattmeters a fairly accurate tally is obtained of the economy of the different parts of the system.

The main steam piping consists of a 10-inch header collecting the steam from the three boilers and a 10-inch main to the Stratton separator, which is located in the upper story over the engine room, the lower end of the separator coming down through the engine room ceiling. From the separator the steam goes to a cross, and from the three branches of this to the three engines, all horizontal runs being made above the engine room ceiling, so that the only piping in the engine room is the vertical drop of the steam pipes to the engines and of the exhaust pipes to the exhaust header under the floor below. A view of the arrangement of the separator, the cross and the valves in the attic above the engine room is shown at the head of this page.

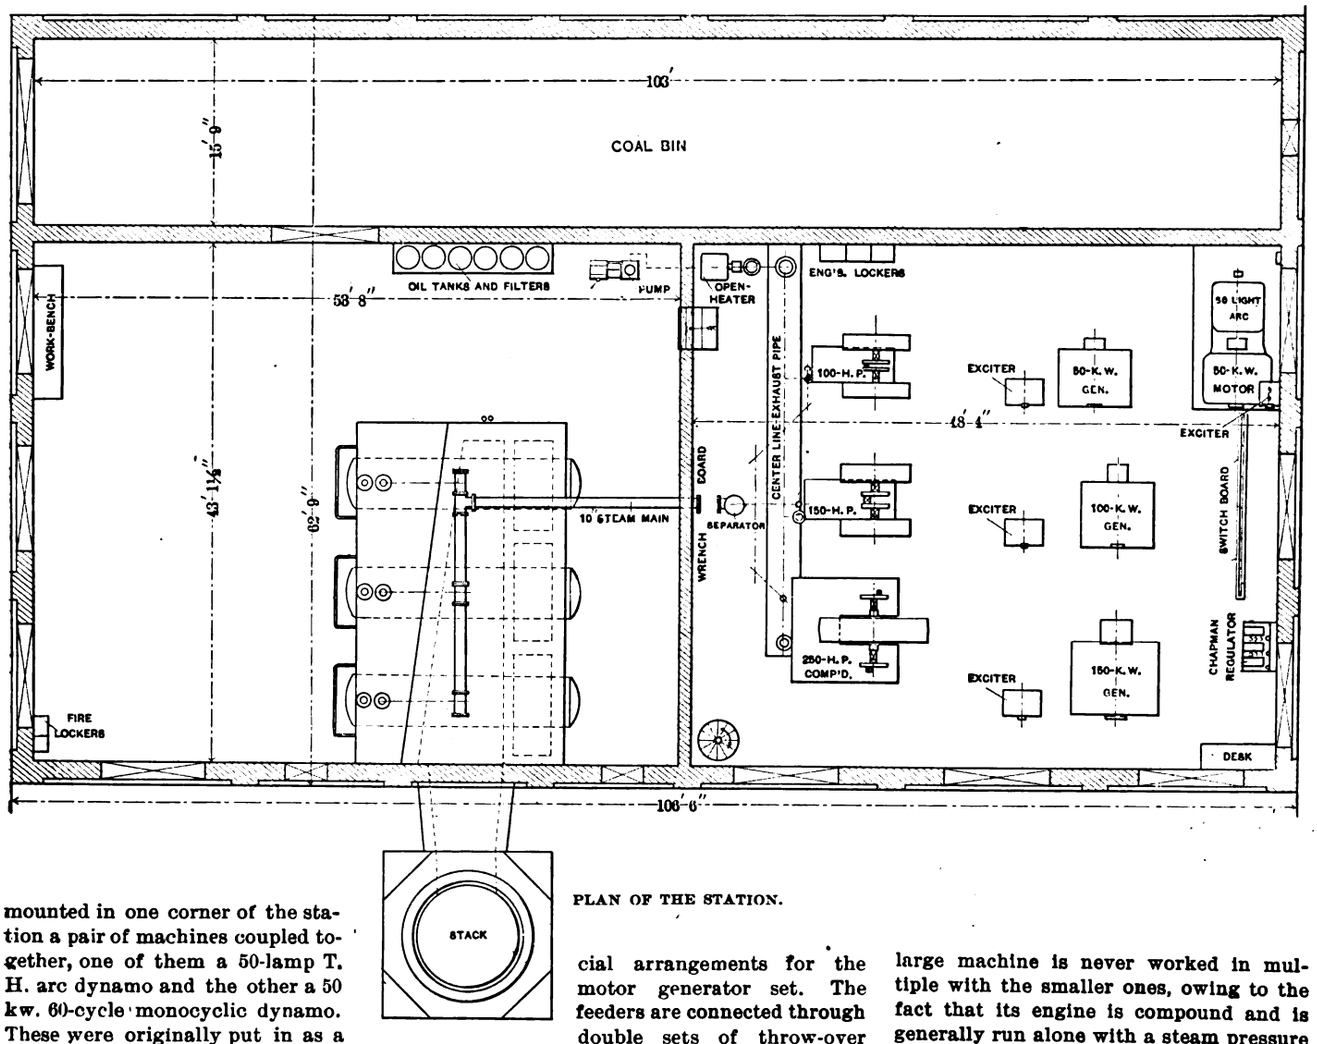


THE PRIMARY METER BOARD.

Digitized by Google

The prime movers consist of two simple Ideal and one cross-compound Ide engines, all built by the Harrisburg Foundry & Machine Works, and to each of these there is belted one alternating current generator. The exhaust steam is taken over to the open heater above mentioned, which is simply tapped off from the exhaust riser through two grease extractors. The dynamos are all General Electric monocyclic, 60-cycle machines wound for 2,100 volts and fitted with rectifiers and composite fields. They are of different sizes, namely 50, 100 and 150 kw. ratings, to absorb the outputs respectively of the 100, 150 and 250 h.p. engines. Each dynamo has mounted on its terminal plate an Elden circuit breaker, in which, as is well known, both the field and armature circuits are broken when the breaker operates.

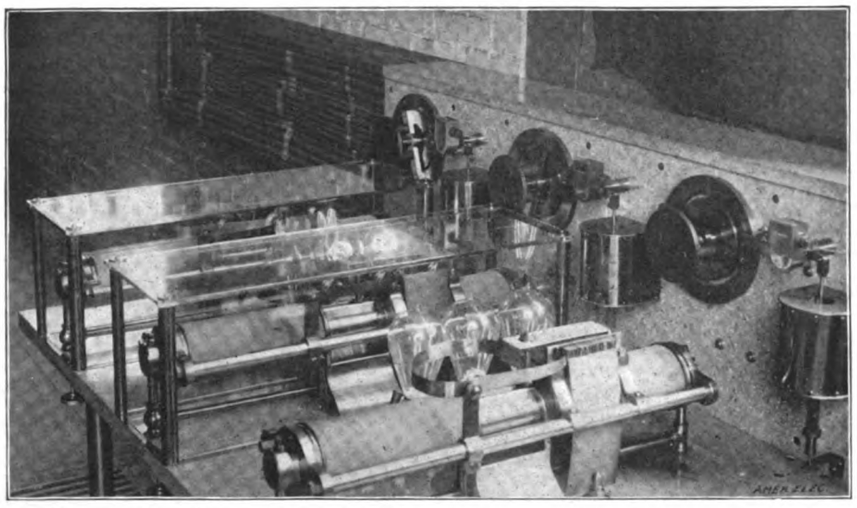
Besides these three generators, there is mounted in one corner of the station a pair of machines coupled together, one of them a 50-lamp T. H. arc dynamo and the other a 50 kw. 60-cycle monocyclic dynamo. These were originally put in as a motor generating set, the purpose being to run the monocyclic machine as a motor from one of the other generators, and from it drive the arc dynamo. It has been found preferable, however, to drive this coupled pair by a pulley surrounding the coupling and a belt run tandem with the other belt on the small engine. The motor dynamo set has no sliding rails, and the belt is tightened by an idler pressed upwardly against its under side. The exciter of this alternator is ingeniously mounted on a bracket on the wall and the bracket is worked up and down by a screw to tighten its belt. When the machine was used as a motor this exciter served to bring it up to synchronous speed.



THE CONNECTIONS OF FEEDERS TO BUS BARS.

The switchboard is quite an elaborate affair, owing to the fact that arrangements are provided for running the machines either singly or in multiple, necessitating three sets of bus bars with special arrangements for the motor generator set. The feeders are connected through double sets of throw-over switches, so that they may be supplied from any one of the three sets of busses. The bus bars, main switches, fuses, etc., are all, of course, triple pole to provide for the two main and the one teaser terminals of the monocyclic machines. Just as in the multipling of compound wound direct current machines, there is necessary an equalizer connection to prevent unstable running due to the series field; this is provided on this switchboard by a double pole equalizer and equalizer switches which cross connect both ends of the series field windings of the machines to be run in parallel. The dynamos are regularly worked in multiple, and even when only changing over from one machine to another the fresh machine is synchronized and thrown in parallel with that already running, which is then taken out, thus transferring the load without the slightest interruption of the current delivered. The machines are synchronized with receptacles and plugs connected with phasing lamps in the usual way.

Each machine has its own set of three pole bus bars and the four outgoing feeders are fitted with double sets of double throw switches, by which they can be thrown to any one of the three sets of bus bars. Two of the latter may also be connected by bus junction switches. The large machine is never worked in multiple with the smaller ones, owing to the fact that its engine is compound and is generally run alone with a steam pressure of 125 pounds, 45 more than are carried by the same boilers when working the single cylinder engines.



The voltage is indicated by a bracketed alternating current voltmeter supplied over pilot wires run back from a point on one set of the feeders about two-thirds of the way into the city, thus getting the major part of both the ohmic and inductive drop, the latter of which must be par-

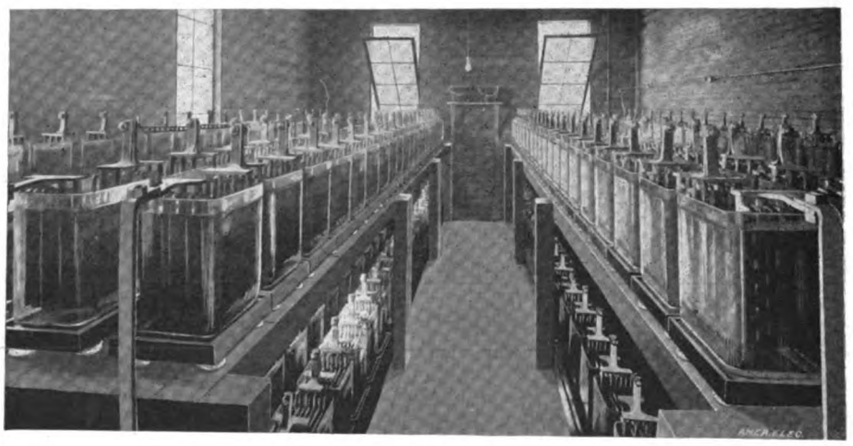
PLAN OF THE STATION.

Digitized by Google

ticularly watched, owing to the running of induction motors. On the same account the compounding ratio of the generators has been made adjustable by using for the shunt of the series field of each machine a Carpenter enamel rheostat mounted on the generator panels of the switchboard. The fields have an unusually heavy series coil, and during the summer, when the motor load is larger than at other times, the rheostats are turned to give a greater ratio of compounding than during the winter, when the load is less inductive. In order to obtain practically constant potential on the station lamps they are also fed from lines run back from taps on the main feeders about two-thirds of the way to one of the points of distribution.

THE AUTOMATIC VOLTAGE REGULATORS.

To further assure the maintainance of constant potential with all the precision obtainable in a plant of this size, Chapman automatic voltage regulators are used. The equipment of these instruments is worked out with unusual care and finish to make a most attractive and showy appearance. The three regulators are mounted on a low table of pink Tennessee marble and each is covered with a plate glass box. Each has the adjustable series or compounding coil by which they may be made to overcompound for the line drop. The combination of automatic voltage regulators with composite wound generators is something not often found, but the experience obtained in this station shows it to be a successful one. When running in parallel, separate regulators, one for each machine, are not connected up, as they would, on account of the overcompounding feature, tend to seesaw the load from machine to machine, unless fitted with some device which would act as the equivalent of an equalizer. One voltage regulator is worked on one of the machines in parallel; its operation affecting the voltage of both, owing to the way in which alternators mutually adjust each other to the same voltage when running in parallel.



The loads of this isolated plant or central station, whichever one pleases to call it, differ from those of the average central station in that they are concentrated in several small areas, whereby they may be supplied through a few large and efficient transformers instead of a lot of small house to house transformers. There are four loads, as mentioned above, each supplied by its own feeder, the largest of these being the mammoth summer hotel, the Wentworth, which has between six and seven thousand lamps wired up on the three-wire system in part, and with its own distributing switchboard fed by a bank of a few large transformers. The hotel has also its own potential regulator or induction booster, so that the voltage can be controlled by any one at the hotel itself, a wise provision, as the distance from the power house station is almost three miles. Another potential regulator at the generating station is used for separately controlling one of the other feeders, the remaining two depending on the composite winding and the compounded automatic voltage regulators.

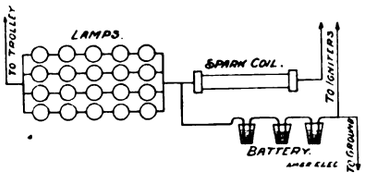
Upstairs above the engine room there is a special meter board made of slate and carrying Thomson integrating water meters in glass cases, one in each of the outgoing feeders and one in each of the teasers on the circuits which carry motors as well as lights. The indications of these meters are carefully compared with those of the secondary meters on the other side of the transformers on the same lines, and the two record within three or four per cent. of each other, showing that the losses in both the high tension distributing lines and the transformers come within this small figure. Such high efficiency is, of course, possible owing to the concentration of the loads and the use of large transformers. A view of this meter board appears on page 204 and shows also the way in which the vertical wires from the switchboard below are kept taut by means of bolts and nuts in porcelain bushings. The load curves of this plant of course differ considerably from those of the average central station, the heaviest loads being in the summer and then only for a very brief interval of an hour to an hour and one-half during the evening. During the month of August last the total number of kilowatt hours recorded was 17,140, which cost 3.85c. per kw. hour, including labor and the rather low depreciation of two per cent. on the station, a very fair figure considering the low load factor. The coal burned during the same month was 92 tons, 300 pounds.

The chief engineer of the station is Mr. A. M. Barton, to whom thanks are due for the information given above.

## Electric Railway Power Plant Driven by Gas Engines.

For fluctuating loads small electric roads are so notorious that they have become a by-word among many engineers, who, when they wish to express the idea of extremely annoying current variations, compare them with the load of a two-car railway. One of the chief arguments against the use of the gas engine has been its inability to regulate well or even work at all with extreme load changes, so that the operation of such a road by gas engines indicates a distinct advance in gas

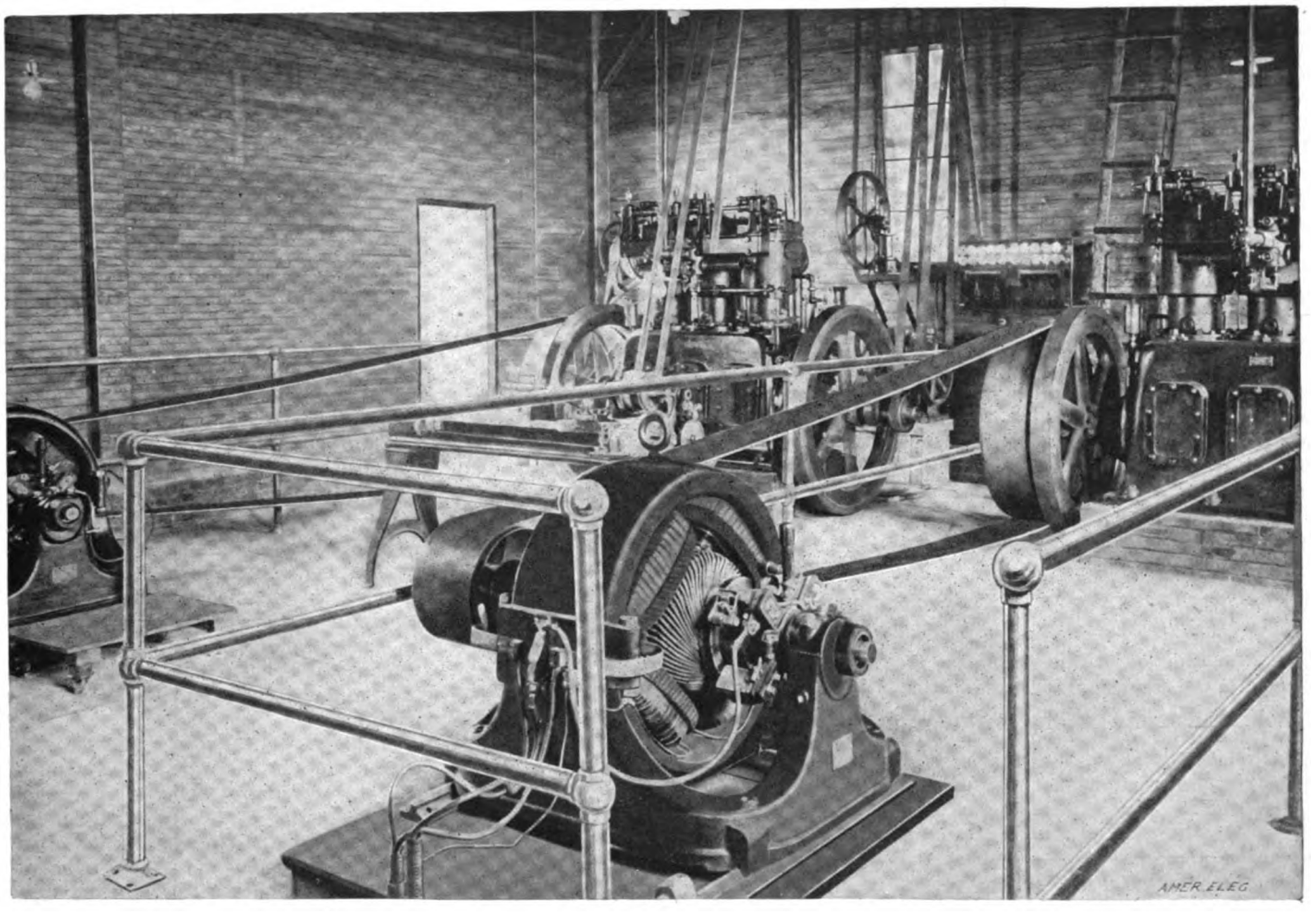
THE STORAGE BATTERY ROOM OF THE HUNTINGTON RAILROAD PLANT.



Digitized by Google

engine design and electrical engineering.

The Long Island Railroad Company has a network of trunk lines ramifying over the island from which it takes its name, but these lines unfortunately do not, as a rule, run closely along the shores where the popoulation tends to concentrate. Particularly is this the case with the Port Jefferson branch, which runs along a section of the Sound shore on the northern side of the island. The road follows an elevated tableland from one to three miles back from the shore, according to the indentations of the latter, the nearest point to the village of Huntington being about two miles from the town center.



Following a policy which it intends to adopt throughout its whole system, the railroad company has bought up the franchise of the local horse railway and equipped the line with an electrical system for the purpose of working it as a feeder to its main line. The road is single-tracked, about three miles in length, runing down from the station to the village and thence to the shore in a neighborhood occupied by the handsome country seats of wealthy New Yorkers. At the shore end is the power plant, while at the other end the line climbs 165 feet up to the plateau of the steam railroad with grades running up to 4½ per cent. The load curves on such a system can be easily imagined. Running with one car, as it often does, a comparatively heavy current is demanded while the car is climbing the grade, the loads at all other times being small or nothing.

The power house equipment consists of

THE IGNITER CIRCUITS.

two Westinghouse, 3-cylinder, vertical gas engines, each of 50 nominal b.h.p., taking their gas supply from the adjacent works of the local gas company. These engines have the standard features of Westinghouse design, notably the regulation by varying the charge of the fuel per stroke, instead of the hit or miss method of governing, this feature making them particularly well suited for traction work. The only details about them departing from customary practice are the arrangements of the igniting circuits. Current for the electric igniters is taken from the 500 volt railway generators and passed through 20 incandescent lamps, connected in four groups of five lamps each in series, as indicated in the accompanying sketch of connections. From these lamps it goes to the spark coil and thence to the igniters. The high voltage, however, tends to make the spark persist across the igniter contacts and hold a small arc, which, of course, immediately causes "back fire" in the mixing chambers as soon as the admission ports are opened. To overcome this there is shunted around the spark coil and igniters a set of what might be called storage batteries, consisting simply of three ordinary glass tumblers with lead strips bent over and dipping into the ordinary sulphuric acid solution in them as the sketch shows. These take the current when the igniter circuits are open, reducing the voltage across the igniters to about seven volts, and absorb a charge at such times, which is given out again to the igniters as soon as their circuits are closed. The igniters are supplied by a battery of 12 Edison-Lalande primary cells when the engines are starting.

THE DYNAMOS AND GAS ENGINES OF THE HUNTINGTON PLANT.

Each engine is belted to a 37½ k.w. Westinghouse, 4 pole, 550 volt generator. In a neighboring room is a storage battery of 265 cells of chloride accumulators, having a maximum discharge rate for short periods of 44 amperes. These are worked without booster or end cell switch, directly in multiple with the dynamo or dynamos, the latter being fitted with special compound windings, by means of which their voltage is made to fall off as the load rises to such an extent that the battery will take the greater part of the load fluctuations.

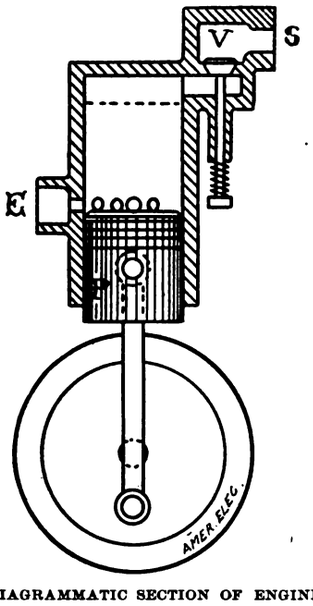
The road has been running since June

Digitized by Google

20, 1898, with one car during the winter time and three open cars during the summer season, having carried over 5,000 passengers in a single day. The ordinary car mileage is about 200 miles per day, the gas consumed amounting, it is stated, to about 46 cubic feet per car mile; the total operating expenses, with gas at 90 cents per 1,000 cubic feet, and including motormen's and conductors' wages, being about 13 cents per car mile.

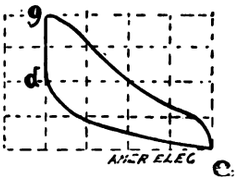
The road is now in charge of Chas. F. Wingate, Superintendent, and Frank Tryon, Jr., Engineer.

## A SIMPLE STEAM ENGINE WITH A REMARKABLE STEAM ECONOMY



There has appeared in the verbal and communicated discussions of the American Institute of Electrical Engineers a description of a small and simple steam engine which has given most surprising results in steam used per h.p. hour. The engine is one developed by Prof. Elihu Thomson for steam automobile work and closely resembles one recently designed in France for the same purpose by M. Serpollet. It has four cylinders each 2½ ins. in diameter and 3 ins. stroke, all single acting and worked single expansion, thus being virtually four small engines, each of a little over 1 h.p. capacity, the output of the whole being about 5 h.p.

The economy obtained with this small machine reached the surprising figure of 20½ lbs. of water per h.p. hour, the output being measured by a dynamo driven by the engine; the amount of water per indicated h.p. being undoubtedly less than 20 lbs. The steam pressure carried was between 160 and 200 lbs., but there was a considerable and variable degree of superheating, the engine being worked at times with the steam pipe red hot.



The departures from ordinary designs in the construction of this engine are indicated in the accompanying cross section and consist mainly in the arrangement of the valves, the exhaust port consisting of a number of holes, E, arranged in a ring in such a position that they are uncovered by the piston, B, at the extreme outward position of its stroke. In order to use a high degree of superheat the steam is admitted by a simple poppet valve, V. The clearance is large, giving a cycle much like that of a gas engine with the idle revolution removed. A puff or explosion of steam, as it might be called, is admitted by a very brief opening of the poppet valve and this expands until the piston uncovers the exhaust ports. The exhaust line is not horizontal as in the ordinary steam engine, but from the time that the exhaust ports are re-covered by the piston the compression is continuous and adiabatic until the piston arrives at the inner end of the stroke and a new charge of steam is admitted. A typical indicator card is shown in the accompanying cut. Some of Prof. Thomson's comments upon the engine are as follows:

"The conditions are such that there is no re-traversing of passages, no re-traversing of even the cylinder portion. The steam enters, goes forward and out, and it is running steadily forward, so that we do not have any of those inter-actions that use up energy. We have a temperature gradient from one end to the other of steam cylinder.

"The engine was in good condition, of course, but not exceptionally so. Its simple construction permits of relatively easy maintenance. When I made the engine I expected to realize a result of about 30 pounds of dry steam per brake h.p. hour, which in itself would have been roughly about twice as economical a result as is shown in the best tests of such very small engines, of which I was able to obtain any data. I was skeptical of the result of the first tests, and freely expressed my doubts, but by going over the work and watching it personally, while insisting that everything be done to have the errors count against the engine rather than in favor of it, I became convinced that my expectations had been greatly exceeded, and that a result of 20 pounds per h.p. hour, or slightly better than that, had been, in fact, obtained, as I have indicated.

DIAGRAMMATIC SECTION OF ENGINE.

CARD SHOWING ZERO CUT-OFF AND 100 PER CENT. COMPRESSION.

"It remains to finish and test an engine of larger capacity and to do it under such varied conditions as will be likely to point out the relative values of those features which undoubtedly contribute to the still lower consumption which will probably be obtained.

"The small engine tested was designed for automobile work, it being regarded as extremely desirable that but little water and fuel be carried, and but little steam escape during work. The clearance is great and the manner of exhaust and admission such that no trouble is ever experienced with condensed water in starting.

"The engine is now in use upon a steam automobile, having a coil-pipe boiler heated by ordinary kerosene. It runs satisfactorily even under the very extreme condition, adopted in some experiments with it, of a steam supply pipe at a bright red heat. But this is, of course, abnormal and only indicates the wide range in character of steam which is permissible. That it is not injured by excessive heat in the steam suppled is due, doubtless, to the poppet valve admission, and the extremely early cut-off which permits the entrance of only a momentary puff of hot steam when the piston is full in."

## THE CANDLE POWER OF ARC AND INCANDESCENT LAMPS.

### THE AMYL ACETATE LAMP.

BY PROF. WILBUR M. STINE.

The failure of candles as standards of light strength was found to be caused by the uncertain composition of the combustible and by the charring and alteration of the wick, and certain mechanical effects of the heat generated by the candle flame. Again, the failure of the Methven screen was due to the complex nature of illuminating gas and the impossibility of reproducing any given quality of gas, and the further objectionable feature of a gas chimney. The pentane flame is being abandoned as a light standard from much the same causes; sufficiently pure pentane can not be obtained commercially, and especially the heating effect of the flame on that part of the wick-tube in which the pentane vaporizes, this in itself causing the flame to alter in its illuminating power.

In this survey it appears that the principle sources of variation in the standard of light are due to the complex and uncertain quality of the combustible, and to the wick or the arrangement for vaporizing the combustible. An improved standard, then, must be free from these objectionable features. Up to the present time the most successful improvement over the former light standards is one of German origin designed by Hefner-Alteneck and announced by him early in 1884. This new standard was developed in the course of a lengthy investigation of the previously existing standards of illuminating power. Hefner's first care was to find a suitable combustible, chemically simple, and one that should vaporize readily and avoid the charring of the wick. His final selection was amyl acetate, which he burned in a specially modified spirit-lamp. As now used this lamp is essentially as he first designed it, but with a few refinements and modifications which increase its accuracy.

Description of the Hefner Lamp.—The standard form of the Hefner lamp is

Digitized by Google

shown in vertical section in Fig. 1. The pair of toothed wheels actuated by a worm gear are for adjusting the height of the wick in the tube C. When in use the cap D is unscrewed and removed. The wick-tube C is made in German silver and must accurately conform to certain prescribed dimensions. Moving concentrically with the wick-tube is a plate H, which carries a pillar topped with the Kruss optical flame gauge shown in elevation in Fig. 2. The essentials of the flame gauge are a magnifying lens and a screen of ground glass fastened in the eye piece. The glass screen has a diametrically horizontal scratch made on it, accurately cutting the optical axis of the gauge. As further indicated in the figure, the distance from the top of the wick-tube to the optical axis of the gauge is 40 millimeters. This length must be adjusted with the greatest possible precision and the adjustment is tested by the use of a gauge shown in Fig. 3. This test gauge is placed over the wick-tube, and when the top of the wick-tube is viewed horizontally through the slits there should be merely the very slightest observable clearance if the wick-tube is of the proper height. The top of the gauge is ground off to a slight bevel, giving a truly horizontal edge. This edge, viewed through the optical flame gauge, must sharply coincide with the scratch on the glass screen. This most ingenious arrangement of gauges enables the operator to test the accuracy of this most essential dimension of 40 millimeters. The function of the optical flame gauge is to indicate the adjustment of the flame to the standard height.

The Combustible.—Amyl acetate is a colorless and very mobile liquid which

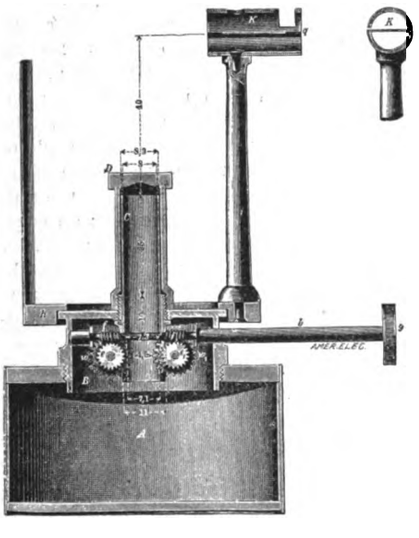


FIG. 1.

vaporizes rapidly on exposure to the air. It has a pungent but pleasant fruity odor. Chemically, it may be regarded as derived from the combination of amylic alcohol and acetic acid. Having the chemical formula, $C_5H_{11}C_2H_3O_2$ it contains only carbon and hydrogen as oxidizable constituents, and in this respect leaves little to be desired.

Amyl acetate is prepared commercially by the distillation of amylic alcohol obtained from fusel oil, with a mixture of acetic and sulphuric acids, or by distilling a mixture of ethyl or ordinary alcohol with sulphuric acid and potassium acetate. It has recently come into extensive use in the arts. It is an excellent and rapid solvent for shellac and similar resins and celluloid. Not a few brands of armature or insulating varnish are made up with this solvent, as is readily apparent from their peculiar odor. Similarly a widely used make of metallic lacquers contains celluloid dissolved in amyl acetate. Being so extensively used, many cheap grades of this chemical are on the market, having a more or less yellow color. Under no circumstances is this quality of amyl acetate suitable for photometric purposes.

The Purity of the Amyl Acetate.—For the photometric purpose of burning in the Hefner lamp, only chemically pure amyl acetate should be employed. At present this is somewhat difficult to obtain in this country, but doubtless the difficulty will be obviated upon the increased use of the lamp when the chemical supply

FIG. 3.

houses shall have learned the requirements for the purity of amyl acetate for a light standard. In Germany the investigations of the Hefner lamp have been so thorough and general that amyl acetate of the requisite purity can be readily imported thence.

The German Gas Commission has prescribed certain tests that may be applied by any one in order to be assured that the amyl acetate burned in the lamp is satisfactory. The prescribed tests are:

(1.) The specific gravity at 15° cent. shall be from 0.872 to 0.876.

(2.) When distilled in a glass retort at least 90% shall pass over between the temperature limits of 137° and 143° Cent.

(3.) The reaction should be practically neutral and blue litmus paper not sensibly reddened by it.

(4.) It should mix with an equal bulk of either benzine or carbon disulphide without becoming milky.

(5.) A clear solution should result upon shaking in a test tube 1 c. c. of amyl acetate with 10 c. c. ordinary alcohol of 90% strength and 10 c. c. of water.

(6.) A drop placed on white blotting paper should evaporate without leaving a greasy spot.

These tests, though readily applied in a chemical laboratory, are yet too complicated for general practice. Should the use of the Hefner lamp become general in this country as it has in Germany, it would necessitate that tested amyl acetate could be obtained from a reliable and au-

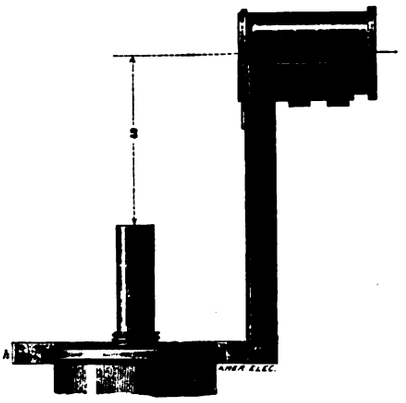

FIG. 2.

thoritative source. In Germany the National Physical Institute (an institution of a character to be urgently needed in this country) and the Gas Association undertake this authoritative supply.

The Wick.—The fact that this light standard operates with a wick does not necessarily imply that the wick introduces a factor of uncertainty in the light value. In the case of the candle it does to a marked degree, because the vaporization temperature of the combustible is higher than the temperature at which cotton chars. In contrast, amyl acetate vaporizes at a comparatively low temperature, so low in fact that cotton does not perceptibly char under its influence. In the candle the wick chars and is really a part of the combustible feeding the flame; in the Hefner lamp it does not char but simply acts as a supply tube by capillary action to keep the end of the wick moistened. The only requirements for the wick are—that it shall be perfectly clean and entirely fill the wick-tube, and not be compressed too tightly, but cause a sufficiently rapid flow of amyl acetate to maintain the end of the wick in a moist condition, or, what amounts to the same thing, that it shall supply the amyl acetate as rapidly as it is consumed. For mechanical reasons, so the wick shall not catch in the teeth of the adjusting wheels, it should be woven preferably than twisted.

The Color of the Flame.—The amyl acetate flame has a decidedly red tinge, and this is one of the most objectionable features of this light standard. It is impossible to compare the illuminating power of lights which especially differ in color. Even the candle flame is whiter than the flame from amyl acetate. The color contrast is especially marked with white incandescent light and bluish arc light. The unfortunate color of the flame of this

Digitized by Google

lamp, probably more than any other feature, has prevented its general international adoption.

The Flame Height.—As already indicated, the prescribed height of the flame above the edge of the wick tube is 40 millimeters. This particular height was selected after elaborate tests had shown that it corresponded to the most constant behavior of the flame. The rate at which the illuminating power of the flame increases for each increment in height above 40 millimeters is 2.5% per millimeter, or 1 per cent. for each 1/64th of an inch. For each millimeter less than 40 millimeters the decrement in illuminating power is 3%. Though at first glance it might seem to be a grave objection to this particular light standard that its illuminating power changes so greatly for slight alterations in flame height, in practice the magnifying optical gauge is found to be so sensitive in its indications that one may maintain the flame practically at the required height with ease, and the errors due to such causes in the hands of a skilled operator are sensibly negligible.

Reproducibility.—In this respect the Hefner lamp may be safely asserted to excel all other light standards. The combustible is chemically simple and definite, and the wick is without influence on the light value so long as it is clean and not compressed to such an extent that it fails to keep the end of the wick constantly moistened. The essential mechanical details require excellent workmanship, but as the proper dimensions are so accurately known, the structural requirements can be met.

The Influence of Humidity.—We now come to the discussion of certain influences which may introduce very large errors in the estimation of the illuminating value of a flame. All flames in their illuminating powers—candle, gas, pentane or amyl acetate—are very sensitive towards atmospheric humidity, though not all to the same extent. Liebenthal, a most reliable investigator, has determined the value of the effect of the atmospheric humidity on the illuminating power of the amyl acetate flame. He measured the light strength of the flame at frequent and regular intervals for a period of two years. The greatest variation of light strength which he found in these tests was 8.5%. This possible error in photometric measurements is so great that it may well throw doubt on all comparisons of light strength in which no correction has been made for atmospheric humidity. The general technical reader has no doubt been often confused, and, to a certain extent, disgusted with the great discrepancies in published photometric data, and possibly has come to the conclusion—and who shall say that it is entirely a mistaken one—that photometry is not a scientific branch of measurement. At some time or other probably each incandescent lamp factory has sent special lamps to colleges and technical laboratories to be rated. Upon their return they have generally been found to disagree more or less widely. The photometrist in all such cases has been roundly censured. Especially since the publication of Liebenthal's data in 1895 a certain part of the discrepancies may be avoided. With all this knowledge in possession it can be stated with considerable assurance that no ultimate measurement of illuminating power based on either the amyl acetate or pentane lights should be accepted which are not explicitly accompanied with the amount of the humidity at the time of measurement, and whose values are not corrected for the particular humidity.

Conforming to the ruling of the German Physical Institute, now generally accepted, the amyl acetate lamp gives normal illuminating power when the humidity of the air amounts to 8.8 liters to the cubic meter of dry air. If h denotes tne humidity in liters of moisture to the cubic meter of dry air and I denotes the corresponding illuminating power of the flame, the correction is made by the equation:

$$I = 1.049 - 0.0055h.$$

All measurements of illuminating power purporting to be authoritative should now be accompanied with this equation and the data for correction. It may be interesting to add that Liebenthal used the Assman hygrometer to measure the humidity.

The Influence of Atmospheric Pressure.—As pointed out in the first paper in this serial, the illuminating power of a flame decreases as the atmospheric pressure lessens. In the particular case of the amyl acetate flame the variation is small and for a change in pressure from 30 to 29 inches it only amounts to nearly one-quarter of one per cent.

The Influence of Carbon Dioxide.—This gas, when present in the air in appreciable quantity, acts like humidity to decrease the illuminating power of the flame. However, for the usual range of carbon dioxide content of the atmosphere the influence of this gas on the illuminating power of the amyl acetate flame does not exceed one-quarter of one per cent. and is negligible in effect.

A precaution must be added: In case the lamp is used in a small room, unless the ventilation is excellent, the carbon dioxide from the breath of the operators and the flame under test may become so great in amount that it will introduce a sensible error.

The Adoption of the Hefner Lamp.—At the Niagara meeting of the National Electric Light Association a report was adopted containing as one specification, "The Hefner-Alteneck amyl acetate lamp is recommended as the primary standard, it being, on the whole, the most reliable and uniform. It possesses the additional advantages of having been subjected to most exhaustive tests to determine its behavior under different conditions, and of being readily obtainable in standard form from authoritative sources."(1)

Also on January 19, 1897, the American Institute of Electrical Engineers adopted a provisional report to the effect that "The Hefner-Alteneck amyl acetate lamp furnished with test certificates from the Physikalisch-Technische Reichsanstalt (German Physical Institute) at Charlottenburg, Berlin, should be temporarily adopted as a concrete standard of luminous intensity, or candle power."(2)

(1) Electrical Engineer, June 16, 1897, p. 676.

## ECONOMY OF MULTIPLE EXPANSION ENGINES.

BY WM. S. ALDRICH.

It has been quite the fashion recently to place all the blame for waste in the production of electric power upon the supposed uneconomical working of multiple expansion engines with rapidly fluctuating loads. By this type of engine is meant that in which the number of expansions is carried out in more than one cylinder—in two, three or four cylinders, as the case may be—by compound, triple or quadruple expansive working of the steam. The expansion of the steam is carried on either intermittently, as in engines with receivers between the cylinders, or continuously in the tandem and other arrangements of the non-receiver or "Woolf" type of multi-expansion engine.

Primarily, the variation in economy due to the variable number of expansions incident to the load changes is responsible for almost all of the odium which has attached to multi-expansion engines for electric supply service. At the outset it is presumed that in any given plant the engines would be worked under conditions favorable to the greatest economy if the loads were not so variable. That is, at least in the case of the larger generating units that are designed for the use of high pressures and preferably superheated with high ratios of expansion and operated condensing. The principles underlying the treatment of this topic do not touch the question of the value of the condensing system, dealing as they do with more or less known effects on economy due to variations in the expansive working of steam, rather than with the small unknown quantities pertaining to the efficiency of condensing under varying loads.

The transient or instantaneous changes in load of electric railway service are here considered in their effects on economy as compared to the more or less permanent changes of load in lighting service. The distributive and the disconnective systems of installation of steam motive powers are treated with special reference to electric light supply. The influence upon economical working of the method adopted for speed regulation, whether by throttling governor or cutoff mechanism, is discussed with particular reference to the wide range of variations in railway service.

The influence of the accessories of a

(2) Proceedings A. I. E. E., 1897, p. 90.

Digitized by Google

steam power plant upon the economy under variable loads is touched upon merely, not being of such commanding importance as the manner of working the steam in the multiple expansion units. The changes due the latter are productive of marked effects upon economy under variable loads, whether the expansions are carried out in one or more cylinders, but especially in the latter case. The use of superheated steam, the effect of cylinder condensation, the quality of the steam throughout its working, and the condition of the cylinder walls of the last or low-pressure cylinder at the point of release, all influence the economy under variable loads. It is a question how best to meet the exigencies that arise in each stage of the expansive working that the best results may be obtained under wide variations of initial and intermediate conditions, but with fixed terminal conditions. The variations in economy of multi-expansion engines are clearly due to the variable manner in which steam is necessarily worked from early to late cutoff in the several cylinders. It is also, in some types, a question of the best way to secure an economical continuous expansive use of the steam; and this has been considered in its relation to the non-receiver type of multi-expansion engines. Economy of installation and operation—the economy of the plant, the maximum kilowatt hours per pounds of steam supplied is really the question that mostly concerns stockholders and managers, and is therefore the true measure of value in comparing the economical performance of various installations.

In the electrical service there are two distinct conditions to be met, supply for lighting and supply for railway work. In the former the load is quite uniform for a greater or less period and is not subject to the sudden and wide fluctuations incident to the latter service. This has made it possible to meet the demand for greater economy in electric light supply by one or the other of two representative systems in the arrangement and management of the steam plant; namely, the distributive and the disconnective systems.

In the distributive system of arranging the steam power for lighting plants the subdivision of such powers into convenient and usually duplicate units is carried out. This is on the principle now fully recognized as applicable to all types of engines, namely, that they have a certain economical range of load beyond which it may be necessary, though not desirable, to operate them. For large blocks of load permanently thrown on or off the station, other generating units are thrown into or out of service to meet such demands as they arise under any given set of conditions. While this is evidently more necessary for simple as well as non-condensing compound engines with somewhat limited range of economical load, it is none the less important in handling the usual compound and other multiple expansion engine units when operated condensing.

This principle is right both in theory and practice. It recognizes the clearly defined limits for the economical working of the engine as a unit. It is convenient of application, the engineer usually having two or more such duplicate units slowly turning under light steam, ready to be thrown in at about the time of the day when such increased loads are expected on the lighting circuits. It reduces the expense of operation, losses due to friction, and the wear and tear of motive-power machinery. It enables the whole plant to be operated for electric light supply at a nearly uniform rate of steam consumption per kilowatt-hour of output. A lighting station so arranged will be able to maintain a high load factor. It is more economical to meet an increase of load of from 500 to 1000 kilowatts, by throwing into service another 500-kilowatt engine-dynamo unit than to attempt to supply both loads from a single 1000 kilowatt unit. The extent to which such subdivision may be carried is of course governed by the probable character of the lighting service to be supplied. At first, two or three duplicate units will probably give sufficient range, to which may be added other similar units to meet the demands of expanding business.

In the disconnective system of steam motive power for lighting stations a large triple or quadruple expansion engine is installed, so designed and constructed that one or more cylinders may be disconnected or thrown out of gear to suit the load requirements for a few hours and insure a more economical working of the cylinders remaining in service. Such unshackling of two or more connecting rods with other changes, takes but a small amount of time, it is true, but has not been found altogether meritorious. It may cause delay at a somewhat critical moment. It is a system that has been tried and found wanting at a critical time in the late war on the armored cruisers "New York" and "Brooklyn." While the central station manager is usually able to provide for such an exigency, the same idea was entertained regarding the cruisers on the blockade off Santiago, namely, that to insure the greatest economy, one or more of the cylinders of the multiple expansion engines should be disconnected during ordinary duty, fully expecting that when the time for the extraordinary should arrive all of the cylinders and their gear could be connected up in short order. In general, it may be said that a duplicate unit may be thrown into service with greater readiness and far more certainty of meeting the increased demand than by throwing into gear the parts of a disconnected multiple expansion engine. On the other hand, the disconnected system invites engine builders to argue the advantages of large multiple expansion engines for first installment, to be afterwards loaded up as the work of business expansion goes on. It is a question of providing for the future in the first installation or of providing similarly for increased business by installing duplicate units when the occasion arises.

In the case of the disconnective system it is apparent that changes at the engine itself are not the only ones called for, if any attempt is made to observe the underlying principles of the economical working of steam. To change from two to three cylinders, from compound to triple working, should be met by corresponding changes in the boiler pressure, dictated by the considerations of maximum economy. The same may be said of the change from three to four cylinders, from triple to quadruple expansion. Such increased boiler pressure, it is true, may be provided for in one and the same boiler plant; but it has been found by experience better to provide separate high-pressure boilers for the requirements of the higher ratios of expansion in triple and quadruple working. Otherwise, high-pressure boilers have been installed and kept in service throughout and the pressure reduced through the use of reducing valves. These latter have been so designed and operated as to conduce to greater economy with the smaller number of expansions through the slight superheating of the steam as it is reduced in pressure.

The problem of speed regulation of engines in electric supply service is far more important in lighting than in railway work. It is also a more difficult problem in multi-expansion engines than in single or two-cylinder units operated usually by one or two valves. Furthermore, the question of throttling compared with cutoff regulation will still be open until exhaustive experiments are made with both systems and with representative engines of simple and multiple expansion types under widest fluctuations in load. Until such a time, there are equally good reasons for throttling as for cutoff regulation, in order to maintain uniform speed under change of load in the case of simple or multiple expansion engines fitted with valves of the common slide or piston type. The four-valve type of engine, whether of the Corliss or later design, occupies a field so distinctively its own and is operated within such limited range of speed that it is not likely to enter the field of the smaller high-speed direct-connected units, whether these latter be simple or multiple expansion.

Regulation by throttling the initial pressure, in engines operated under a fixed cutoff, certainly has inherent advantages at light loads. The greatly reduced steam pressure through a properly designed throttle valve will be accompanied with the slight superheating that is so desirable at light loads. It is hardly probable that the undesirable extreme will be reached in throttling regulation; that is, the case of the initial pressure being so low that the expansion is carried below the back pressure or atmospheric line, in the case of non-condensing engines. In high-speed direct-connected multi-expansion engines, upwards of 300 horse-power or more, the English practice is remarkable as presenting well-authenticated experiments which would

Digitized by Google

show that throttling regulations under these conditions is quite as economical as cutoff regulation, in the consumption of steam per indicated h. p. hour. In throttling regulation there are not the disadvantages due to high initial pressure at all loads with consequent variations in steam losses by leakage, by excessive frictional loss due to compression and the increased losses due to cylinder condensation, as in the case of cutoff regulation. Moreover, the resulting efficiency in either case, when determined by reference to the work done and not merely by reference to the indicated h. p. —to the pounds of steam consumed per kilowatt-hour output at the switchboard, is found to be considerably in favor of the throttling system.

The frictional losses and liability to derangement of complicated cutoff mechanisms in these high-speed multi-expansion engines are additional points to be considered in such an installation. The equal liability to be thrown out of adjustment by wear or careless and ignorant setting will lead to uneconomical steam distribution in cutoff mechanism that is not at all likely to occur in throttling regulation. With these types of engines throttling regulation may be brought within quite as narrow a range and by refinements of design and construction will be found to give as close regulation as the cutoff mechanism. The effect of fly-wheel inertia is important in either case and, if not supplied by the heavy armatures of the generators, must be otherwise provided for. The value of this is so important in speed regulation that it is of itself sufficient to more than offset the disadvantages of one system compared with the other, if introduced to such an extent as to make it a controlling factor in comparing the regulation by throttling to that of cutoff mechanism.

Regulation of speed by variable cutoff is the controlling feature of almost all types of engines in this country. In the older engines of the compound and triple expansion type such regulation was obtained by a variable cutoff on the high pressure cylinder alone. It proved entirely satisfactory for steady loads or those only slightly variable, as in the case of mill engines, and in electric light service. Such method, however, proved very unsatisfactory, both from the standpoint of close regulation and of good economy, when electric railway service came into vogue with its sudden and wide fluctuations in loads. It is possible to obtain quite close regulation in large multiple expansion units and without detriment to economical working even in railway service.

Simultaneous control of the cutoff valves on each cylinder of a multiple expansion engine has been found practicable and satisfactory. In this manner the distribution of steam in each cylinder may be made more or less proportioned to its size and to its share of the total load. Under certain conditions of such service it may be necessary to sacrifice, for a moment, economy to regulation. This is apt to occur in the case of the receiver types of multiple expansion engines at moments of extremely light loads due to early cutoff in each of the cylinders. The back pressure is increased in the receivers acting as a brake upon the engine, and likely to give an aggravated case of negative power by forming a looped indicator diagram. This may be provided for, however, by allowing considerable "drop," as it is called, in the receiver, which drop in pressure will be greatest under heavy loads and least under light loads. Of course, with a fixed back pressure such looped indicator cards and consequent negative power are equally detrimental to good economy.

In a future number the influence of various accessories upon the economy of the different type of engines will be discussed.

## EFFICIENCY OF SMALL MOTORS.

BY ALTON D. ADAMS.

Owing to the extended and extending use of small electric motors of from ½ to 10 h.p. capacity, the greater part of power distribution being in these units, much importance attaches to efficiency in such machines.

The word efficiency is frequently used in various senses, but is intended here to express the ratio of mechanical power given off by the motor, divided by electrical power entering at the brushes.

Efficiency, as here used, means the above ratio when the motor is doing full rated work, unless stated to apply at some definite fraction of load.

Various features of motor construction are sometimes stated as direct factors in motor efficiency, which are at most but secondary in their effect, or may have their influence entirely offset by other features.

For example, efficiency is said to depend on the shape of teeth or area of armature core, extent of pole pieces, length of air gaps, area of magnet core, number of turns in armature winding, and the length or depth of magnet coils.

The facts are that any one of these features may be varied within wide limits without material effect on efficiency, provided other parts are made to correspond.

Thus electric motors of various makes, having about the same efficiency, vary, for the same capacity and voltage, by more than 50 per cent in magnet core areas, 60 per cent in armature turns, 100 per cent in length of air gap and more than 100 per cent in depth of magnet winding.

A more definite idea of the character and location of the several losses in motors will enable purchasers to very nearly determine the efficiency in any case by very simple means.

All energy lost in electric motors usually comes under the three following heads:

1. Loss in armature and magnet windings.

2. Losses in iron cores and poles.

3. Losses by friction of bearings, commutator and air.

The losses in armature and magnet windings are easily calculated when the resistance of each in ohms, also when the volt and ampere capacity of a motor, are known.

Armature resistance, depending on the size, length and quality of wire used in winding, being once fixed, cannot be changed by any variation in section of armature core, shape of teeth, or length of air gap.

In the same way, magnet coil resistance, depending on size and weight of wire, fixes the loss for magnetizing power, and this cannot be varied by any change in pole pieces or area or length of magnet core.

If size and length of armature wire are not known, the armature resistance may be easily found by noting volts between brushes when a current as nearly as possible equal to the full capacity is sent through the armature, the magnet coils being disconnected and armature at rest, by the formula, $\text{amperes} = \frac{\text{volts}}{\text{ohms}}$.

As the volts between brushes will in many cases be small, a voltmeter reading to tenths should be used for the above reading.

When the armature resistance is known, the rate at which work is lost in it can be found from the formula, watts = (amperes)$^2$ × ohms, the amperes used in this formula corresponding to full load of motor, and the ohms being those found for the winding.

If magnets are series wound, the resistance and loss in winding can be found by the same means as for the armature.

Should magnets be shunt wound, an ammeter reading at least to tenths should be connected in coils when they are taking current from the supply line at rated volts of motor.

The reading in amperes and the volts of line give the expenditure of watts in magnet coils from the formula

Watts = volts × amperes.

Iron losses may be conveniently divided into those from local currents and those from hysteresis.

Local current losses occur in pole pieces when armature slots and air gap are not properly proportioned; also in armature cores when the discs are not properly insulated from each other. All these losses, however, are reduced below one per cent in well-designed motors.

Hysteresis losses result from magnetic reversals in the iron armature core, and cannot be avoided, but their amount can be maintained at a small figure by the use of the best iron or steel for the purpose.

The amount of loss due to hysteresis depends on the weight of iron in the armature core, the saturation, or webers per square inch of section, the rate of reversals and the quality of iron used.

As the quality of iron and the saturation of armature core cannot be easily found after a motor is completed, it is not convenient to find the hysteresis loss independent of friction, but for motors from 1 to 10 h.p. of good makes, hysteresis losses are from 1 to 3 per cent.

Digitized by Google

Work is done to overcome friction in a motor between shaft and bearings, brushes and commutator; also between the armature body and the air.

The most ready and convenient way to determine the sum of hysteresis and friction losses in an electric motor is to connect the unloaded armature, together with a voltmeter and ammeter, to the supply mains of the rated pressure, and then note volts and amperes at the armature terminals.

The watts found from these readings include nearly all the friction local current and hysteresis losses whatever the load; also an additional loss due to noted amperes flowing through the armature resistance.

The loss due to armature resistance when the motor runs empty is found from the formula, watts = (amperes)$^2$ × ohms, in which the amperes is the armature current. This loss in watts being deducted from the total watts for free operation, represented by watts = volts × amperes, leaves the total watts lost as local currents, friction and hysteresis.

Watts due to loss in armature-winding with full rated current, plus watts lost in magnet coils, plus watts due to local currents, friction and hysteresis, as obtained above, give a sum total of losses in the motor at full load.

The total watts taken by the motor from the line, at full load, minus the total losses as above found, and then divided by the total watts, gives the motor efficiency, which may be expressed by the formula

$$\text{Efficiency} = \frac{\text{total watts from line} - \text{watts lost in motor}}{\text{total watts from line.}}$$

To show about what may be expected in motor efficiency, the accompanying table has been prepared, giving watts lost in armature winding, magnet coils and for friction, local currents and hysteresis combined, also full load efficiency for motors from ½ to 10 h.p. as commonly made by first class concerns.

Poorly made motors of much worse efficiency than given in the table can be found on the market, and it is also true that motors of better efficiency can be had, but the table is intended to show efficiencies which any well built motor may be expected to show.

Watt losses in armature and magnet windings shown in the table are what the writer knows to exist in many motors now on the market, by actual computations based on the resistance of these windings.

Watt losses due to friction, hysteresis and local currents are based on data from various sources and correspond very nearly with many actual tests.

Motors of various makes will be found to vary in relative watt losses of armature and magnet windings; some motors, for example, have a much larger loss in the armature coils than above indicated, with a corresponding decrease of loss in the magnet winding.

Motors with windings proportioned in the last named manner are intended to give a high efficiency at partial loads, but there is more tendency to spark on change of load and overload than with the more usual proportion of windings.

As may be noted from the table, losses due to hysteresis, local currents and friction are in most cases greater than the winding losses, contrary to the more common idea, and in the matter of local currents and friction some gain in efficiency may be expected.

DATA OF SMALL MOTORS.

| Watts Delivered to Motor. | H. P. Delivered by Motor. | Watts Lost in Armature Winding. | Watts Lost in Magnet Coils. | Watts Lost Friction Local Current Hysteresis. | Total Watts Lost. | Full Load Efficiency. |
|---|---|---|---|---|---|---|
| 548 | ½ | 40 | 44 | 91 | 175 | 68% |
| 995 | 1 | 65 | 60 | 134 | 249 | 75% |
| 1,913 | 2 | 110 | 99 | 212 | 421 | 78% |
| 2,798 | 3 | 180 | 110 | 320 | 560 | 80% |
| 4,648 | 5 | 170 | 176 | 473 | 819 | 82% |
| 6,661 | 7½ | 220 | 220 | 626 | 1,066 | 84% |
| 8,674 | 10 | 260 | 264 | 690 | 1,214 | 86% |

Cost of construction is the present, and seems likely to remain in the future, the practical limit of efficiency, the fact being that present efficiencies can be somewhat increased if expense is not regarded.

In the case of a 10-h.p. motor, the efficiency can be readily raised to above 90 per cent, but at a considerably increased cost.

As motor users come to understand the relation between motor efficiency and cost of power, efficiencies may be expected to approach the absolute limit.

## COMPRESSED AIR AND LIQUID AIR.

The scope of electrical engineering is so great that a new development in almost any branch of the mechanic arts is of immediate interest to electrical engineers, hence the interest taken by this class in the recent revival of compressed air traction in New York City, following as it does so closely upon many optimistic statements about liquid air, a commodity so new that fallacies concerning it are difficult to disprove. In the storage of power by means of compressed air, the air is, as a rule, compressed to several thousand pounds per square inch in order to economize space. It is then expanded through a reducing valve to a pressure of perhaps 150 or 200 pounds before it is used.

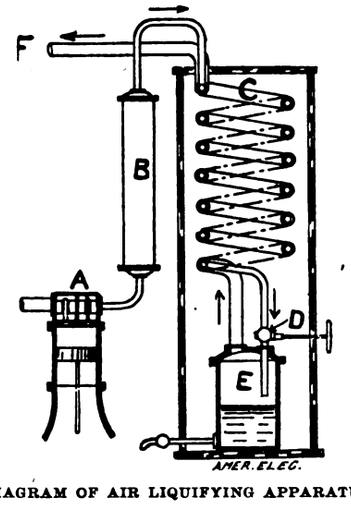

DIAGRAM OF AIR LIQUIFYING APPARATUS.

With liquid air it will be possible to economize to a far greater extent in space, and that without the use of heavy and expensive steel flasks and the dangers that accompany extremely high pressures. The air that could be compressed with a pressure of 1000 pounds to the square inch into a tank with a volume of 11½ cubic feet, would only fill 1 cubic foot in the liquid state and could be kept in the latter under no pressure but with a free vent to the atmosphere, the vaporization being minimized by careful heat insulation, which would be necessary on account of its extremely low temperature, which would be about 300 degrees below zero F.

The extravagant claims recently made concerning the power which liquid air will exert give a false idea that it contains a great amount of stored energy, which is quite the reverse of the case, the liquid state representing the absence of energy from a given amount of air. To obtain any power from it it must necessarily be given heat just as water must be subjected to heat to obtain power for the steam engine, and just as compressed air is heated in the traction system now operated in New York City. The most glaring fallacy concerning air recently published is the statement to the effect that by using a certain amount of it in machines a greater amount can be generated. That this violates the fundamental law of conservation of energy has been vehemently stated, but is a difficult matter to prove, in that the liquifaction does not consist in giving energy to air, but in taking energy from it.

In a sense liquid air does generate itself when made by the process invented by Dr. Linde of Munich and adopted by Mr. C. E. Tripler of New York, the instigator of some of the fallacies. The general principle of the apparatus is shown in the accompanying diagram, where A is a pump compressing air to several thousand pounds pressure per square inch in the receiver B, where it is cooled and passed at full pressure into the inner tube of the concentric pair of tubes coiled as shown at C. The air is allowed to escape through a valve D, into chamber E, fitted with a vent through the outer tube of the coil, and thence to the atmosphere at F. By a well known law of thermodynamics, a perfect gas, when it expands without doing mechanical work as through an orifice, does not change in temperature, but if the gas is so compressed as to approach the condition of a saturated vapor, it will, when expanded through an orifice, be reduced in temperature. This is the principle of ammonia and carbonic acid gas refrigerating machines.

The cooled air escaping from orifice D rises through the outer tube of the coil and further cools the incoming high pressure air in the inner tube, which becomes still cooler in expanding through orifice

Digitized by Google

D, until finally the temperature becomes so low that part of the air expanding from D is liquified. It will be seen, however, that the liquifaction absolutely requires compression which absorbs power, and this power is enormously greater than any that can be obtained by the most perfect machine, utilizing all the power which the air would give in re-expansion to the atmospheric condition under normal temperature.

## LIGHTNING AND LIGHTNING ARRESTERS.

BY HENRY E. RAYMOND.

The discussion which has been started relative to the behavior of different types of lightning arresters, under certain fixed conditions, has proved very interesting to me, and I trust that others have also been interested to an extent which will warrant a rather more extended recital of experiments in this line, and the conclusions reached thereby. Some years ago I was interested personally in the disastrous effects of lightning on high tension lines, and came to the conclusion that either there was not enough known concerning the action of these discharges, or that what was known was insufficiently or improperly applied.

Most of the troubles were caused by using arresters with too great a striking distance, and conversely by the destruction from arcing of arresters having a low point of break-down. The conditions varied so greatly that it seemed impossible to strike the mean relation. After reading every thing I could find on the subject, I made a lot of crude and rather blind experiments, using the Leyden jar arrangements, as described by Prof. Lodge, and also using static electricity from belts in connection with condensers.

I tried the old idea of stringing two wires parallel, and grounding one. The grounded wire would divert a brush discharge from the insulated one, and diminish the volume of a disrupted one. Then I tried a lot of equally simple experiments with high potential and commercial frequencies. The whole lot did not amount to much, except in that they showed a difference between their results and the action of a line discharge, and consequently suggested doubts as to their value.

Th actual behavior of all my devices connected with an overhead line was very noticeably different from the results pictured by Prof. Lodge, and later by Mr. A. J. Wurts.

It was once stated to me that a high ohmic resistance in the shape of a tank of water, if connected directly from the line to earth, would tend to dissipate the charges on a line. I tried this, and found that unless the tanks were very large, or unless a prohibitive current leakage was allowed, there would be little tendency for any discharge to earth through the tank. A short length of tank in series with a gap, however, has done very effective work.

I let this experimenting drop for a year or so, and took notes on the action of a number of different types of arresters installed on working lines. The arresters were so situated that they could all be observed at one time from one point, and the discharges which passed through each counted and critically noted. It is the purpose of this article to compare the behavior of the sparks, which jumped the arresters, with that of artificially produced discharges, which were applied to similar arresters under similar conditions. The primary idea was not to find which of two or more arresters presented the least opposition to a disrupted spark, but to obtain sufficient data from which to draw reasonably correct theoretical inferences. Incidentally, it was expected that the best form of gap and path would be found, and that also it would be found to what extent the best forms were influenced by dynamo current, etc.

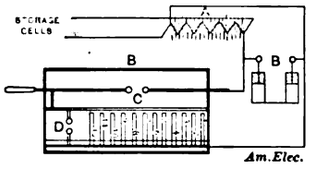

FIG. 1.—RESISTANCE FRAME, INDUCTION COIL.

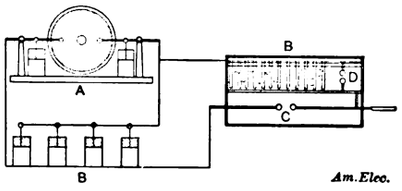

FIG. 2.—RESISTANCE FRAME, HOLTZ MACHINE.

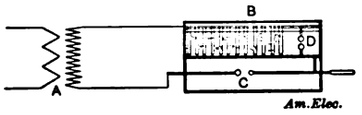

FIG. 3.—RESISTANCE FRAME, HIGH POTENTIAL TEST.

As may be seen in the cuts given herewith, the experiments were conducted along different lines and under several sets of conditions. The primary sources of electrical tension were an induction coil, a Holtz plate machine, and a high potential transformer. It was developed early that the number and disposition of Leyden jars did not materially affect the value of the tests. That is to say, that apparently the most trying conditions under artificial means of discharge was when but few jars were employed. Therefore, as a matter of convenience, the final experiments were all made with the jars arranged as in Fig. 1.

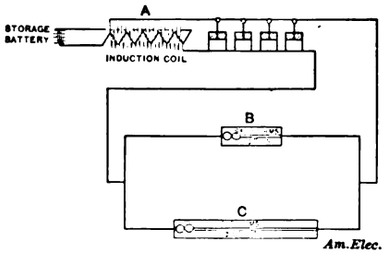

FIG. 4.—ARRANGEMENT TO TEST RESISTANCE OF VARIOUS LENGTHS, FORMS AND VOLUMES.

In order to determine the relative impedance or reactance of ohmic resistances equal in length, but unequal in resistance, when placed in the path of a disruption discharge, the device B in Fig. 1 was made. The same arrangement was tested as shown in Fig 2 and Fig. 3. A is the source of energy; B, the frame holding the rods; C is an adjustable gap in series with the path of discharge, and D is an adjustable gap in multiple with the resistances. These resistances, which varied from 10 ohms to 5000 ohms, were arranged parallel to each other. One end of each was joined to a common connection, the others separated by small equal distances from a rod which constituted the other side of the gap under test.

It is interesting to note that in these cases the sparks when once started were identical for respective resistances. The very high frequency of the Leyden jars discharge and the low frequency transformer spark were both affected by the resistance in that the volume or quantity of discharge was for each rod inversely proportional to the resistance. The Leyden jar discharge took a longer no-resistance gap than the high potential transformer discharge did. The rods of lower resistance, from 10 to 60 ohms, appeared to have about equal effect on the discharge used.

Using the Leyden jars, the gaps were then varied so as to obtain equivalent striking distances, and as near equal volumes of discharge as possible. It will not be necescary to give all the figures in detail. The highest resistance had in series with it a gap one-third the length of the metallic gap, and one-half the length of those in series with the lower resistances. The longer the gap at C, the greater was the voltage and quantity of the discharge, and the more marked was the opposition of the resistance to the passage of the discharge.

The arrangement in Fig. 4 was used to test the relative opposition of resistances of various lengths, forms and resistance. It was found in one case that when C held a resistance of 340 ohms 24 ins. long it offered as great a resistance as did B when it held a resistance of 2500 ohms 6 ins. long. This increase of impedance due to length is especially noticeable in the use of Leyden jar discharges. To a lesser extent it is noticeable on line discharges, as evidenced by the non-success of long tanks to ground, and the success of same when shortened and put in series with a gap. A considerable length will tend to retard the discharge if it be of equivalent resistance. An exceedingly small surface, however, will do so to a greater extent.

It has been asked lately why discharges do not "leak" away from a railway line through the car lamps. Probably for the same reason that my line discharges would not pass through the long tanks directly to ground. The length is too great for the resistance and cross section and corresponding surface. In spite of this, though the discharge frequently passes

Digitized by Google

through several lamps, short-circuiting the others, I will venture to state that there are more instances of this than of motor burn-outs.

The natural conclusions which would be drawn from the results of these experiments are that where a resistance is placed in the path of a discharge, it offers a choking effect, and tends to impose a greater opposition than a certain relative gap would; and that an arrester containing in its circuit an ohmic resistance would be less effective than one consisting solely of metallic discharges. The suppression of the dynamo current must be provided for, however, and this in the no-resistance types necessitates a somewhat longer gap. There are, of course, certain relative values for resistance and gaps in parallel to obtain equal sparking conditions, but these values vary so much with the nature of the discharge that no definite relation can be determined from these tests for the practical conditions of service.

Besides the action of varying discharges influencing the relative proportions of resistance and gap in parallel, is the very important factor introduced by the size of machines. We all know that an arrester may be designed which will readily prevent passage of current from a small dynamo or plant, but which, when placed on a circuit operating from large ones, will hold an arc every time.

A non-arcing arrester will interrupt an arc from moderate sized machines with three gaps 1/64 inch for each 1000 volts. In order to interrupt an arc backed by several thousand kilowatts this same arrester will often need as much as from 5 to 8 gaps for each 1000 volts.

The arrester with resistance in circuit has the advantage in that the resistance practically eliminates the factor which the size of plant kilowatt capacity introduces.

While it is probably true that these little experiments may give us an idea as to the possible action of an arrester on a line wire in commercial operation, it is not likely that they will prove in any way conclusive. It is a dangerous matter to jump at conclusions when considering such an agent as lightning and its effects, and, recognizing this danger, I have spent a number of years observing, at all times of the day and night, the actual behavior of discharges from lines when in operation and when idle, and have collected a considerable amount of data on the effects which resistance, different gaps, air, mica, etc., have on the visible action of electrostatic discharges. Comparison between these results and those from the artificially produced spark showed a marked dissimilarity.

It was easy to prove that the Leyden jar discharges were of high frequency, and to note the effect this frequency had upon the various experiments made. The rapidity of oscillation naturally made the insertion of resistance a marked factor, and the absence of inductance in any amount made more pronounced the tendency of the discharge to jump the metallic gap with no resistance in series, in preference to one which contained a certain ohmic resistance. I believe that the common idea that lightning discharges possess enormous frequency of oscillation is a fallacy, and that the Leyden jar discharges have a frequency far in excess. It seems probable that under most conditions atmospheric discharges have a frequency of but a few thousand periods, or even a few hundred, while these condenser ones have oscillations of several hundreds of thousands.

It was noticeable in the Leyden jar tests that the lower the voltage of discharge, the less was the factor of impedance introduced by the resistance. That is to say, the less the exciting current and the shorter the series gap, C, the less the tendency to avoid the resistance; and conversely, the greater the quantity and voltage of discharge, the greater the tendency to avoid resistance. Now, from these facts we may deduce readily the following ideas:

First, that discharges of low frequency are much less affected by resistance than are those of high frequency, and, as a corollary, a discharge but slightly opposed by resistance is presumably of low frequency. Second, the greater the capacity of the circuit, the less resistance influences the discharge. Third, that a circuit containing great inductance and capacity will permit of discharge but slightly affected by the resistance in circuit, if in short lengths. These hold good for moderate lengths of resistance with reasonable surface, and are influenced by the amount of resistance in ohms much less than by the length of the same.

As to the conditions tending to produce these factors, we may judge with considerable accuracy. We know that the higher the capacity and self-induction of a condenser and the connecting circuit the lower will be the frequency of the discharge oscillations. We know that the larger the capacity of the condenser, the lower will be the voltage a certain charge can produce.

With these considerations in view, we can hardly place much value upon such laboratory experiments as I have described here, and such as have been referred to from time to time. The circumstances attending the action of long overhead lines would be difficult to approximate in the laboratory. We might obtain a relative capacity and an equal induction, but not an equivalent one.

We could not approximate the many external influences. We could not produce a discharge similar to atmospheric ones, in their low frequency, without a capacity in condensers and an inductance which would be impracticable from their distributed condition.

One might naturally ask here, "why should I not place my confidence in laboratory tests, and what known reason is there on which to base distrust of their value?" The best answer I could give would be a description of some observations and experiments I have made with arresters connected to a line. It will not be necessary in this case, any more than in the description of the jar experiments, to go into any great detail, nor to give many of the figures and tests, so I will just give a few of the most distinctive ones.

One of the first to suggest itself was the arrangement shown in Fig. 6. The purpose of this was to see what benefit a reactance coil was in a line wire. It had been supposed that this coil would offer a great impedence to the supposedly high frequency discharges. It apparently did nothing of the sort, for, with no machine on the line at this point, the discharge would jump both arresters about equally well, although the arrester B was the choice. When the machine was running, the tendency for B to discharge was far greater, and B would often rapidly discharge, while A was entirely inactive.

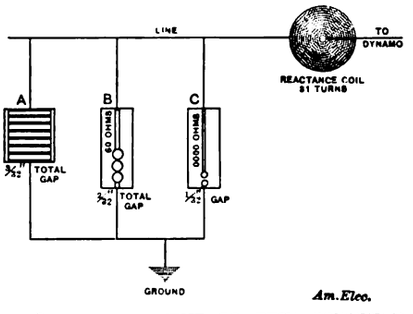

FIG. 5.—ARRANGEMENT TO TEST COMBINED EFFECT OF RESISTANCE AND GAP.

This I lay to the fact that the capacity of the dynamo with the small inductance of the section, as compared with the whole line, produced discharges of high frequency, which were beaten back from A by the coil in the line, and had to pass B. It is not difficult to picture the possible result of the practice, now so common, of putting in choke coils indiscriminately and providing no discharge path from the dynamo side of the coil.

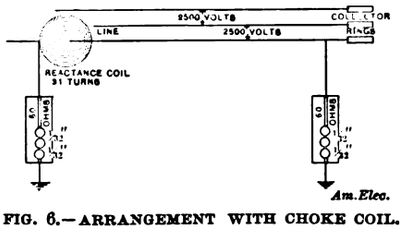

FIG. 6.—ARRANGEMENT WITH CHOKE COIL.

Fig. 5 shows an arrangement designed to test the combined effects of resistance and gap form. As may be seen, A has six gaps 1/64 in. each, and no resistance; B has two gaps 1/32 in. each and 60 ohms resistance, 6 ins. long, ¼-in. diameter; C has one gap 1/32 in. and 6600 ohms in series.

In a future issue the results of experiments on lines in service will be recounted and discussed.

**The Sale of the Fort Wayne Property.**—The Fort Wayne Electric Corporation's plant and other property were purchased by the General Electric Company at the receiver's sale on April 18th for $356,400, of which sum $185,000 was returned to the General Electric Company for the debenture bonds of the Fort Wayne Corporation which it held. The balance, with collectable accounts, etc., amounting to $150,000, will be disbursed in part payment of the indebtedness, which is $900,000.

## ECONOMIES FOR SMALL MANUFACTURERS.

BY LYMAN C. REED.

Some very recent and glaring examples of the energy wasted through ignorance, by small manufacturers, having come under the notice of the writer, it seems that a profitable field for the consulting engineer should be open in this direction.

Small manufacturers when within reach of a central station, as a rule, prefer electrical energy to other forms, as it is the cleanest and easiest to handle, and in most cases by far the cheapest. That the proprietor fails to study his needs before buying his motor or installing his machines and shafting, is frequently the cause of a certain waste of energy which shows each month on the meter bills, but is not otherwise perceptible. It is this class of installations which are discussed below, with the endeavor to point out the main errors which occur in the original setting up of the machinery and motor.

We will take, for example, the case of a small printing establishment which came under the writer's direct notice, and give in detail the results accomplished by a careful test of the machinery and motor. The machinery consisted of three small "donkey presses" belted to one line of shafting, and capable of being run by foot power if the current from any cause failed. To the same shaft was belted a countershaft, from which a large press was operated. The belts were abnormally heavy, being from 6 to 8 inches wide, the proprietor evidently being under the impression that he was using a great deal of power.

The motor, a five h. p. Eddy bipolar 500-volt machine, ran at 1800 r. p. m. and was belted to a counter-shaft, which, in turn, ran the main line of shafting at 150 r. p. m. The efficiency of the motor was found to be 80%, and the total work required of it was 2.3 h. p., including the amount consumed in running the motor. It was found that 1 h. p. was being used by the motor alone, and 1.3 h. p. for the total work required, with everything running at full load. The shafting was found to consume 0.6 h. p., leaving only 0.7 h. p. to represent work done. The enormous loss is readily appreciable, as only 30% of the power consumed was available in actual work.

An efficient remedy was applied by cutting down the belts and changing the motor from 5 h. p. to 2 h. p. The small motor had the same efficiency as the larger one, namely 80%, and ran at 1950 r. p. m. Pulleys of the same size were used, so that 8% more work is now done in the same time. The 2 h. p. motor requires only 0.4 h. p. to operate empty, thus saving 0.6 h. p. and bringing down the total load to 1.7 h. p., which is well within the rated capacity of the motor. As the large press is used only for a few hours per day, the average working load is about 1.2 h. p., against a former average of 1.8 h. p., giving a net saving of 33 1/3% in the operating expenses of the installation, with 8% more work accomplished. A total saving of about 40% is made by the change. The shafting and machinery were all in good order and apparently, to the proprietor, everything was ship shape. This illustration is only one of the many which come to the writer's notice and which emphasize the fact that a little money spent at the start in obtaining expert advice would, in the end, very greatly benefit the manufacturer.

Shoe manufacturers, as a rule, use motors often of twice the capacity they need, simply because they are ignorant of the amount of energy required for the machines they have. The machines may be all labeled with the amount of power required to run them, and in figuring up the size of motor they wish to buy, these amounts are generally added together to obtain the size required. As a matter of fact the period a machine is not in use equals and often exceeds the time it is running, and the general average where a large number are running is about half the rated output of the motor.

An illustration will probably be the best way of clearly showing the losses incident to lack of forethought in this direction. A shoe factory, running some 20 machines for the various processes of shoemaking, installed a 20 h. p. multipolar motor of a standard make, running at 850 r. p. m. The load, when everything was on loose pulleys, averaged about 5 h. p., including the losses within the motor.

The general operating load averaged from 7 to 10 h. p., never going above the latter figure. The motor, running empty, took 2.66 h. p., showing that its efficiency had been sacrificed to speed. The number of hours the motor ran was carefully recorded and it was found from the record of a Thomson recording wattmeter that the average throughout the month was 8 h. p. The efficiency of the motor under this load, therefore, falls as low as 66 2/3%.

The prime remedy to be applied in a case of this sort is to install a motor of 10 h. p., with an efficiency of 90%, which is easily attainable by increasing the speed to say 1500 r. p. m. A total saving of 21% is accomplished at the average load of 8 h. p., and 23 1/3% if the load averages 10 h. p.

On an average net bill of $100.00 per month, the amount saved by substituting the 10 h. p. motor for the 20 h. p. is $250.00 a year beside the first cost of a 10 h. p. motor being about 1/3 less than a 20 h. p. The average manufacturer without a mechanical or electrical education is completely at the mercy of contractors, who, of course, try to sell as large a motor as possible and put up as much shafting and pulleys as they can well crowd in.

Numerous examples could be given of first class installations where all the machinery and apparatus were the best obtainable, and yet certain wastes were taking place which could in no wise be ascertained without a thorough test. It is almost safe to say, and we do not say it without ample data at hand to prove the assertion, that an average of 15 to 20% can be saved on the common run of installations of a similar character after carefully looking into the conditions which exist.

A prolific source of wasted energy was the now almost obsolete belted elevator where the motor and shafting ran all day irrespective of the service required of the elevator car. As high as 90% of the energy used has been found to be consumed in simply running the motor and shafting.

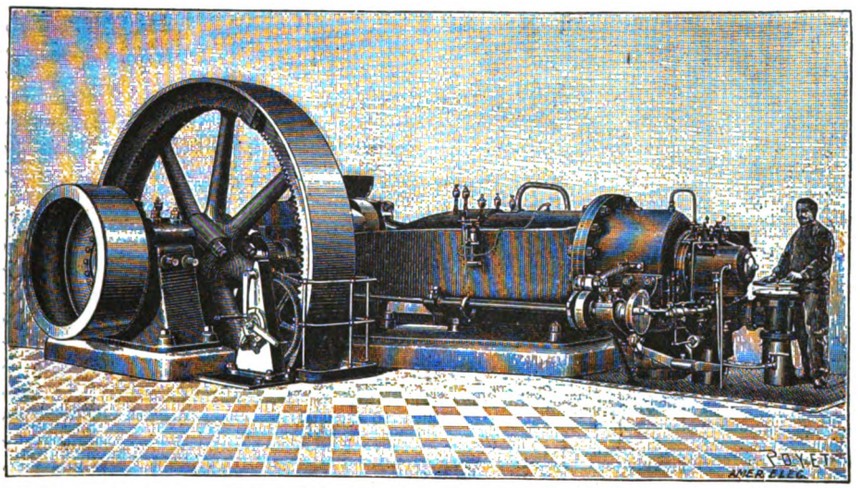
As a rule what goes up in an elevator eventually comes down, hence the only energy that should be required is the overcoming of the frictional resistance occasioned by the movement of the car and its necessary appointments. This of course has never been fully attained, but the present method of direct connection reduces the loss to the minimum obtainable from smooth running and well designed machinery.

Manufacturers are sacrificing to slow speed the efficiency of their motors, as recent tests on some of the best makes show. A bipolar 18 to 20 h. p. motor running at 1500 r. p. m. should not take over 1 h. p. running empty, if well designed, and the increased power consumed in reducing the speed by a countershaft—should space for a large pulley be lacking—should never exceed 0.2 h. p.

The essential point in buying any motor is to ascertain its efficiency and then get as small a motor as possible to do the work required. A slight overload for a few minutes, or even an hour's duration, will not hurt the machine, and the nearer the motor is worked to its full capacity the greater amount of available energy can be utilized at the machines.

The cheapening of a product always produces an increased demand and more universal application, and along these lines it will be found of great benefit to the central station to help as far as possible in seeing to it that the ignorant consumer is not uselessly wasting the energy for which he pays.

Many complaints by consumers are made in a general way on high bills. The meter is tested and found correct, no salient defects are noticed by the adjuster, and the payment of the bill is demanded on its merits. A little care and a close attention to the consumer's needs by the central station would, in many cases, prevent hard feeling and at the same time secure an ardent advocate of the use of electricity as a motive power.



The many uses to which electricity is put in the running of all sorts of machinery make the study of efficiencies and the resulting economies in operation a profitable as well as fascinating one. The kaleidoscopic nature of the problems presented keeps the electrical engineer constantly on the alert and makes the time-worn battle cry, "A penny saved is a penny earned," the slogan of the onward march of electrical development.

# Among our Foreign Contemporaries

**Electrical Energy from Blast Furnace Gases.**—Much has been written lately in the foreign journals calling attention to the enormous waste of energy in the gases which escape from blast furnaces for the manufacture of iron from its ores. These wastes are so enormous that the power from a few furnaces would be enough to run quite a large central station. Not only is there a waste in the gases which escape unused, but those that are used for heating boilers are also largely wasted because they are not well adapted for running steam boilers. A recent article by Mr. Witz in "L'Eclairage Electrique" gives some figures which are of interest and give a very good idea of this enormous waste. A hundred ton furnace, for instance, wastes about 2000 h.p. in the gases, part of which is used for auxiliary machinery, leaving, however, an enormous amount which is absolutely wasted and could be utilized by electrical transmission. Furnaces of 150 to 200 tons capacity are not rare, there being one in America using even 700 tons every 24 hours, in which the material for combustion is reduced to three-quarters or a ton per ton of iron. A thermic balance sheet is given in which the heat units for 24 hours have been worked out, which shows that the charge of about 92,000 kg. of coke contains 629 million heat units; to this must be added 416 million which is recovered from the re-heaters, making a total of 1045 million. That consumed by the chemical reactions in the furnace amount to 182 million; that utilized for re-heating 473 million; that utilized for the production of steam 50 million, leaving about 340 million calories, or over half that in the coke, as wasted energy escaping with the gases. The portion which develops steam for the engines is utilized very uneconomically at the rate of at least 22 cu. m. of gas per indicated h.p. hour, which is at the rate of only about 3 per cent. efficiency. With the aid of gas engines only about 3.5 cu. m. of these gases is required per h. p. hour, and at this rate, if the gases now used in the boilers are consumed in gas engines instead, the horse power obtained would be 2381, instead of 380, as at present with steam engines. This would involve the use of very large gas engines, which have heretofore been considered impracticable, but they are now being built for 200 and even 500 h. p., the latter with double cylinders being readily increased to 1000 h. p. An engine for 180 h. p. at 87 per cent. ignitions is shown in the adjoining illustration, which will give some idea of the size.

The diameter is 800 mm., the stroke one meter and the speed 105 revolutions; it appears that there is one ignition for every four movements of the piston. It has run continuously for 120 hours without a single premature ignition. The tests made were made by that writer himself, who is an authority. It is proposed to use the remaining 1900 h. p. from a hundred ton furnace to operate the dynamos of a central station for distributing the power. A group of such furnaces is therefore quite as valuable a source of power as a large waterfall. It is even argued that when these gases are utilized the iron produced by the furnaces may be considered as a mere bi-product.

A GAS ENGINE USING BLAST FURNACE GASES.

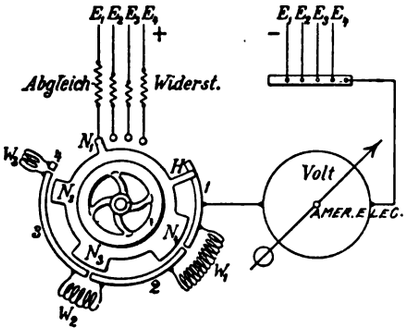
**Wehnelt Interrupter for Induction Coils.**—Much has appeared in the foreign journals concerning this simple and curious device for replacing the make and break of an induction coil; it was fully described in the March number of the "American Electrician." Among all that has been published the following extracts may be of interest: A very curious result was obtained when an ampere meter for measuring the primary current was placed in circuit, it was found that when the induction coil was short-circuited, that is, cut out of circuit, the current became very much less, an apparent paradox. Thus with 70 volts the current was 20 amperes when the coil was in circuit and only 15 when the primary was short circuited; with 110 volts the difference was even greater, the current being 25 amperes with the coil in circuit and only 4 to 5 when it was cut out. Numerous observers have experimented with alternting currents and it was found that the interrupter acted quite well with such currents, but it seemed to operate only with the waves in one direction and then only at the moment when the current was sufficiently great. The effect is therefore not as good as with direct currents, but it has the advantage that the secondary current is similar to that obtained when a direct current is used in the primary, that is, for vacuum tube experiments it is practically a unidirectional current; the apparatus therefore enables a pulsating direct current to be obtained from an alternating one, although not very efficiently. Some observers found that the apparatus is apt to become fatigued, that is, after running a while it refuses to operate properly; some believe this is due to the heating of the liquid, while others found that this was not the case, as it became fatigued even when the liquid was cooled with a bath. One experimenter found that the fatiguing could be remedied by momentarily reversing the current. As the glass tube in which the platinum wire is fused is apt to crack, it was considered better by some to use an ebonite tube and pass the platinum wire through a small hole in the bottom. Another method would be to use very thin glass. It also seems better to make the platinum as short as possible and use mercury or a thick copper wire leading to the inside end of the platinum, in order to carry off the heat. When the self-induction is diminished the frequency rises and with no self-induction at all the apparatus will not work. It was found that the platinum point had a capacity like a condenser and that this, together with the self-induction, produced what is known as a resonance effect. This would mean that a careful adjustment of the self-induction may be required to produce the best effects. Frequencies as high as 4000 were obtained by one experimenter and as low as 2 or 3 per second by another. It was also found that the apparatus would work equally well with a solution of potash instead of sulphuric acid, the advantage of that being that an iron vessel may then be used for the solution, acting at the same time as the other terminal in the place of lead. Two interrupters in a series act in general like a single one of half the capacity. The apparatus works better when a stream of acid flows past the anode to remove the bubbles. A somewhat surprising result was obtained in that the spark length of small coils was very greatly increased, while with large coils the gain was not nearly as great. With small coils giving 6 c. m. sparks, for instance, it was possible to obtain two and even nearly three times the spark length, while with large coils

Digitized by Google

there appeared to be a maximum spark length of 20 c.m.; it was likely, however, that this may have been due to the fact that the most favorable conditions were not obtained; it is argued that the primary current does not have time to reach its maximum in those large coils before it is interrupted and therefore the induction is not so great. A modification, which scarcely bears much resemblance to the original, was suggested in a London paper, in which a large globule of mercury was substituted for the lead plate, distilled water for the acid, and an aluminum wire for the platinum, the wire being brought close to the mercury. It is said that the mercury will periodically contract and thus operate as an interrupter. It is claimed that this form will operate with a low voltage and a small current.

---



**Induction Coil Interrupter for Alternating Current.**—Although an alternating current seems at first sight to be very suitable for the primary of induction coils, yet it has not been found to be so in practice and those who have access to an alternating current lighting circuit only, for operating their coils, are compelled to use batteries or accumulators. An ingenious form of make and break for such cases was recently described by Mr. Villard in the "Revue Generale des Sciences." It consists essentially of a tuning fork, which in the usual way with sliding weights is tuned so that it vibrates synchronously with the alternating current of the circuit. The end of one prong of the fork has a stiff wire attached to it, which passes between the poles of a permanent magnet, which should be made of a thick, hollow cylinder, opened so as to present long narrow pole faces parallel to which the wire passes. The alternating current is passed through this fork and the wire, which will cause the fork to vibrate and the end of the wire is then made to dip into mercury; the current will thus be broken only when in one direction and the coil will therefore act as though it were supplied from a continuous current source.

---

**High Resistance Wire.**—Another new alloy for high resistance wires is being brought out in England and is mentioned in a recent note in the London "Electrician." The tests made by a certain standardizing institute showed a specific resistance of 85.13, presumably microhms per cu. cm. at 20°C; the temperature coefficient is 0.0007 and the specific gravity 8.1. It is claimed that it can be heated to 650°C wthout fear of injury. This specific resistance is about like that of the Krupp alloy and is considerably higher than that of manganine.

---

**Measuring the Voltage at the Ends of Feeders.**—When, as is is usual in a central station, a number of feeders run out in different directions, all being connected in multiple, and it is then desired to indicate at the station the mean voltage at the distant ends of these feeders, some difficulties arise. It has been claimed that if the potential wires which are used for that purpose and run from the station to the ends of the feeders, are all made to have the same resistance, and if the station ends are then all connected to the same voltmeter, its reading will be the mean of the different voltages at the ends of the various feeders. This, however, is shown by Dr. Teichmueller in the "Elektrotechnische Zeitschrift" leads to errors, which, in an example, was shown to be over one volt for ordinary 100 volt circuits, an error which is too great to be neglected. Still greater errors are produced if that same voltmeter be used also with a single pair of potential wires, or worse yet when it is used for measuring the voltages of dynamos or bus bars at the station; errors of 5 to 6 per cent. can thus be made, the reason being that the potential wires have certain resistances and that by using more or less of these or none at all, the indications of the voltmeter will be different. He then explains how to overcome this by means of a switch shown in the adjoining cut, the principle of which is simply

A PILOT WIRE EQUALIZER.

that the instrument is calibrated once for all with a certain external resistance in series with it, say about 100 ohms; the external resistances are then so arranged on this switch that in any case the external resistance is equal to the same 100 ohms whether one, two or more pairs of potential wires are used. In the illustration shown there are four sets of potential wires; all the negative ends are connected together to one pole of the instrument, while the positive ends are first connected to equalizing resistances, which make the resistance of each pair equal to that of any other. The switch shown below these is arranged, as will be seen from the figure, so that none of its three resistances are in circuit when the voltages are measured at any single pair of wires, as is shown in the position indicated. When the switch is moved to the right so that the lug N comes in contact with the ends of the potential wires, thus connecting any two of them together, the resistance $W_1$ will be in series with the volt meter. Turning it still further so that three are in multiple, the second resistance will be switched in circuit and so on. This apparatus has been adopted by one of the leading companies in Germany.

**Insulation Recording Instrument**—An instrument for periodically recording the insulation resistance of a network of wires, recently devised by Travilleur, is described very briefly in the London "Electrician." It is based on the principle that when a voltmeter is connected between one of the wires and the earth, and a reading taken, after which it is shunted by a known resistance and another reading taken, the insulation resistance of the network may be calculated from these two readings, knowing the resistance of the shunt and the voltmeter. The instrument is an ordinary voltmeter whose shunt is automatically switched into circuit once an hour by the same clockwork which revolves the drum on which the record is made. The resistance of the voltmeter and shunt in this case were 1200 and 500 ohms respectively for 200 volts between the outer wires, or double this for 440 volts between the outers. It may be used for two or three wire systems, but unfortunately it is limited to those cases in which the middle wire is not earthed.

---

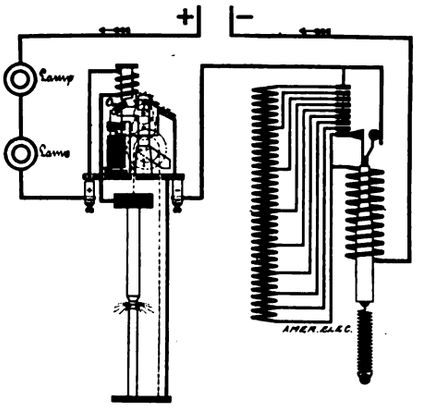
**A Simple Way of Measuring Illumination.**—In a recent paper read before the French Academy of Sciences a very simple and convenient method of measuring illumination, such as that of daylight, was described; it has the advantage that no standard lamp need be used, but, on the other hand, it gives only relative values and requires the use of sensitive paper. The apparatus consists of a box having a succession of any desired number of holes; the first is covered with a single film of collodium, tinted with a coloring matter called aurentia; the second has two such films, the third three, and so on. Underneath these is exposed a strip of sensitive paper, that made of prussiate of iron being thought to be preferable. The exposure must, of course, be for a definite length of time in each measurement. After developing the images of these holes will have various degrees of density of color. If the holes have numbers marked on the films, then the highest number which is readable on the sensitive paper indicates the relative illumination. By standardizing such an apparatus with a standard source of illumination it might be possible to obtain quite fair results. It would seem, however, that such a method may be largely dependent on the color of the light and the chemical rays which it contains, and that it is not dependent alone on the true illumination in foot candles. The rays from the arc light, for instance, are somewhat different in that respect from those of the sun; for relative measurements, however, of the same source of light, quite good results might be obtained.

---

**New Method of Compounding.**—What seems to be a rather interesting and novel method of compounding was recently devised by an English electrician named Sayers, and consists in the use of a third brush, the field being excited between one of the main brushes and this third brush, which is placed a short distance from the

Digitized by Google

other main brush. It is claimed that such a machine will be self-regulating for voltage at different loads and that it may even be made over-compounding. It was natural to suppose that this would produce inequalities of the field and that there would be bad sparking under this third brush, but Mr. Feldmann, a German engineer, recently made a thorough investigation, described in the "Elektratechnische Zeitschrift," in which he found that the claims were substantiated, that over-compounding is also possible and, what may seem surprising, there was no appreciable sparking under the third brush; this brush was made of carbon. The regulation may be changed from constant voltage to over-compounding by a slight movement of this extra brush.



---

**Increasing the Torque and Maximum Load of three Phase Motors.**—In an interesting paper by Mr. Marcher, in the "Elektrotechnische Zeitschrift," he shows that with the same iron framework the starting torque, the maximum torque and the maximum load which will cause the motor to stop, are greatly increased by diminishing the impedance. He shows this analytically and then proves it in actual cases. By merely changing the number of windings on the stator in the ratio of four to three he found that the impedance at no load had diminished to about a half; that the best efficiency and power factor was then at about double the overload and that the maximum torque rose in about the same proportion as the impedance was diminished. The load which would cause the motor to stop was 3.8 times as great, and the motor would start with five times the load at the normal speed and load. The exciting current and that at no load, however, was increased at the same rate at which the impedance was diminished. Curves indicating how the output and torque varied with the current, showed that for the same current both these were increased to about double their former value. He also shows that adding resistance in the stator circuit of a short circuited motor for starting purposes, and the increasing of the air space, are both very poor methods.

---

**Arc Lamps on Incandescent Circuits.**—When arc lamps are run on constant potential circuits, such as those used for incandescent lamps, it is always necessary to insert a dead resistance in series with them. The reason for this is that most arc lamps regulate by the action of a shunt coil, the potential at the terminals of which varies for different currents; if it were not for the dead resistance this voltage would remain constant, as they are connected to constant potential mains; the dead resistance is therefore necessary to produce a variation in the voltage with the current in order to bring about regulation. Many attempts have been made to do away with this resistance, as it wastes about 25 to 30 per cent. of the energy in a circuit in which two arc lamps are connected in a series across 110-volt mains. It seems now that this important problem has been solved practically by means of a differential arc lamp which has been in satisfactory use to a large extent for some months in Berlin. With these lamps practically no such dead resistance is required, and therefore the energy is more fully utilized, with the great advantage that three lamps instead of two may then be connected in series across 110-volt mains. As will be remembered, a differential lamp is one in which the regulation is effected by both a shunt and a series coil, and any variations in the current irrespective of those of voltage, are then also used to operate the regulating apparatus.

A diagram of this lamp is shown in the adjoining illustration, in which three lamps are shown in series, of which one is represented with all the connections. It will be seen that the regulation is effected by both a series and a shunt coil and that there is, in addition, on the right,

A CONSTANT POTENTIAL ARC LAMP REGULATOR.

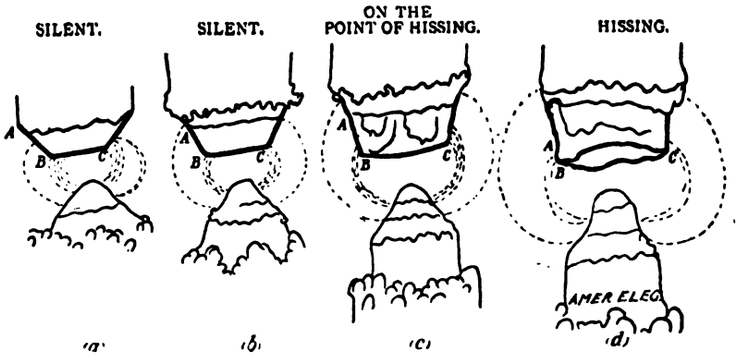
a dead resistance, which, however, is used only for starting, and is cut out by a movable core in the solenoid through which the main current passes; the resistance is therefore only in circuit momentarily, to prevent great current rushes. By using three such lamps in series instead of two of the ordinary form, the amount of light produced is increased in the ratio of about three to four; a room formerly requiring 12 lamps will then be equally well lit as far as the amount of light is concerned, by nine of the differential lamps, and, besides this, the amount of energy required will be less. When five or six lamps are connected across 220 volts instead of four, the increase of light is about 25 per cent. In that case it is better to use a dead resistance in each series, but merely for starting the lamps.

---

**Brushes Made of Alloys.**—Various alloys have been suggested for the material of brushes with the object of combining conductivity with as little friction as possible. The following alloys suggested by Boudreaux in the "Elektrochemische Zeitschrift" may be of interest. An alloy is made of copper with 0.20 per cent of bismuth, 0.30 per cent. of cadmium and 1.50 per cent. of antimony. These proportions may be varied depending on the purpose for which the brush is to be used; the quantity of the ingredients should be doubled, for instance, if the commutator is of a hard bronze—like copper alloy, and to be tripled if of steel. Copper brushes are said to generate much more heat by friction than brushes made of these alloys. The metals may either be melted together, as usual, or they may be mixed as fine powders and then compressed together, with the aid of heat, into the desired form and consistency.

---

**Interior Illumination.**—In many measurements of the loss of light due to the globes around arc lights, the amount of light given off in a definite direction is measured both with and without globes. It is evident, however, that this is not correct, and would give results which are far from the real ones. The globe diffuses the light so that most of it is not sent in one particular direction, as in the case of the bare arc. The only proper way to obtain the real loss in a globe is to measure the total spherical illumination in both cases and then compare the means. This was done by Mr. Utzinger, who found that the means in the two cases were 320 and 360, with and without the ordinary glass globe, but whether it was a milk glass or ground glass globe is unfortunately not stated. These figures show that the real loss is only 11 per cent., and not 30 per cent., as has often been stated. In a recent paper by him, reprinted in the "Zeitschrift fuer Beleuchtungswesen," he gives these results as well as some others which may be of use in determining the amount and distribution of light for interior illuminations. When the greatest possible uniformity in illumination is required he recommends using a white reflector below the lamp, reflecting all the light against the ceiling, from which the room is then illuminated. Usually in this method the arc is inverted; that is, the positive carbon is made the lower, so that most of the light will fall on the ceiling without reflection, but this, he says, produces an unsteady light, owing to the fact that parts of the carbon and impurities fall into the crater; he therefore seems to recommend making the upper carbon the positive, as usual, even though this involves a greater loss. This method of reflection on to the ceiling is also recommended in the case of enclosed arcs in which the arc is apt to wander from one side to the other, and by reflecting it all onto the ceiling the inequalities in the light are reduced. In this way even greater uniformity may be obtained in interiors than by daylight through windows. The following figures will give a good idea of the illumination obtained. The dimensions of the room were 13.6x7.10 x 3.5 meters high and there were two direct current open arcs of 12 amperes, with a reflector beneath, reflecting all the light to the ceiling, which presumably was white. The mean illumination was 66.5 meter candles and the variations were



Digitized by Google

only 25 per cent. above and below this. Daylight illumination gave 12 times this, but it is said that with 50-meter candles it is quite as easy to read as in daylight, while 10-meter candles is said to be the hygienic minimum. (A meter candle is the illumination produced by one candle at the distance of one meter.) The loss of light in this double reflection method is 35 to 40 per cent., but as globes would otherwise have to be used, it is really only 20 to 30 per cent. as compared with the usual arcs in globes. Practically, however, there is no difference in the amount of energy required, for the reason that when the illumination is uniform a less intense illumination is quite sufficient. When alternating current lamps are used in this way about one-third more energy is said to be required.

**Filament of Carbide of Silicon.**—The efficiency of an incandescent lamp, as is well known, depends on the temperature to which the carbon can be raised without too rapid deterioration; the higher this temperature the better the efficiency. It is therefore very desirable to discover some material which can stand a higher temperature than carbon. According to reports published in the English papers, such a material has been found in the form of a carbide of silicon from which lamp filaments are now being made for what is known as the "Premier" lamp. Liquid cellulose is mixed with powdered silicon and is made into threads which are carbonized at a very high temperature so as to cause the carbon and silicon to combine, and after the filaments are ready they are flashed, or treated, as it is commonly called, in a vapor of silicon and carbon, a process analagous to the usual treatment in hydrocarbon gases. It seems that such filaments also have the good property of not falling off in light or blackening the bulbs appreciably. According to a report by Prof. Ayrton such a lamp started at an efficiency of 2.8 watts per amyl-acetate candle, and ran for 600 to 800 hours without any material decrease in the light or efficiency and without causing blackening of the bulbs. This improvement is said to involve a saving of about 25 per cent. of the lighting bills, assuming, we presume, that the cost of the lamp and the price of the energy per kilowatt remains the same.

**The Hissing Arc.**—Those who have worked with arc lights have, no doubt, been greatly annoyed with the hissing state into which arcs are apt to fall. In a recent paper reprinted in the English electrical journals Mrs. Ayrton, with her usual thoroughness, describes very careful researches made with hissing arcs, the results of which will be of assistance to those working with arcs. For each length of arc she found that the voltage diminishes as the current increases, up to a certain point, when the arc suddenly becomes very unstable and then passes to the hissing stage when the current is further increased; for this stage, however, the voltage remains practically constant for all further increases of the current, meaning by voltage the difference of potential between the carbons. Among other things she shows the following: A silent arc may be made to hiss by increasing the current sufficiently; the largest current for a silent arc is greater the longer the arc; when the arc begins to hiss the voltage falls about 10 volts and the current suddenly rises two to three amperes; when the current is constant and the arc silent, it will hiss when shortened; and, finally, for the hissing arc the voltage is constant for any given length of arc, whatever the current. It was also shown that the largest current that would flow silently with any given length of arc was increased by using thicker carbons. For hissing arcs the voltage is the same for any given length of arc whether the carbons are cored or solid. There is a maximum value of the current for each pair of the carbons for sustaining a normal silent arc, and any currents greater than this will cause hissing, no matter what the length of the arc is. There is a straight line law connecting the voltage with the length of the arc, both with hissing and with silent arcs. Hissing will start only when the current is greater than it can be with any silent arc of the same length. The longer the arc the less will the voltage diminish in changing from silence to hissing. The smallest hissing current depends in a measure, also, on the voltage of the generator.

She also made an elaborate study of the form and appearance of the ends of the carbons in the normal and the hissing arcs, and found that the whole appearance of the crater changes with hissing; the chief change is in the positive carbon, in which the crater becomes larger while hissing, and extends up around the edges, or, in other words, in the hissing arc the crater becomes so great that it extends up around the sides, overflowing, as it were. Some idea of the appearance of the arc is shown in the adjoining illustration, in which the arc was kept at 2 mm. and the currents were 6, 12, 20 and 30 amperes, respectively, beginning at the left-hand side. The first and second arcs were silent, the third was at the point of hissing and the fourth was hissing; the extension of the crater, however, is not very clearly shown in these; but it will be seen how the positive carbon loses its point and becomes more cylindrical. When, therefore, the crater occupies only the end of the positive carbon, the arc is silent, but when it also extends up the side the arc will hiss; the crater, of course, becomes larger as the current increases. All these experiments refer to arcs which have been running for a long enough time to have all the conditions adjust themselves to that particular form of arc. By keeping the same length of arc and gradually increasing the current, a hissing point will always be reached. Moreover, the longer the arc the greater must be the area of the crater and consequently the greater the current before it extends up the side of the carbon; hence the longer the arc the greater will be the silent current. The thicker the positive carbon the greater is the largest silent current for any particular length of arc. She found, furthermore, that the actual cause of the hissing was due to the oxygen getting at the carbon and thus burning it instead of volatilizing it.

THE ARC IN VARIOUS CONDITIONS.

**Mechanical Traction in Paris.**—At the end of the last year there were not less than 31 lines in Paris on which 12 different systems of mechanical traction were used, six of which systems, or 13 lines, were electrical. Six of these are operated with accumulators, while the rest are overhead, conduit, surface contact or combinations of these. Paris is evidently going about it in the best way to find out for itself which is the best system. It is an expensive and slow process, but it is a safe one.

**Automobiles.**—At the end of a long series of articles discussing the various forms of automobiles, a Frenchman, Mr. Lavergne, compares the various kinds of power and concludes that steam will be used for general transportation, petroleum for touring, and electricity for the service in cities.

**A Proposed Electric Railway Up Mt. Blanc.**—Electric traction has simplified the problem of mountain railways so greatly that lines which were heretofore impossible, or at least impracticable, are now quite within the limits, and become merely a question of cost rather than one of surmounting engineering difficulties. That bold project, the line up the Jungfrau, in the Alps, which is now under

Digitized by Google

construction, has given rise to projects for ascending Mt. Blanc by an electric line. Most of these projects are rather illusionary, one of them, for instance, being to bore nearly horizontally into a mountain to a point below the top, and then ascending by means of an elevator and a vertical shaft. Recently a new and more reasonable project has been worked out by a Frenchman named Fabre, a brief description of which is given in "L'Electricien." The idea is to tunnel just below a ridge which extends along the side of the mountain, thereby avoiding the glaciers, which, of course, cannot be pierced, as they flow, and would have to be avoided by going under them, which is expensive; the glaciers, of course, do not pass over these ridges and are thereby avoided. Owing to the very high altitude, the workers will have to live on the mountain in building the upper end of the line, so as to get accustomed to the rarified atmosphere, and all material for that part of the road must be carried up; the lower end of the line will therefore have to be constructed first, and it would take a long time to complete. As the top of the mountain is a large mass of ice, it is impracticable to have a station there, but there is a convenient spot on a promontory, about 800 feet lower, to which it is proposed to run the line. The total length will be about 6 miles. It will be a rack and pinion line driven electrically, the power being generated by a neighboring waterfall. The total cost is estimated to be about two million dollars.

---

**Express Trolley Service in Germany.**—What is said to be the first express line operated in Europe was recently started between Duesseldorf and Crefeld in Germany. The speeds obtained, which are from 33 to 36 miles per hour, are not very high according to American ideas, all the more so as the average is only about 24, but in Europe, especially with an electric line, this is considered quite a high speed. The distance is only 12 miles and a trip with one intermediate stop is made in half an hour, a car running every hour. Instead of the trolley wheel, the well-known contact bar, which is used so frequently in Europe, is used. A novelty consists in the use of two trolley wires, presumably to assure better contact and avoid arcing. There is only one motor on the car and that is a gearless one of 40 h. p., the idea being to avoid the disagreeable noises due to the gearing. These data are taken from a very brief description in "L'Electricien."

---

**Electricity from Refuse.**—There has been considerable discussion and experimenting in England concerning the generation of electrical energy for a city, using as a source of power the city refuse, which must be disposed of, and includes ashes, garbage, sweepings, etc. Perhaps one of the best indications that such a system is not only promising, but is doubtless a success, is the fact that it has just been decided to erect a large plant of this kind for the Hackney Vestry on the recommendation of a very noted English engineer, Mr. Hammond. The plant can hardly be considered an experimental one, as the cost will be over a million dollars, and to start with two units of 1000 h. p. each are to be installed. Whether or not the statement made some years ago by a noted English scientist is true, that there is enough energy in the refuse of a city to light the whole city, remains to be seen, but that there is considerable energy in it seems assured. Such a plant, of course, must be credited with the expense which would be otherwise encountered in disposing of the refuse. It does not follow, however, that if such a plant is successful in England it would be so here, as the nature of the refuse seems to be quite different. The English, for instance, do not eat watermelons as freely as we do, and these, together with many other vegetables constituting our garbage, do not even contain enough energy to evaporate the moisture in them.

---

**How to Balance an Armature.**—As is well known, high speed armatures must be carefully balanced or they will produce vibrations; a crude, but a very common way, of finding out whether an armature is balanced is the usual method of laying it on two horizontal rails, when an unbalanced excessive weight will cause it to revolve. Mr. Hill, in the London "Electrical Review" shows by calculation and measurements how very unsatisfactory this method is, as an excess of weight by no means too small to be negligible, it not sufficient to produce movement when thus tested, or at least only when it is near the right or left-hand sides, where its leverage is the greatest. In a 16.5-inch armature, for instance, weighing somewhat over a thousand pounds and intended to run at 750 revolutions, he assumes that there is an excess of weight of about two pounds at the periphery on one side, and he find that this will produce a movement in the test, only when the excess of weight is within a comparatively small angle above or below the horizontal line. If not balanced, this weight is sufficient to produce a centrifugal force of 263 pounds, which would be sufficient to cause considerable vibration. He prefers mounting the armature on bearings, which are free to move, then driving it and finding the location of the excessive weight by means of a piece of chalk held near the revolving armature.

# The General Electric Company's Annual Report.

The seventh annual report of the General Electric Company for the year ending January 31st, 1899, was issued April 26th in anticipation of the coming annual meeting of the stockholders at Schenectady, May 9th.

The report of the First Vice-President, Eugene Griffin, covering the sales department, announces total sales as billed to customers amounting to $15,679,430, with a calculated direct profit of $2,584,896, the increase in orders amounting to 21 per cent. The orders received during the year amounted to $17,431,327, as against $14,382,342 for the previous year. Eight million four hundred thousand incandescent lamps were ordered during the year.

The report of the Third Vice-President, E. W. Rice, Jr., covering the manufacturing department, noted particularly the increase in the company's facilities. Among the additions to the works are the large iron foundry at Schenectady, described in the last issue of "The American Electrician"; the brick and steel machine shop, covering 3¼ acres, which is now being equipped with the necessary machinery, and extensions amounting to about 40,000 sq. ft. to other existing buildings in Schenectady.

At the Lynn Works the capacity of the steel foundry has been increased 40 per cent. A new building is now under way for the manufacture of meters and instru-

CONSOLIDATED PROFIT AND LOSS ACCOUNT OF JANUARY 31, 1899.

| DR. | | CR. | |
|---|---|---|---|
| Balance January 31 1898 (deficit)... | $11,725,561 | Reduction of capital stock, August 17, 1898 | $13,884,800 |
| Reduction of book value of patents, franchises and good-will, June 30, 1898. | 4,000,000 | Balance carried down | 1,840,761 |
| | $15,725,561 | | $15,725,561 |

ments with an area of 35,000 sq. ft. At the Harrison Works a new building containing about 60,000 sq. ft. will be completed this summer.

The area of the factory buildings now in use aggregates about 1,800,000 sq. ft. (41.3 acres enclosed) and the number of employees now at work is 9,000. The cost of additions during the year amounted to $387,353, and that of machinery practically $400,000, all of which was charged against the general earnings of the company, as were expenses for maintenance and repair, plus an allowance to provide for depreciation.

The report of the Second Vice-President, J. P. Ord, covering the finances of the company, is summarized in the accompanying balance sheet and statement of profit and loss. By vote of the directors there was charged to profit and loss on June 30, 1898, half the book value of patents, franchises and good will, or $4,000,000. There has since been written off the expenditures during the year in acquiring new patents and patent liquidations, $269,440, leaving the patents, etc., standing on the books as at the time of the previous report of $4,000,000. The book value of the plants also remains the same as at the time of previous reports, additions as above mentioned having been charged against profit and loss.

During the year the valuation of both common and preferred stock has been reduced 40 per cent. All the accrued dividends on the accumulative preferred stock from July 1st, 1893, to January 31st, 1899, were charged off against the surplus, leaving the latter at the figure of $156,571, as against a deficit of $1,840,761 at the beginning of the year. Following the policy of the last few years, the company has no notes payable, nor is there under discount any paper bearing the company's endorsement or guarantee. Sales have been maintained on the basis of short credit to desirable customers and all purchases have been paid for in cash. The company has not borrowed any money, but, on the contrary, has bought $300,000 of the $6,000,000 of its outstanding debentures.

## NOTES.

**Automobile Artillery.** — An English cycle corps is about to experiment with an electrical motor tricycle, carrying a Maxim rapid-fire gun, the weight of the gun and carriage being only 140 pounds.

**The Nernst Lamp in Practical Use.**— Negotiations are now progressing for a trial of the Nernst lamp for street lighting in Berlin, Germany. It is proposed to light some of the avenues in the Thier-Garten district by this means.

**Honor to Volta,**—The telegraph operators of Italy have asked for subscriptions from operators the world over for the purchase of a bronze crown to be placed at the foot of the statue of Volta in Como, Italy, at the time of the celebration, this month, of the hundredth anniversary of Volta's discovery of the primary cell.

**Inspection Trips of Electrical Students.** —The electrical engineers of the senior class of the Worcester Polytechnic Institute this year visit the following places: The Stanley Works at Pittsfield, Mass.; the power transmission plant at Mechanicville, N. Y., and the works of the General Electric Company at Schenectady.

**The Convention of the Southwestern Gas and Electric Street Railway Association,** which was planned for April 19th, has been postponed to May 17th on account of the prevalence of smallpox in the Southwest. It will eventually be held in Austin, Texas, and an electrical exposition will be held in connection with it.

**A Motor Carriage Exhibition at Berlin.** —During the month of September, 1899, there will be held at Berlin an international competitive exhibition of automobiles and motors and accumulators therefor. A progressive series of tests, races, etc., will be held in connection with the exhibition.

**Municipal Ownership of Street Railways in Detroit.**—By a bill recently passed in the State Legislature of Michigan, a commission of three, among them Gov. Pingree, has been appointed to buy for the city 180 miles of street railway in Detroit, now owned by Messrs. R. T. Wilson and Tom Johnson, as well as any suburban lines that they may choose.

**Power Transmission for Irrigation.** — For the lifting of water from artesian wells for irrigation purposes in Southern California, there is often required considerable power, which, because of the high cost of fuel, makes the wells valueless. The Mt. Witney Power Company of Visalia, Cal., has ordered a power transmission plant with a generating capacity of 1800 horse power, which will distribute power to five sub-stations in five separate towns, the power being largely used for pumping purposes.

**Central Station Development in Brussels.**—The municipal electric lighting system in Brussels, according to a consular report, is to install five new vertical engines of 1000 h. p. each. The city owns two plants, which are to be connected apparently by trunk feeders. It was proposed to erect a large central generating station outside the city limits, but this plan has been abandoned in favor of separate stations nearer the centers of distribution.

**Railroad Rates to the Coming Electric Light Convention.**—The Trunk Line Association has granted a rate of a fare and one-third, on the certificate plan, from all points in their territory and return, for delegates and friends attending the twenty-second convention of the National Electric Light Association, to be held in New York, May 23, 24, 25. It is expected that the same rate will be granted by the other railway associations at an early date.

**A Vertical Headlight Ray.**—Experiments have been made on a locomotive running between Cincinnati and Indianapolis with an electric headlight fitted with a mirror which deflects upward part of the rays issuing from the light. It is claimed that this beam is visible from a great distance and gives an indication of the approach of a locomotive often before the ray sent straight ahead is seen.

**Electric Vehicle Interests in Chicago.**— Mr. Samuel Insull, President of the Chicago Edison Company, has organized and is president of the Woods Moto-Vehicle Company, which will absorb the Fischer Equipment Company of Chicago and build self-propelled vehicles for business and pleasure, under the patents of C. E. Wood. The authorized capital is $10,000,000. It is said that the company will be closely affiliated with the Chicago Electric Vehicle Company, the incorporators of which are interested in the Chicago Edison Company.

**The Consolidation of Automobile Interests.**—A combination has been effected between the Pope Manufacturing Company and the Electric Vehicle Company, and through the latter with the Electric Storage Battery Company, for the manufacture and running of automobiles. A company called the New Columbia Motor Carriage Company, with a capital of $3,000,000, has been formed to handle the work. Under the consolidation the construction work will be carried on at the works of the Pope Company in Hartford, the batteries will be, as before, made by the Electric Storage Battery Company of Philadelphia, and the numerous sub-companies, which the Electric Vehicle Company, as a parent concern, has established throughout the country, will exploit and use the completed products.

**The Training of New York Motormen.** —The Metropolitan Street Railway Company of New York has a training school for the men who run the cars on its extensive underground trolley lines through the busy streets of New York City. The school occupies a loft in the car barns at 7th Avenue and 50th Street, equipped with dummy car platforms and their usual appurtenances. Here the men are taught the elementary steps in car control, as well as the rules and considerable information on car construction, wiring, details, etc. Three days are given to this kind of instruction, after which the student is sent out on a car with one of the old hands and only allowed to take a car alone after about three weeks of training. A sort of post-graduate course of lectures is given on Friday evenings.

Digitized by Google

**Exhibitions in Philadelphia.**—The Philadelphia Bourse has established an Industrial Exposition partly in the basement and partly on the 7th floor of the Bourse Building, the total space occupied amounting to 54,000 sq. feet. The exposition department hopes to get a great many of the exhibitors in the coming electrical show in New York to remove their exhibits permanently to this exhibition. The Philadelphia Commercial Museum and the Franklin Institute have also organized the Philadelphia Exposition, which will be held from Sept. 14th to Nov. 30th, 1899, on a tract of land 56 acres in extent on the west bank of the Schuylkill River. The buildings are so connected as to constitute one grand structure some 400x900 feet in extreme dimensions, inclusive of court yards.

**An Automobile Carrying Its Own Generating Station.**—A heavy motor truck for freight work in city streets has been built by the Fischer Equipment Company of Chicago on the general principle hitherto developed in the Patton motor car. Power is derived from a 3-cylinder 8 h. p. vertical gasoline engine located in the forward part of the truck under the driver's seat; this is direct coupled to a dynamo which charges a battery of 40 cells of 144 ampere hours capacity. The dynamo and storage battery in turn supply the two 5 h. p. motors geared to the rear wheels. The engine is kept in continuous operation while on the road, charging the battery when the motors take a small current or none at all, supplying the motors direct when the load is moderate, and being helped out by the battery at times of heavy load. The weight of the truck is 9000 pounds.

**Increased Demand for Power Transmission in Sacramento.**—The Sacramento Electric Gas and Railway Company, which is now transmitting 4000 h. p. from Folsom to Sacramento, is about to add the fifth 1000 h. p. unit, for which its works were planned, which will only partially supply the increasing demand at the receiving end of its system. On this account it has contracted with the Yuba Electric Power Company for 5000 h. p. more. The Yuba company now operates 1,500 h. p., furnishing current to various other points. The new plant will be constructed with a capacity of 15,000 h. p. The present dam will be enlarged, a new timber flume 8½ miles long, 7 feet wide and 5½ feet deep will be built with a grade of 12.8 feet per mile. An insurance reservoir will be constructed at the forebay with a capacity sufficient to furnish 10,000 h. p. for six days continuously at the normal head, which will be 688 feet. The overhead line to Sacramento will be of aluminum wire worked at 40,000 volts pressure.

**The Telegraphic Transmission of Pictures.**—Several prominent newspapers have put into experimental use the instrument called the Telediagraph, developed by Mr. E. A. Hummell of St. Paul, Minnesota, for the transmission of line drawings telegraphically. On April 19th newspapers in the following places: St. Louis, Chicago, Philadelphia, Boston and New York, exchanged photographs and other pictures with apparent success, judging by the reproductions in their columns. The principle of the instrument is as follows: A tin foil sheet is marked in an insulating ink with the design to be transmitted and wrapped around a cylinder. The cylinder is rotated under a contact, which is run along the cylinder by a screw much as is the needle of a phonograph, the marked portions of the tin foil making and breaking the circuit as the contact passes over them. At the receiving end is a similar cylinder wrapped with paper and a carbon manifolding sheet and kept in sylchronous rotation with that at the transmitting end. The incoming currents affect a stylus, which records upon the paper marks corresponding to the raised portions of the tin foil at the transmitting end.

**Rapid Transit in New York City.**—The spirits of all New Yorkers who hoped to see a satisfactory rapid transit system up and down Manhattan Island were raised during the last of March by the offer of the Metropolitan Street Railway Company to construct a tunnel which the Rapid Transit Commission has for so many years been attempting to get under way, either with public or private ownership. The Metropolitan's plan proposed several improvements not previously considered, notably the connection of the tunnel to the surface at various points for the running of through cars from the existing street lines into the tunnel and vice versa. The company's proposition, however, was a little too selfish for the approval of those supposed to look out for the best interests of the community, and objections were raised to the perpetual franchise, the free use of the tunnel as a subway and other features of the proposition, which caused the company to withdraw its offer on April 17, evidently in the hope that the extreme need of rapid transit would force the city to grant it these rights in due time. The course of the struggle will be an interesting one to watch, as the franchise will be the most valuable ever granted by any city the world over. In the meantime the State Legislature has passed a new rapid transit bill, providing for private ownership of the tunnel with a franchise limited to fifty years. The Metropolitan Company refuses to consider this and there are rumors that the Manhattan Elevated Railroad Company will bid for the undertaking. Efforts are also being made to have part of the municipal indebtedness charged against the county, which would allow the city to build the road without exceeding the constitutional debt limit. One of the daily papers has even started a popular subscription list and obtained nominal subscriptions for stock to the extent of about twenty millions of dollars.

**Progress of Traction Consolidation in Brooklyn.**—Another step has been made during the month of April in the consolidation of the traction interests of the Borough of Brooklyn, New York City. The Brooklyn Rapid Transit Company, which already controlled the Brooklyn Heights and the Brooklyn Queens County & Suburban Railroad, and had acquired the greater part of the stock of the Nassau Electric Railroad, contracted with the reorganization committee of the Kings County Elevated Railroad and the Fulton Elevated Railroad Company to acquire the properties, privileges and franchises of these companies in exchange for $2,000,000 of the stock of the Rapid Transit Company. With one of these the Transit Company gets still another route on private right of way to Coney Island. viz., the Brooklyn and Brighton Beach Railroad, and has begun work equipping it with electric traction apparatus. The Transit Company has also contracted with the Long Island Railroad Company to lease for a period of 999 years the Prospect Park & Coney Island Railroad, the New York & Coney Island Railroad and the Prospect Park & South Brooklyn Railroad, and made a traffic arrangement with the Long Island Company whereby the through steam trains of the latter may be run over the local elevated tracks in Brooklyn. The one company now controls 85 per cent. of the surface mileage and all of the elevated mileage in the city of Brooklyn, including practically all of the available routes to Coney Island. The one independent surface company, viz., the Coney Island & Brooklyn Railroad Company, it is expected will join the consolidated interests in the course of a short time.

**Foreign Visitors in America.**—During the month of April several British engineers visited the United States on tours of inspection of electric railway work. Among them was Prof. A. B. W. Kennedy, one of the most prominent of British electrical engineers, who is consulting engineer for tne London County Council with special reference as to whether or not the underground electric conduit system is practicable for the conditions found in London. Prof. Kennedy, in pursuance of this investigation, visited New York, Hartford, Boston, Schenectady, Buffalo, Niagara Falls, Chicago, Pittsburg, Washington, Baltimore and Philadelphia, on a flying trip extending over but two weeks, and at its conclusion expressed himself as very much interested in what he had seen. Accompanying Prof. Kennedy was E. W. Monkhouse, an electrical engineer of London, who desired to make a careful investigation of electric railway practice in this country in behalf of other clients. On April 13, Dr. Edward Hopkinson, managing director of Mather & Platt, Ltd., and Bertram Hopkinson, nephew of the late Dr. John Hopkinson, arrived in New York, and are now making similar investigations in various cities of the United States with a view to acquiring a general understanding of the best American practice in electric railroading. They expect to return in May.

### The Electrical Exhibition—Greeting.

Ever since the dawn of civilization one of the greatest institutions of instruction and entertainment has been the gathering together for public inspection of the products of man's handiwork. In modern times it takes various forms, from the primitive county fair and the oriental market, through the permanent exhibitions and perhaps the department store, to the great international expositions. With the increasing specialization of industry and consequently of interest, specialized expositions are coming into existence, and one of the most sturdy and promising of these is the electrical exhibition of New York City, which promises to rival in regularity of occurrence and extent of country from which it draws both exhibitors and visitors, such great affairs as the world famous Russian fair of Nijni Novgorod.

The third exhibition opens in Madison Square Garden on May 8th, and promises to be of even greater value to the engineer and interest to the layman than were its predecessors of 1898 and 1896. The fame of these has spread so widely that the electrical exhibition is now far from being local in character or patronage. Electrical engineers from all parts of the country make a point of timing their annual visit to New York City during the month of the electrical show, and this year the annual convention of the National Electric Light Association will bring its attendants to the Garden.

While this pilgrimage of the technical men is what makes the show of value to the exhibitors, the financial success of the exhibition company is dependent upon the popular interest in the more sensational and less scientific exhibits on the part of a large portion of the enormous population resident in the metropolitan district, in and about New York City. The special department of particular novelty and interest this year will certainly be that embracing the automobiles, which will be attractive to both the general public and the engineer. Second only to this will probably be the interest exhibited in wireless telegraphy, the possibilities of which during the last few weeks have excited the most intense attention in England.

### General Electric Finances

The annual report of the General Electric Company, an abstract of which will be found on another page, exhibits a remarkable game of battledore and shuttlecock with the profit and loss balance, the final outcome of which, combined with the healthy growth of its business and profits, should be most gratifying to the stockholders.

In the first place the 40 per cent. reduction of the valuation of the stock, removing from the column of liabilities $13,884,800, wiped out the profit and loss deficit which the company had struggled with for many years and had finally brought down to some $12,000,000. The surplus of $2,159,000 obtained by the capital reduction was immediately turned again into a deficit of $1,840,761 by the 50 per cent. reduction of the valuation of patents, franchises and good-will effected June 30th, 1898, which removed from the column of assets $4,000,000. The profits for the year, however, figured up to $3,896,884, as against about $2,000,000 during the previous year, covering this deficit and giving over $2,000,000 surplus, which was largely used in paying up the unpaid accrued dividends of some 30 per cent. on the 7 per cent. cumulative preferred stock up to Jan. 31st, 1899, leaving finally a small surplus of $156,570.

The reduction of the preferred capital by $1,700,000 means an annual gain to the benefit of the common stockholders of about $120,000, which, with the rapidly increasing business and the increasing ratio of profits to total business, should soon begin to give some dividend on the common stock. Altogether the report is a very flattering one, especially for a year in which there has been the industrial depression of an international complication, and the revival of activity which has already followed the war may be expected to combine with the improvements already manifested in General Electric finances to make a most flattering appearance next year.

### Gas Engines in Railway Power Plants.

It has been the common belief that the gas engine would prove an unsatisfactory prime mover for traction service, owing to its unsatisfactory operation with rapidly varying loads. There will be found on another page a description of a street railway plant where the load conditions are about as severe as might be imagined—a plant working from one to three cars, on a profile showing a heavy grade for about one-third of the length of the line.

To be sure, the power house is equipped with a storage battery, but this is used not to improve the regulation, but on account of the inherent inability of the gas engine to carry extreme overloads. The gas engine reaches its greatest economy at maximum load and is consequently rated as near this output as possible, a small allowance, generally 10 per cent., being given to insure that the engine will maintain full speed with varying qualities of gas, etc. Thus an engine which gives on test 55 or 56 h. p. would be rated at 50 h. p., and if given an overload of more than 10 per cent. would slow down and perhaps stop, while a 50 h. p. steam engine would easily stand a 25 per cent., or in the case of four-valve engines, a greater overload before it would be pulled up. To carry a load, therefore, with peaks running up to 100 h. p., for example, it

Digitized by Google

would be necessary on the one hand to install at least a 90 h. p. gas engine, while on the other hand an 80 h. p. steam engine would do the work. With such a load the gas engine would be practically always working at a low percentage of its most efficient load and consequently at a poor economy, while the steam engine would be working with loads not much below that of maximum efficiency. The storage battery is therefore more necessary for a gas engine than for a steam engine with such a load as that described in the article referred to, but should undoubtedly, for best economy, be used with either.

---

Besides the well-known fuel economy of the gas engine, as compared with the steam engine, particularly in small units, the former requires less space than the equivalent steam plant and may be run with considerably less attention, so that one man at a gas engine power house might attend to quite a large equipment, or in the case of a small equipment, might do considerable other work, besides simply attending to the plant. The first cost of a gas engine installed is about equal to that of the equivalent steam engine with boiler, pumps, piping, etc., installed, and the depreciation is no greater than that of the steam engine and certainly less than that of the boiler.

---

**125-Cycle Transformers on 60-Cycle Circuits.**

Many central station engineers, contemplating the purchase of alternating-current dynamos of the now generally approved frequency for lighting work, viz., 60 cycles, hesitate on the score that they will be obliged to change all of their transformers and meters on their 125 or 133-cycle lines to suit the new periodicity. A slight knowledge of alternating currents confirms them in this fear. With a frequency one-half as great, they reason, the rate of change of lines of force on a given transformer will only be half as great, and the e. m. f. which that transformer will stand will therefore be reduced 50 per cent., so that putting 60 cycle current on to 125-cycle lines will have results as disastrous as the biblical putting of "new wine into old bottles," or, to be more precise, will burn the transformers out. As a matter of fact, there is but a trifling difference between two transformers designed for the same load, efficiency and regulation, for 60 and 120-cycle circuits respectively, and transformer manufacturers, as a rule, put out identically the same instrument for both uses. Many central stations regularly run circuits during part of the day on high frequency and the rest of the day on low-frequency machines.

---

The behavior of a 120-cycle transformer with 60 cycle current, as compared with its action under the frequency for which it was designed, is as follows: The ratio of transformation is, of course, exactly the same, as are the copper losses and the eddy current losses in the iron. The 50 per cent. reduction of the frequency necessitates a doubling of the density of the alternating magnetism in the iron to maintain the same rate of change of lines of force, upon which depends the voltage. Transformers for 120 to 133 cycles are designed for a low density in order to keep down the iron losses, so that this doubling is easily attainable. It, however, increases materially the magnetizing or leakage current, making it three or four times as great as on the higher frequency. This reduces the power factor of the station output, particularly if there are a lot of small lightly loaded house to house transformers on the lines. However, on account of the reduced frequency, the inductive drop in the lines and machines does not increase in proportion to this increased lagging current. The doubling of the density multiplies the hysteresis loss per cycle by about 3, as the loss is proportional to the 1.6 power of the density. However, the number of cycles being reduced 50 per cent., the hysteresis loss is only really increased about 50 per cent. The regulation remains about the same.

---

Care should be taken, however, in such a change, in the matter of meters. All recording ammeters or wattmeters of the induction type, such, for example, as the Shallenberger meter, will have their speed very materially reduced on the lower frequency, while meters of the type in which the motor is fitted with a commutator, such as the Thomson indicating wattmeter, will work with equal accuracy on any frequency.

---

**Individual Motors vs. Group Driving.**

Now that electrical means have come to be generally accepted as the best for the distribution of power to numerous points of use in industrial establishments such as machine shops, printing offices, etc., one of the important problems is the division of the electric motor units. The chief losses of the shaft and belt system are eliminated by the use of a few large motors, each driving a number of closely grouped machines by means of the usual overhead shaft and cone pulley. The substitution for such a motor, shaft and pulley, of individual motors, one for each machine, increases greatly the cost and reduces the efficiency of the installation, as the smaller motors are more wasteful than the larger ones. It also increases considerably the aggregate h. p. capacity of motors required, as each individual motor must be capable of carrying the maximum load of machine it drives, while with the group arrangement these maxima never carry simultaneously, and the load curve of the group driving motor is correspondingly smoothed out.

---

A discusion of this subject at a recent meeting of the American Institute of Electric Engineers brought out the general opinion that the efficiency, and within limits the first cost, of the installation are minor matters compared with many gains that might be called incidental, but overwhelmingly dictate the use of individual motors except in rare cases of very small units, etc. In a machine shop clear head room is of almost inestimable value for crane work, as it is in printing offices and similar establishments for clear lighting. Group driving, as ordinarily carried out with overhead shafting, obstructs the head room almost as much as does a complete belted system, so that individual motors are necessary to obtain these advantages.

---

With rare exceptions the cost of the power in any industry involving power driven machines or machine tools seems to be between 1 and 5 per cent. of the total cost of the finished product, so that a reduction of the efficiency of power distribution by, say 25 per cent., amounts to a very small increase of the cost of the product of the works, which may be far more than made up by the increased effectiveness of that comparatively expensive element—labor, caused by such an apparently trivial improvement as better light, handier crane movement, readier speed control or increased flexibility of arrangement.

---

Again, the improved appearance of a shop without belts has its effect on the neatness of the work of the operatives, especially if the material worked upon is easily soiled, as is paper. With oil dripping hangers, etc., gone, the walls may be painted white and the tools covered with aluminum paint and the quality of neatness and general "ship-shapeness" will readily find its way from the equipment to the work done.

## HOW TO MAKE AND USE A PHOTOMETER.

BY PROF. ARTHUR J. ROWLAND.

The time has passed when an incandescent lamp is accepted as having the candle power marked on the label. It is a common thing to make tests of lamps from every barrel lot to see what they really are. The rating of a lamp by its watts per candle power is recognized as the only way to estimate its value, when new at least, and determinations of the true rating often precede and follow the award of large contracts.

That these values may be determined by lamp users there must be a means at their disposal for measuring candle power. So it is that a photometer, once considered an instrument solely for use in a physical laboratory, has come to be one found in many central stations and isolated plants. Within a couple of years past, commercial photometers have been made and offered for sale by most, if not all, the manufacturers of scientific apparatus. They have been devised to make photometer measurements reasonably simple, not requiring elaborate or expensive apparatus, and yet yielding results sufficiently accurate for the every-day work of the lighting plant in determining the c.p. of the lamps bought, and determining whether that of old lamps has fallen so low that they must no longer be continued in service, to say nothing of tests of c.p. variation through the life of lamps from different lamp factories in order to get a proper estimate of their relative worth. At the price such instruments are to be had it is doubtful whether it is worth while to make one. There is, however, a great satisfaction to many people in using an instrument they have themselves constructed.

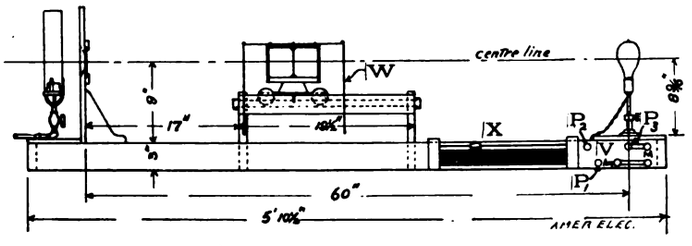

FIG. 1.—THE PHOTOMETER COMPLETE.

In the photometer here described, and for the construction and use of which directions are given, an attempt has been made to gather into one instrument the good points of a number, and at the same time to avoid their defects. In this an especial indebtedness is owed to a portable photometer made by the Newark Ornamental Iron & Sign Works, of Newark, N. J., which must be here acknowledged.

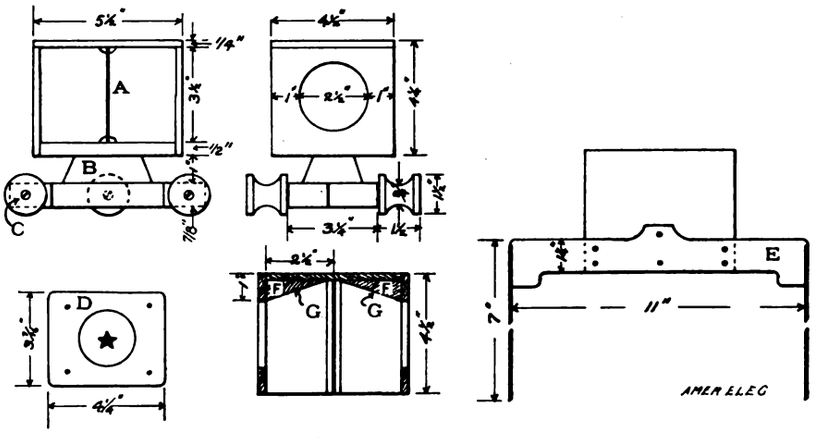
### CONSTRUCTION.

For the construction shown no materials are required which are not readily attainable at small cost, nor are there any processes of manufacture involved which are beyond the capabilities of a man with very simple tools and ordinary mechanical ability. In many things, some simple change might make a more finished instrument, but more machine work would be involved. Such modifications will eadily suggest themselves to anyone undertaking the construction.

A general drawing of the instrument is given in Fig. 1. The frame, which supports everything, is of ⅞-in. white pine 3 ins. wide, set together in an open rectangle 5 ft. 10½ in. long by 6¾ ins. wide over all. This frame may be supported at a convenient height by brackets on any side wall. At the left is an argand gas burner, in front of which is a board with an adjustable slot cut in it, the slot being directly in front of the argand flame. At the other end, on a suitable stand, is the incandescent lamp whose c.p. is to be measured. Between them is a frame on which travels a car containing a piece of paper set in a plane at right angles to a line joining the two lights. This paper has a grease spot on it, and in use the car is moved backward and forward until a place is found where the grease spot disappears. The c.p. of the lamp is then read off on a scale immediately below the car. For adjusting the e.m.f. on the lamp terminals a rheostat is provided, shown between the incandescent lamp and the track for the car at X in the drawing. The instrument is in principle a Bunsen photometer.

In Fig. 2 the car is shown in detail. The car proper is of wood, open in front, closed at the back, with ends cut away in openings 2½ ins. in diameter. Halfway between these two ends is the screen—seen in edge view at A. This is of two pieces of sheet metal (see D), about No. 14 or No. 15 B and S guage in both of which there is cut a circular hole 2 ins. in diameter. Between these pieces is put the paper with grease spot, as shown, and the two plates held together with small screws so the paper and grease spot can readily be renewed when necessary. The compound plate, D, slides in place from the front of the car in small wooden guides as at A.

To the right of the frame D in the figure is a section of the car taken halfway between the top and bottom. The two blocks F, F are wooden ones, extending from bottom to top of the car on which pieces of mirror are mounted. These mirrors should be of good quality, as near alike as possible and covering a large part of the surfaces G, so that an observer sees in each of them the reflection of the paper and grease spot—one side of the paper in one and the other side in the other. The exact angle at which these mirrors should be placed will best be determined in each case by trial. As shown, the results should be perfectly satisfactory. The piece B, between car proper and base, on which the wheels are mounted, is to be of lead. It may be cored out some, but is to give weight and stability to the car on the track and so must be heavy. The base to which wheels C are secured is of wood ⅞-in. thick and shaped to carry the lead block and three wheels as shown, two running on the forward track and one on the rear track. These wheels are simply porcelain insulators or knobs, which any central station will be likely to have in stock, or which may readily be procured from any dealer in electrical supplies. They run on wood screws as axles. If they are turned from iron or brass, B may be made of wood. The three parts making up the car are put together with two slender bolts passing down through all, from the car. E, in another part of the figure, shows a brass plate of about No. 12 or 14 guage, screwed to the top of the car and with light stiff wires (about No. 10) soldered to it and projecting forward. To each of these wires is hung a curtain of black drilling, 4½ or 5 ins. wide and 10 or 12 ins. long, hung as shown at W (Fig. 1). These curtains are to screen the eyes of the observer from the lights at the end of the bar. When this car is finished, it must be



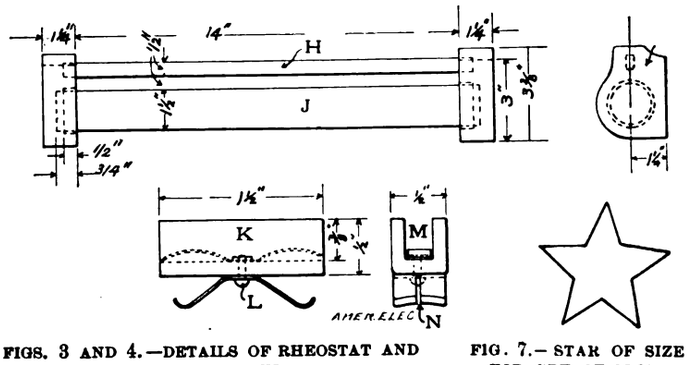


FIG. 2.—THE CAR IN DETAIL.

Digitized by Google

painted black all over. Not a shiny black, but a dull, dead black, such as may be had at least cost probably by cutting a little lamp black with turpentine and adding just enough shellac varnish to make the black stick, but not get glossy.

FIGS. 3 AND 4.—DETAILS OF RHEOSTAT AND CONTACT MAKER.

Before taking up another part of the photometer, a few words as to methods of making the screen will be well put in. The sort of paper used is not of great importance. It must be white and quite nearly opaque. Preferably both sides should be as nearly alike as possible. The grease spot must be as transparent as possible, have a very clearly defined edge and the more edge the better. In Fig. 7 there is shown a star which is a good size to use and which has plenty of edge. To make the grease spot, cut the star out of brass plate (say ⅛-in. thick) and mount it on a rod set perpendicular to the plane of the star. Melt some paraffine over a water bath, put the star into the paraffine and let it warm some; then take it out, let it drain and set it down on the paper selected. A number of grease spots having been made, pick out the best for use. I have found a typewriter's paper, imitation linen, smooth, and rather thin, quite satisfactory—care being taken not to use any part containing a water mark.

The car runs on a track of which a satisfactory idea may be had from Figs. 1 and 6. The two tracks are of common ½-in. iron pipe, shown at P (Fig. 6), slipped through end pieces, whose form and size are shown in the same figure; and finished by iron caps screwed on each end. It will be necessary to pick out good smooth pieces of pipe for the purpose and perhaps do a little filing, so that in use one will not unconsciously tell by the "feel of the track" when the car is in some certain position along it. Q, in Fig. 6, is a strip of 7-16-in. wood which is in front of the pipe tracks in Fig. 1, and is to have the scale for reading c.p. mounted on it.

The framework must be mounted rigidly in place and the distances between it and the end fixtures, as well as the distances between them (the screen and the incandescent lamp) made exactly as shown. It is on the accuracy of these measurements that the value of the table given below, determining the c.p. scale, depends. The scale of c.p., to be mounted on the strip in front of the iron tracks as before mentioned, may be put on a piece of cardboard tacked to the board, the divisions laid out as per table below with waterproof india ink and then the whole shellacked over to preserve it and prevent weather changes from warping the cardboard out of shape.

FIG. 7.—STAR OF SIZE FOR GREASE SPOT.

The table is to read c.p. from eight to thirty. This is an abundant range for 16-c.p. lamps. Half candle powers may also be marked off by divided distances between marks on the scale, except for values when these are given in the table. A pointer is attached to the car directly under the greased paper (as per Fig. 1) by which to read car position and so c p.

At the left end of the frame is an argand gas burner (See Fig. 1). An oil lamp might replace the argand burner, but if gas is available it will be much more convenient to use. In the figure the argand burner is shown quite near the slot board; so near indeed that it is probable the board will have to be covered with asbestos paper on the side next it. To procure the results mentioned in Part II. it will be necessary to keep the burner up close. The exact position of the gas burner is not of importance except that it must be directly behind the slot when viewed from the car. The screen is shown in detail in Fig. 5. It is arranged with a slider to control the width of the slot S, which is 1 in. x 2 ins. at largest opening. If facilities are at hand it will be well to provide a screw and nut on the slider to control the width of the slot within small limits and readily. Bevel off the slot in fashion shown at R.

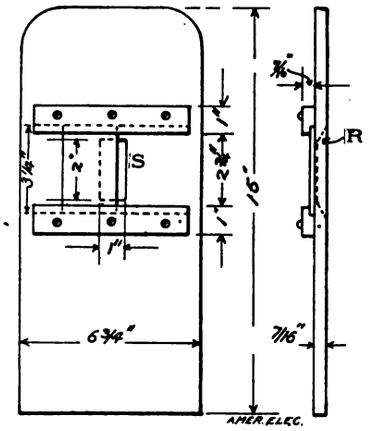

FIG. 5.—DETAILS OF SCREEN.

At the right hand end of the frame is the standard to hold the incandescent lamp, connection board and rheostat. An ordinary lamp socket has a ⅛-in. pipe screwed into it and this drops into a ⅜-in. pipe in a cast iron base through a ⅜-in. cap drilled at the end and with set-screw put through to hold the lamp rod at any height. The lamp cord is brought from the socket as shown and its ends carried to the two binding posts, $P_3$ and $P_4$, respectively. The mains are connected to the binding posts at M (Fig. 1), voltmeter at posts between which the letter V is put, and ammeter, if used, at posts on each side of Am, as marked. Otherwise this ammeter gap is bridged by a copper link. Two connecting straps are shown on the face of the frame and other connections are completed inside so that the circuit is from one post at M to $P_4$, then through the lamp to $P_3$, to brass rod marked H (Fig. 3), through the contact into the rheostat coil, then to P, and so out at the other side of connections for the mains. The voltmeter connected thus reads e.m.f. on the lamp terminals and the ammeter, both the current through the lamp and voltmeter, so that if this latter takes appreciable current, as it usually does, allowance must be made, unless the voltmeter is always off circuit when the ammeter reading is taken.

For the rheostat construction see Figs. 3 and 4. J is a round wooden core which, with end pieces, is preferably made of hard wood. Over J is a thin covering of asbestos paper, put on smooth and tight, and shellacked to place. Over 14¾ ins. of length at the middle of the rod is wound a tight spiral of No. 20 German silver double cotton covered wire also shellacked to place. This coil may be secured at its ends by tieing it down as with an armature coil or by soldering together the last two or three turns at each end. Along one side of the cylinder so formed, after the shellac has dried, and under the brass rod H (¼-in. thick x ½-in. wide), the insulation on the outside is to be rubbed off with sandpaper, making a path over the bared wire, ⅝ or ¾ ins. wide. This leaves each turn insulated from its neighbors, but makes it possible to connect readily with any turn of the solenoid. Bridging the distance from H to the wire on J, and making the contact just mentioned, is the contact device of Fig. 4. This is a brass body K, cut from ½-in. square rod, with an opening M, which rides easily on the rod H. Secured to it are German silver springs, as shown within, to make contact

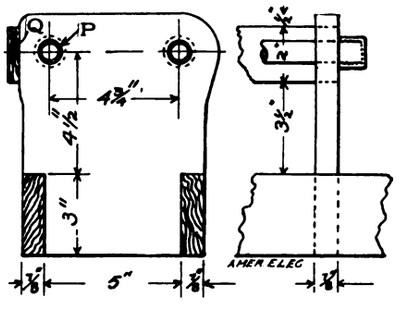

FIGURE 6

FIG. 6.—DETAIL OF TRACK AND SCALE ARRANGEMENT.

Digitized by Google

with the rod, and outside to make contact with the turns of wire on the coil. A bolt like that at L can be had from almost any old lamp socket. It had better be very securely put in place. As the success of the rheostat depends on this contact device, it must be carefully made and the lower spring piece divided on each side as at N, so there may be four contacts on the

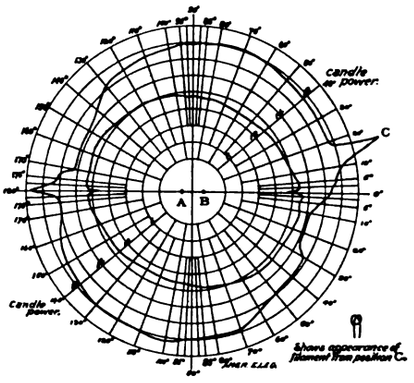

FIG. 8.—DIAGRAM OF HORIZONTAL CANDLE POWERS ON TWO LAMPS, ONE WITH COILED, THE OTHER WITH PLAIN HORSESHOE FILAMENT.

rheostat wires. With this rheostat the volts on a 16-c.p. 110-volt lamp can be controlled over a range of ten volts by almost imperceptible steps and one amp. can be put through it continuously without dangerous heating. The whole thing is held together by wood screws from the ends, O, into the rod J, and then screwed in place at the side of the frame.

After the photometer is all put together and mounted on a side wall, the whole thing must be given a couple of coats of a dead-black paint, and the wall immediately behind the instrument painted the same way. A dark room need not be provided. All very bright lights, however, must be absent from the vicinity of the instrument or turned out when it is in use.

### HOW TO USE THE PHOTOMETER.

Two needs must be supplied before any work can be done with the finished instrument. There must be standard incandescent lamps and a thoroughly reliable voltmeter. The incandescent lamps may be purchased from any of the larger lamp companies, marked with the voltage at which they give 16-c.p. and from what direction they must be viewed to give this c.p. Sixteen-c.p. standards must be used. By a thoroughly reliable voltmeter is meant one which has 110 volts at its terminals when the needle points to this, that always comes to a 110-volt reading when 110 volts is applied, and which can be read to one-fifth of a volt. Unless such a voltmeter is used, only very rough c.p. measurements can be made. Errors as much as ½-c.p. to 1-c.p. in 16 will come in, due to this cause alone, with a voltmeter in use whose readings are slightly in doubt. The circuit used must be one on which the e.m.f. at the lamp can be held steady for a similar reason. An ordinary 16-c.p. lamp changes c.p. about one unit per volt change in applied e.m.f. at the normal or rated e.m.f.

Having the standards and the voltmeter for the work, proceed to measurements this way. Two men are required; one to watch the voltmeter and change lamps, the other to work the car. Connect the circuit, put one of the standards in the socket, set it at its marked voltage and turned so one views it from the photometer car in a direction which makes its c.p. sixteen, light the argand burner, put the car so its index is at mark 16, and adjust the slot at the argand until the grease spot disappears. The argand lamp has now become the standard and is assumed to stay at fixed c.p. for further work. Next remove the standard lamp, put in one whose c.p. is to be determined, bring it to a proper applied e.m.f., and while one man reads the voltmeter and keeps the lamp at a constant terminal potential difference, the other one moves the car backward and forward, seeking a place where the grease spot cannot be distinguished from the surrounding paper, and when the place is found he reads the c.p. of the lamp now in the socket. So work is proceeded with, a return being made periodically to the standard to check the argand burner, which is the working standard, and perhaps also to other lamps as well to procure check readings of their c.p. A check on the argand by the incandescent lamp standard is of course made by putting the car at 16-c.p., adjusting the in-

FIG. 9.—A VIEW OF A ROTATING SOCKET.

candescent lamp in position and applied e.m.f. and observing whether the grease spot is still invisible. The one handling the car must keep his eye solely for observations of the grease spot and will not be able to do good work until he has gotten accustomed to it by ten minutes preliminary work. Also a person without experience in photometric measurements will not be able to get good, that is, concordant and correct results. A practiced observer will have results agree with this photometer so that individual observations never differ by more than a half c.p. in sixteen.

It will be very unusual for the grease spot to simultaneously disappear from both of the images in the mirrors for any one position of the car. This is mainly due to difference in the color of the lights used. Old incandescent lamps are less troublesome than new ones in this respect. In making a reading one should set the car to a position where the difference in tint of spot and field is the same, whichever mirror he views.

It must be observed that when making measurements no reversing of car is to be done, nor is there necessarily a dark room. Simply avoid lights or white surfaces before the eyes of the observer and have the lights in the vicinity of the instrument as few as possible, of as small c.p. as possible, and constant in position and c.p. If one can just manage to read newspaper print from the surrounding lights it will be dark enough. Avoid light most carefully at the incandescent lamp end.

If 110-volt lamps are to have their c.p. determined it commonly happens that the dynamos run at 110 volts. Hence it is well nigh impossible to get 110 volts at the photometer and in any event the rheostat would be useless. One should have a few small storage cells to put in series in the circuit on this account, to raise the e.m.f. to about 120, and then there is abundant opportunity to procure the 110 volts steadily, even under considerable fluctuations in the e.m.f. on the circuit.

A 16-c.p. lamp does not measure 16-c.p. when viewed from any direction. There is a good deal of variation in c.p. according to the direction from which one views the lamp, and especially is this true for coiled or looped filaments. Even the c.p. in a plane at right angles to the lamp axis, the horizontal c.p. is irregular. One can readily see this for himself by holding a piece of white paper near a lighted lamp and observing the bright streaks of light in certain directions. The kind of variation which exists is shown by two curves of horizontal c.p. plotted together in Fig. 8. These were taken from two lamps, one of which had a coiled filament and the other a plain U-form filament.

Most lamp manufacturers are now rating their product by the c.p. measured when the lamps are rotating on a vertical axis at 180 r.p.m.—a value decided on at the National Electric Light Convention a year or two since. A rotating socket is not included in the photometer design here given. There is, however, a cut of a rotating socket recently built for use in the Electrical Laboratory at Drexel Institute here shown, which might replace the incandescent lamp stand in the design given in this article. The one shown in the cut has embodied in it certain features worth noting. There are four brushes rubbing on four contact rings. Two carry current into and out of the lamp through a socket so arranged that the voltmeter connected through the two other brushes is actually connected to the lamp terminals, and so the true e.m.f. on the lamps is known. To maintain a steady rate of rotation the little motor shown is run by two storage cells given up to this duty alone. The speed of the rotating socket is also under control and can be varied through all necessary

Digitized by Google

limits by shifting the little rubber-covered pulley to different radii under the large rotating disc, which is mounted on the stem of the lamp whose c.p. (that is, mean horizontal c.p.) is to be determined. With proper tools and facilities such a rotating device, or one equivalent, can be put on the photometer here described and so a very complete instrument be had.

The standard lamp is better if not rotated. Care must be taken that the standard is not viewed from a position near to one like C, in the figure of horizontal distribution, however, where the turning of the lamp through only five degrees varied the c.p. by more than five units. A plain U-shaped

filament is much the best for a standard lamp.

The candle power of 8-c.p. lamps can readily be obtained with this photometer also. Put a standard 8-c.p. lamp, at some marked voltage, in the lamp socket; put the car at 16-c.p. and adjust the slot at the argand burner until the spot disappears. Then proceed to measure 8-c.p. lamps as though they were 16's, halving the value of c.p. read on the scale in each case for their real candle power. A similar method may be used also in determining the value of the candle power procured from 32-c.p. lamps. Use a standard 32-c.p. lamp as in case of the standard 8-c.p. above, and when readings are made on the candle power scale double the value obtained in each case. Unless the gas used is intrinsically of very good candle power and the argand burner is put very close to the slot board, this last cannot be done since the gas burner will not give enough light. If it is a possible plan carefully avoid any flickering edges of flame showing through the slot when it is viewed from the car position. The following alternative method of measuring 32-c.p. lamps will always be satisfactory.

Set up a second lamp socket (number 2) fifteen (15) inches to the right of the one already provided in the regular construction, or seventy-five (75) inches from the slot. Construct a second scale (number 2) under the one already made (number 1), to be used only when the lamp under test is in the more distant socket.

This scale will be constructed by measurements given in the table below, all measurements being from the slot before the argand lamp.

Use 16-c.p. standard in socket number 1, put the car at 16 candle power on scale number 1, and set the argand lamp by it so the spot disappears. Then put the 32-c.p. lamp, whose candle power is desired in number 2 socket, and measure its candle power in the usual way, but reading its candle power on number 2 scale. If the two sockets are connected in parallel they will be ready for operation alternately at any time, the same instruments and rheostat being used without any change in connections.

## AMERICAN TELEPHONE PRACTICE.

### SELF-INDUCTION AND CAPACITY.

BY KEMPSTER B. MILLER.

Self-induction and capacity play such important parts in the question of long-distance telephone transmission, and seem so little understood among the rank and file of telephone workers and users that this chapter will be devoted to an elementary and non-mathematical discussion of these two phenomena with a view to explaining their existence and effect in a simple manner, rather than to throw any new light upon the subject.

Ohm's law states that for a steady flow of electricity in a given circuit the amount of current in amperes is equal to the electromotive force expressed in volts, divided by the resistance of the circuit expressed in ohms. In algebraic form this becomes the well-known equation:

$$C = E/R$$

Where C represents the current in amperes, E the electromotive force in volts, and R the resistance of the circuit in ohms. Knowing any two of the above quantities, the third may be determined from the equation already given, or from the following, which are derived from it:

$$E = CR$$

and $$R = E/C$$

These three equations, which are merely different ways of expressing Ohm's law, are the most useful in the entire science of electricity. It is unfortunate for an easy understanding of telephony that these equations in their simple forms hold true for a steady flow only, and that when currents which are rapidly changing in value or in direction are considered, we must face a more complex set of conditions.

An electric current flowing through a conductor sets up a field of force about the conductor throughout its entire length. This field of force consists of magnetic lines extending in closed curves about the conductor, and is often termed a magnetic whirl. A freely suspended magnetic needle placed within this field of force will tend to assume a direction corresponding to the direction of the lines of force, and therefore at right angles to the conductor.

If the current flowing in the conductor is maintained at a constant value and in the same direction, the field of force about the conductor will not change. On the other hand, if the current strength fluctuates, the field of force will become more intense and will expand while the current strength is increasing, and will become less intense and will therefore contract while the current strength is decreasing. If the current changes its direction, the field of force existing is entirely destroyed, and is built up in an opposite direction at every such change.

Whenever there is such a relative movement between a conductor and the lines of force of a magnetic field as to cause the conductor to cut the lines, or the lines to cut the conductor, an electromotive force is set up in the conductor which tends to cause a current to flow. The direction of the electromotive force will depend on the direction of the lines and on the movement of the conductor, and its value will depend on the rate of cutting. The field of force may be set up either by a magnet or by a conductor carrying a current, and in either case the phenomenon just described is called electromagnetic induction.

If two wires are formed into parallel coils, each having a large number of turns, then the lines of the field of force set up by the coil carrying the current will cut many of the turns of the other wire, thus inducing an electromotive force in each turn; the result being that the sum of all the electromotive so induced forces will be added, thus producing a much greater effect than if each wire consisted of but a single turn. Furthermore, if the two coils are wrapped about an iron core, the field of force due to the coil carrying the current will be greatly strengthened, and therefore the electromotive force induced in the second coil will be greatly increased, owing to the greater rate of cutting of lines caused by the changes in the strength of the current. This is due to the fact that a given magnetizing force,

Digitized by Google

or force which tends to set up a field of force, will produce a greater number of lines in iron than in air.

It is evident that in a coil of wire carrying a current each turn of the coil is surrounded by a field of force, and that each turn must therefore lie more or less within the fields of force of all the other turns. Each turn will therefore have an inductive action upon all the other turns when the current through the coil is varying. Whenever a diminution of the current occurs the decreasing number of lines of force set up by any one turn will act on each of the other turns to induce an electromotive force tending to cause a current to flow in the same direction. The decreasing field of force around each one of the turns will act in a like manner on all of the other turns, and as all of the electromotive forces in all of the turns will be in the same direction as the current, which is already flowing in the coil their effects will be added and will tend to prolong the flow of current. On the other hand an increase in the current will cause an increasing number of lines to suround each turn, and this increase around any one turn will induce electromotive forces in each of the other turns in the opposite direction to that producing the current already flowing. This phenomenon of induction between the various parts of a single coil of wire each on the other is termed self-induction.

In view of the fact that a decreasing current induces an electromotive force tending to produce a current in the same direction as that already flowing, while an increasing current induces an electromotive force tending to produce current in the opposite direction, it follows that the general effect of self-induction in a circuit is to tend to prevent any changes in current from taking place in that circuit. This accounts for the fact that coils of wire, such as those forming electromagnets, tend to so greatly reduce the flow of voice currents through them; one of the best illustrations being that used in the bridging bell system of party lines, where the ringer magnets are purposely wound with a great number of turns and provided with long, heavy iron cores for the purpose of increasing the self-induction.

It is quite evident that in circuits containing self-induction and subject to rapidly fluctuating electromotive forces, the tendency of self-induction to prevent changes in the current will always cause any change in current to lag slightly behind the electromotive force which produces it. Where the electromotive force impressed upon a circuit varies according to the law of sines, the electromotive force produced by self-induction lags a quarter of a phase or 90° behind the current flowing in the circuit. That this is so may be seen from the fact that the electromotive force of self-induction is a maximum when the current producing it is changing most rapidly, and is zero when the current producing it is not changing at all. The maximum rate of change of the current flowing in a circuit occurs when the current is passing through zero, and its minimum rate of change occurs at the crests of the wave, that is, at its maximum points. It therefore follows that the electromotive force of self-induction is a maximum when the current in the circuit is zero, and is zero when the current is a maximum. This evidently indicates a phase difference of 90°, and we have already seen that this phase difference is a lagging rather than a leading one.

In circuits containing only non-inductive resistance the electromotive force impressed upon the circuit has only to overcome the ohmic resistance, and the value of the current may be obtained at any time by a direct application of Ohm's law. Where self-induction, however, is added the impressed electromotive force, if it be a varying one, must overcome not only ohmic resistance, but the electromotive force of self-induction; and then the current equation becomes

$$\text{Current} = \frac{\text{Electromotive Force}}{\text{Impedance}}$$

The word impedance in this equation may be termed the apparent resistance, and the apparent resistance in circuits having self-induction is always greater than the ohmic resistance. In fact, I, the impedance, is equal to

$$\sqrt{R^2+4\pi^2f^2L^2}.$$

Where f is the frequency of alternations and L is the coefficient of self-induction—a term denoting the total number of lines of force set up in a given coil when traversed by current of unit strength. The equation flow of current may then be written

$$C = \frac{E}{\sqrt{R^2+4\pi^2f^2L^2}}$$

Which is the equivalent of saying that the current flowing is equal to the electromotive force divided by the aparent resistance.

The current flowing in a circuit in which self-induction and resistance are present is the resultant of that produced by the impressed electromotive force and the electromotive force of self-induction. The greater the electromotive force of self-induction the greater will be the lag of the current behind the impressed electromotive force. Furthermore the greater the self-induction the greater will be the apparent resistance or impedance, and consequently the smaller will be the current flowing. The above formula applies only to currents varying according to the sine law, but telephone currents do not vary according to this law, or according to any other definite law, so far as we have been able to determine. This does not, however, destroy the significance of the formula as applied to telephony. Fourier's theorem states that any complex periodic wave motion may be considered as being made up of a number of simple wave motions having 1, 2, 3, 4, etc., times the rate of vibration of the complex wave motion. Telephone currents are very complex and are composed not only of a fundamental tone, but of many overtones; it is by the various blending of these overtones with regard to their relative loudness and their relative positions in phase with respect to each other, that articulate speech is produced. A consideration of the formula for the flow of current, just given, shows that the effect of self-induction is greater upon currents of high frequency than upon those of low frequency, for as f, the frequency, increases, the value of the impedance or the apparent resistance increases, and, therefore, the value of the current decreases. In other words, self-induction tends to weed out the higher overtones in preference to the lower ones and the fundamental tone, thus rendering speech indistinct, as well as reducing its volume.

## INTERIOR WIRING.

BY CHARLES E. KNOX.

### FEEDERS AND MAINS.

In this number the method of installing feeders and mains, known as exposed work, will be considered.

For the purpose of discussion this portion of the subject may be divided into four parts, namely:

1st.—The wire or conductor.

2d.—The insulator.

3d.—The rack, hanger, clamp or other device for holding the insulator.

4th.—The method of supporting the insulator rack or hanger.

1st.—The Wire or Conductor.—It is obvious that a different kind of insulation or protective covering may be used in this class of work from that which is desirable or necessary in concealed work. In the latter case the insulating covering of the wire must be depended upon entirely for the insulation of the feeder system; for even if there be an insulating lining or coat (as there should be) in the conduit used, this should not be relied on to any great extent and should be considered chiefly as an additional protection. In the case of exposed work, on the other hand, we may, if we desire, depend entirely on the insulator for the insulation of the system. For this purpose then it is only necessary to have such a covering on the wire as will prevent trouble from actual short circuits, grounds or such accidental contacts as might be caused by placing a metal bar, monkey wrench, etc., across the conductors or from other similar causes. The liability of this occurring may be greatly reduced by covering the conductors as a whole with wire lathing, galvanized sheet iron or similar covering.

There are many kinds of insulating coverings which will accomplish this purpose other than rubber. Among these are the coverings used on the so-called weatherproof wire, and on the historic underwriters' wire. Even two or three wrappings of tape around the copper wire might suffice, although this would not be as durable and would probably cost just as much as either of the others. The weatherproof wire is best adapted for outdoor work, as it stands up well under changes of weather, moisture, etc. Its disadvantage is that it is not fireproof. Underwriters' wire on

Digitized by Google

the other hand, is fireproof, but is not as good for the purposes to which the weatherproof wire is best adapted. Where the feeders pass outdoors from one building to another, weatherproof wire would be better than either rubber-covered or underwriters' wire.

Of course there are many cases (perhaps the majority) where it would be unwise to use any insulation other than rubber for this class of work. The selection of one or the other depends on many conditions, and each case would have to be considered separately and a decision made according to the conditions. With voltages of 200 or over the tendency to use rubber covered conductors should increase. The point is, however, that in exposed work it is possible in some instances to substitute other insulating coverings for rubber and thereby make a considerable saving in the cost of the feeder system.

2d.—The Insulator.—In this connection this term designates the rest or clamp for insulating the conductor from the supporting hanger, rack, beam, etc. It is very rare that any material is used at the present time for insulators for interior wiring other than porcelain. Glass might be used, but it has many, if not all, of the disadvantages of porcelain for this purpose, and more beside, while its only important advantage is its lower cost. Porcelain for insulators has many advantages. It has high insulating qualities, it is not (when glazed) hygroscopic to any

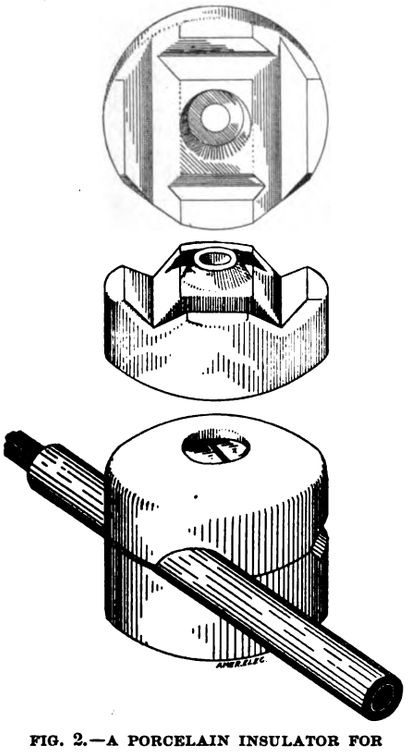

FIG. 2.—A PORCELAIN INSULATOR FOR SMALLER WIRES.

extent, it can be molded in a great variety of shapes and is cheap. Its great disadvantage is its fragility. Therefore in adopting or designing a porcelain insulator for this class of work it is important to select such shapes and forms as will mitigate or avoid this weakness.

Briefly expressed, the insulator should be "chunky." In fact, this word best expresses the idea of the requirement to which all designs of insulators made of porcelain should conform in order to avoid breakage. Any form of insulator having thin projecting edges or lips, or which have been weakened by screw holes or grooves, should be discarded and stouter and more compact designs adopted. If this point be not strictly observed, there is bound to be trouble. I have known cases where a poor design of insulator has been used, and the breakage has been as high as 20 per cent.

Fig. 1 shows a good stout form of insulator for large wires. As will be seen from the drawing, this insulator is split so that while the wire passes through the center of the insulator, the insulator may be taken out at any time in case of breakage and be replaced by another. Fig. 2 shows a fairly good form of insulator for smaller wires. This insulator has the questionable advantage of being to a certain extent universal, having several sizes of grooves in the two parts of the insulator, so that by placing the two parts in varying positions, different sizes of wire may be accommodated.

3d.—The Insulator Rack, Clamp or Holding Device.—For fairly small conduc-

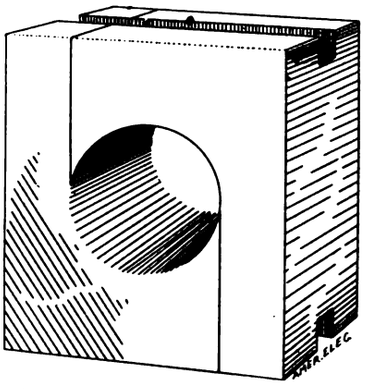

FIG. 1.—A HEAVY PORCELAIN INSULATOR.

tors for which insulators of the type shown in Fig. 2 are used, each insulator may be secured separately by means of a screw, passing through the hole in the insulator, to the beam, wall or ceiling, as the case may be. Where there are a number of these in a row, however, it is a better plan to secure the insulators side by side to a channel iron, which is fastened in turn to the beam or wall.

For insulators of the type shown in Fig. 1, a frame or rack similar to the design shown in Fig. 3, is most suitable. As shown in the drawing, this consists of angle or T iron, to which are secured straps or bars of iron projecting outwardly, into which the slot in the insulator fits. On the outer side of the rack, each insulator is secured in place by separate straps, which at the same time serve to stiffen the rack. By removing any strap the corresponding insulator (and consequently the conductor) may be removed without disturbing the remainder. Where such strength and rigidity is not necessary, the horizontal straps on which the insulators rest may be replaced by ⅜-in. or ½-in. bolts of proper length for the size of the insulator. Of course there is no end to the variety of hangers or racks that might be designed for this purpose.

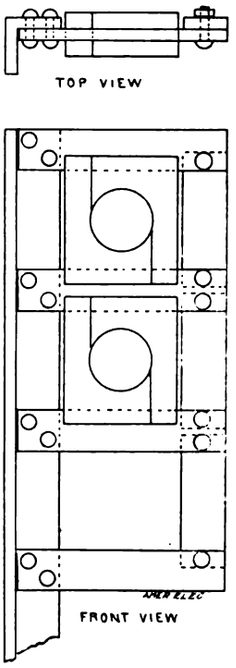

FIG. 3.—A RACK FOR PORCELAIN INSULATORS.

In some instances many different shapes and sizes of racks are necessary for the same run of conductors in order to overcome peculiar conditions encountered in the course of the feeders. Each rack must of course be fitted and adapted for its particular location and requirement.

4th.—Method of Supporting Rack or Hanger.—Where there are beams, girders, etc., to which the rack supporting the insulator may be fastened, it is easy to get a firm support for the racks. Beam clamps to which the racks are secured may be used, or else the beams may be drilled and tapped and the racks fastened in place by stout machine screws. This makes a much more secure support than if the racks were screwed to wood, and also has the advantage of greater security in case of fire, a point which in many instances should be borne in mind.

When the insulating rack must be secured to a brick wall or ceiling, care should be taken to obtain a secure fastening. For this purpose expansion bolts, toggles or some similar device should be used. Never depend on a wooden plug for a means of getting a fastening for a screw; sooner or later (generally sooner) these plugs are bound to get loose and pull out, even if the wood be seasoned. They are a "delusion and a snare," and are the more deceiving, because they seem fairly firm when first put in the brick.

It is frequently necessary to stiffen or guy the racks where they are subject to any great strain owing to the pull or weight of the wires. This is especially true when the feeders change their course

Digitized by Google

(as in turning a corner). For this purpose iron straps or stout steel wires may be fastened to the ceiling or wall at one end, and to the rack at the other end.

As far as possible a direct course or run should be selected for the feeders, for it is probably even harder to make bends or turns in exposed work than it is when the feeders are run concealed. Avoid crossing any pipes, ducts, etc., whenever possible. Steam pipes particularly should be avoided, as both weatherproof and rubber insulation are affected by high temperatures. The conductors should not be allowed to rest or touch anything but porcelain (if they have weatherproof or fire underwriters' insulation) through out the entire course.

When the route has been selected, the start should be made at the switchboard for there is the greatest congestion and

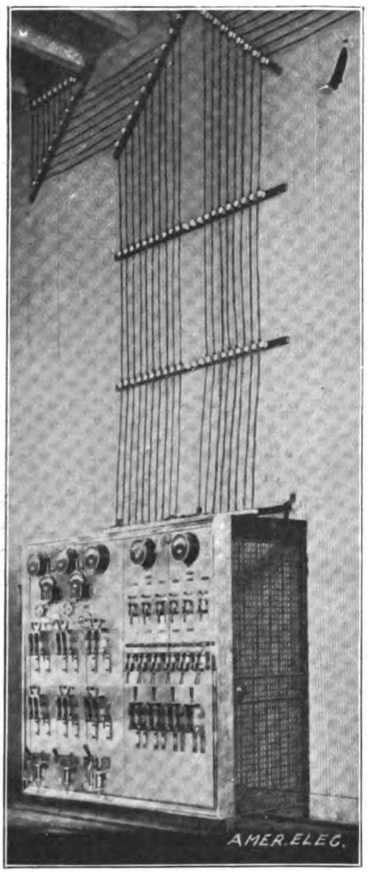

FIG. 4.—FEEDERS RISING FROM SWITCHBOARD.

there the greatest ingenuity must be exercised in order to obtain satisfactory results. In most cases the switch with which a given feeder must connect is prescribed and this makes it all the more essential to start at the board in order to avoid crossing to make the proper connections.

In all cases where the feeders are large or numerous it is well to make a small working model of the feeder system, using small wire or cord for wires and pasteboard for racks. It is much easier handling No. 18 wire than 1,500,000 c. m. and cardboard than iron. Then when the course has been properly mapped out the racks should be set in place throughout the entire course. When the insulator used is of the type shown in Fig 1, one-half of each insulator for each feeder should be set in place in the rack, the conductor then being laid on this half and then the remaining half of the insu-

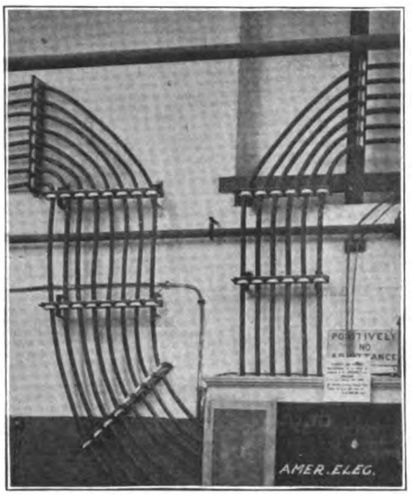

FIG. 5.—A RUN OF HEAVY FEEDERS.

lator put in place and then the straps should be fastened in position. This is a much quicker method than pulling the wires through the insulator and also avoids abrasion. Where it is necessary to pass through walls, partitions, etc., the wires should be protected (unless covered with rubber) by porcelain sleeves or tubes (preferably split in two parts), which are properly protected from breakage. If the conductors be insulated with rubber, sections of lined conduit may be used.

Fig. 4 shows an example of medium-sized feeders rising from a switchboard to the ceiling. In this case the voltage of the installation was 240 volts and rubber covered wire was used. The insulators were the ordinary porcelain "knobs," fastened by machine screws to channel iron, which in turn was fastened to the

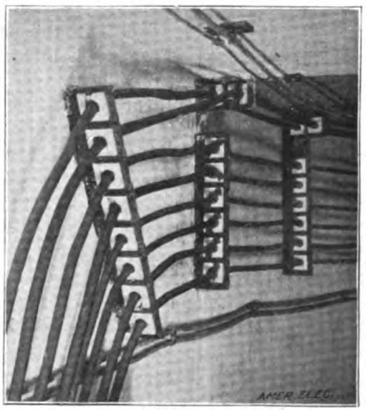

FIG. 6.—A DETAIL VIEW OF FEEDERS SHOWN IN FIG. 5.

iron frame of the partition. The wires were "tied" in the regular manner to the outside of the insulator.

Fig. 5 shows a view of very heavy feeder conductors. In this case the insulator used is of the form shown in Fig. 1, rack being of the design shown in Fig. 3. The wire is triple-braided weatherproof. Fig. 6 shows another view of the same installation.

## STEAM AND WATER STOP VALVES.

### THROTTLE, BLOW-OFF AND SPECIAL VALVES.

Among the improved stop valves to be found in use, and on the market, are many forms of special design which were made to overcome some difficulty. Trouble used to be the constant companion of the old-fashioned valve user, and the manipulator of plug valves used to look for

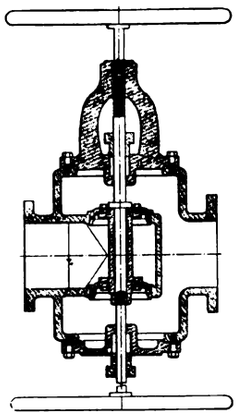

FIG. 1.—DOUBLE-BEAT THROTTLE VALVE.

trouble when he hunted up his valve wrench. But time and engineering have changed all that, until almost every difficulty has been overcome by the use of a specially designed or constructed valve, fitted for the particular case in hand.

The improvement in throttle valves has been most marked. Imagine the circumstances attending an attempt to open a plug valve in a 10-in. steam main against 125 lbs. gauge boiler pressure! It would require a small army of laborers to manipulate such a valve—and plenty of time, also. But with the improved

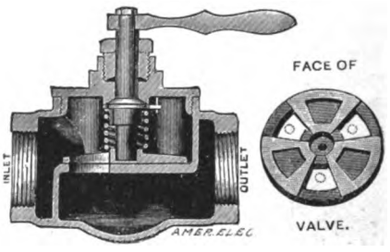

FIG. 2.—GOLDSMITH THROTTLE VALVE.

throttle valves now in use the engineer can control the largest engine with a touch of the fingers.

The throttle valve illustrated by Fig. 1 is a representative of what has been done to advance "throttle valve engineering." This valve was designed by Charles H. Manning, Superintendent of the Amoskeag Company, and was made for the Jefferson mill. This valve is of the "double-beat" variety, and gives the full opening of a 9-in. pipe in two and one-half turns of the hand wheel. As shown by the en-

Digitized by Google

graving, the valve is nearly perfectly balanced and the stem is well supported as it passes through both sides of the valve and carries two stuffing boxes and bearings, besides a third support in the yoke which forms the nut. Being thus supported in three places, there is little danger of spring in the valve stem, or of clattering discs when the valve is being closed. For this illustration and description, also for several others in this article, we are indebted to "Power." Credit is also due to the "American Machinist" and the "Paper Trade Journal" for other illustrations used herewith.

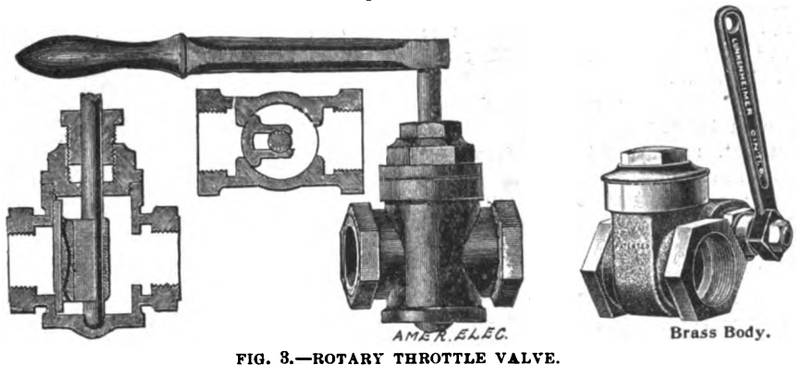

FIG. 3.—ROTARY THROTTLE VALVE.

Fig. 2 illustrates a form of valve made by the Roe Stephens Manufacturing Company, and known as the "Goldsmith Throttle Valve." It is also used for main stop valves, but is especially adapted to large stationary and marine engines, and to large steam pumps working automatically. The design is for the purpose of preventing uneven seat wear and the keeping of scale or sediment from the seats. The discs never leave the seats, and they follow and take up their own wear. The action is positive, and easy and quick under heavy pressures.

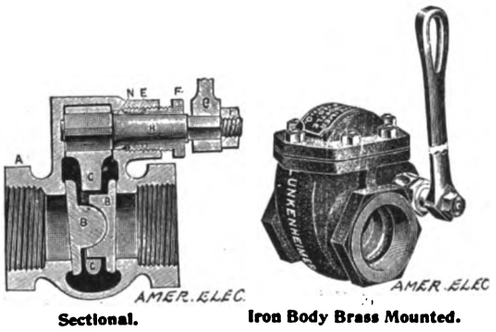

FIG. 4.—LEVER THROTTLE VALVE.

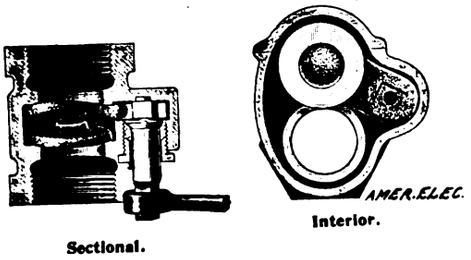

FIG 5.—HANDY GATE VALVE.

A valve of the rotary type, made by the Haydensville Manufacturing Company, is shown by Fig. 3. This is a very quick acting form of valve and compensation for wear is provided for. Only about one-fourth of a turn is required between "full open" and closed, and the valve, having but one stuffing box, and no endwise motion to the stem, leakage is reduced to a very small quantity. The method of attaching valve to spindle is shown in the sectional details of the drawing, and the valve may be removed bodily, at any time, by simply removing the bonnet.

Quite a number of "Swing Lever Gate Valves" are used for throttling purposes. Fig. 4 shows one type and its details as made by the Lunkenheimer Company. This can be operated by a lever on a cord attached thereto, or by a rod attachment. The discs are loose and provided with ball and socket bearings, as shown. They are claimed to wear evenly and make a tight joint. The principle of this valve is to wedge the discs by means of the ball and socket joint, with a full bearing, between the tapering seats. The engraving shows both the iron and brass forms, the former being brass mounted.

A "Handy Gate Valve," made by the same company, is shown by Fig. 5, and this valve must not be confounded with the throttle in the preceding illustration. This valve also has the loose discs and ball joint, but it is not intended for throttling purposes. The stem carries a rotating flange upon which bears a non-rotating friction washer, whereby the necessary friction can be brought to bear on the flanged stem to make it work as easy or as hard as desired. This valve disc is attached directly to the stem by means of an arm, while the throttle valve (Fig. 4.) has a yoke which slips over both discs.

Another form of "lever gate" throttle valve is made by the Wm. Powell Company and illustrated by Fig. 6. This valve is known as the "Star lever throttle," and has double discs which are centered on studs travelling within a slotted carrier, and being confined between the vertical guides of the shell, are constantly rotated at each throw of the lever, causing a continual change of position and assuring a uniform wear of both disc and seat.

This valve carries a wedge block which is loosely confined within the slot of the carrier, between the central studs of the discs, so that at the closing throw of the lever the discs slide up over the wedge and are gradually and firmly forced to their seats. A reverse motion withdraws the wedge and releases the discs. Should the wedge or disc studs wear after a time, from constant use, all that is required to restore the valve equal to new is to put in a slightly thicker wedge, or add a thin sheet of metal thereto. One point is that the construction of these valves admits of their being set at any desired opening.

A unique form of throttle valve, shown by Fig. 7, was designed by Fred W. Salmon, with the intention to combine all the conveniences of the ordinary valve in stopping and starting, from the working side of the engine, also for making it possible to quickly stop the engine in case of necessity, from the other side thereof, should the governor break or unusually high speed from some other cause make a quick stop necessary. The construction of this valve shows a lever upon the side opposite the usual hand wheel, and the nut in which the threaded spindle works is attached to the lever by properly arranged connecting links. A clamp screw locks the lever in any position, and in case of necessity a pull upon the lever closes the valve instantly by bringing down the nut, screw-stem, disc and hand wheel, without the engineer having to get into line with any of the moving parts of the engine, or having to give a hand wheel several turns.

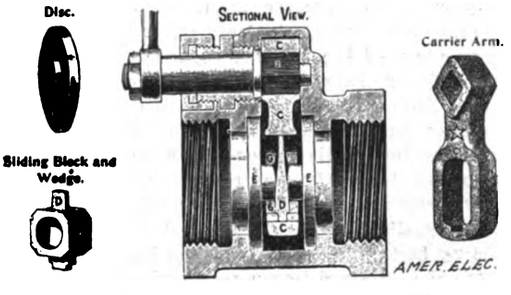

FIG. 6.—STAR LEVER THROTTLE VALVE.

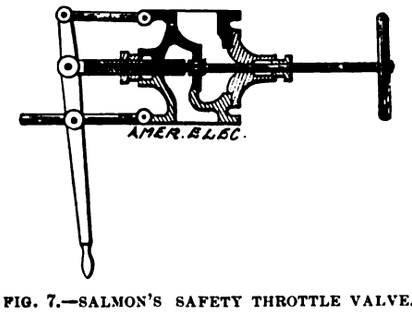

FIG. 7.—SALMON'S SAFETY THROTTLE VALVE.

A good throttle valve is to be desired with every steam engine, but it does not begin to compare with the importance of

Digitized by Google

a reliable blow-off valve on each steam boiler. The importance of this fitting is so great that many inventions have been introduced to steam users. The old plug valve, or stop cock, used to be the reliable standby for this purpose, and it is still used to a considerable extent where the march of progress has not driven it out

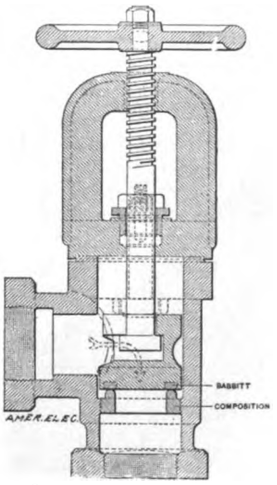

FIG. 8.—IRON BLOW-OFF VALVE.

in favor of a better valve. The form shown by Fig. 8 was designed by an engineer and it is made by the Kelly & Jones Company. This valve is particularly fitted for high steam pressures and muddy or dirty feed water like that from the Ohio or the Mississippi rivers. The side opening of the valve is connected to the boiler, and the construction is such that but little water can escape until the valve has raised far enough to give almost a full opening. This prevents the cutting caused by gritty water passing at high velocity against and under the disc, when only slightly raised. The valve is a sliding fit in the barrel, and has babbitt metal hammered into a recess where it comes in contact with the seat. This valve also possesses the desirable cer-

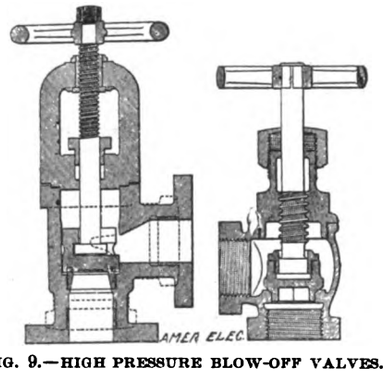

FIG. 9.—HIGH PRESSURE BLOW-OFF VALVES.

tainty, for a blow-off valve, that it can be closed after opening.

Another form of blow-off valve, suitable for very high pressures—up to 250 pounds—is shown by Fig. 9. These valves are made by the Crane Company and may be had in either iron or hard metal. Here, also, the disc is a pretty close fit in the body of the valve so that the disc or plug has to be raised a considerable distance above the seat before discharge takes place. The benefits therefrom are the same as with the preceding valve described.

Fig. 10 presents still another angle blow-off valve, with further peculiarities of construction. The reversible bearing faces in the iron disc are filled with babbitt metal. The disc is solid and fits the barrel closely, so that no scale or sediment can get on top so as to prevent the disc from being raised readily when necessary. The disc is reversible and can be changed at will, thereby increasing the life of the valve.

The seating faces are dovetailed slots filled with babbitt metal, which can be melted out, recast, and then faced off when necessary to renew the wearing surfaces of the valve. The entire trimming can be taken out of the valve by removing the bonnet, then, by unscrewing the small plug at the bottom of the disc and the disc lock-nut around the stem, the disc can be readily inserted.

Some engineers put on two plug or globe valves in order to make sure that the blow-off does not leak. This has proved to be a good thing, although some people claim that it is inefficient, for if one valve

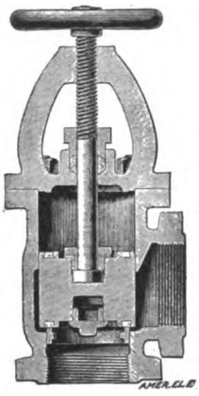

FIG. 10.—LUNKENHEIMER BLOW-OFF VALVE.

fails the other must take all the pressure, and may leak also. In practice this is not found to be the case. The pressure seems to be divided up between them, and each valve carries a share thereof—probably like two resistances in series.

Fig. 11 shows an adaptation of this idea as worked out by the Chapman Valve Manufacturing Company. Practically it is a pair of that firm's standard high pressure steam valves with removable bronze seats and flanged ends, the seats being interchangeable. The outside screw and yoke is to show beyond doubt, at all times, the position of the valves as to whether they are open or shut. In practice it is proper to close first the valve furthest from the boiler. This brings all the wear on the outermost valve, leaving the inner one to keep tight. This order is reversed when the valves are to be opened.

A form of blow-off valve which is coming into favor to a great extent is shown by Figs. 12, 13, 14 and 15. It is known as the "Y" valve, and possesses a good deal of merit, not only for blow-off purposes, but for other uses as well. Fig. 12 shows this form of valve as made by Jenkins Brothers. The construction is such that it has no pocket, or anything to obstruct the passage of steam or fluid. In closing, it shuts against the pressure. Its internal arrangement is similar to that of a regular Jenkins valve, and its giving a full opening and direct passage makes it especially desirable for the mud and dirt of a blow-off pipe discharge.

A somewhat similar form of Y valve is made by the Hydensville Manufacturing Company, and illustrated by Fig. 13. The

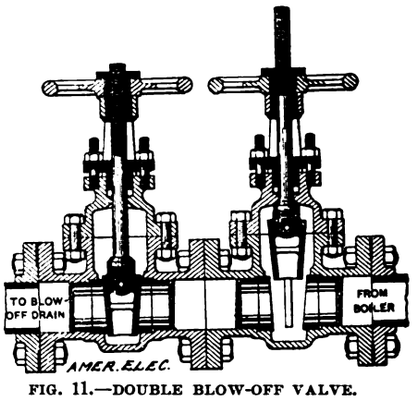

FIG. 11.—DOUBLE BLOW-OFF VALVE.

internal construction of this valve shows a flat seat with a disc fitting down upon it. There is considerable to admire in this arrangement, for there are no corners or crevices in the seat to catch or hold dirt or scale; therefore, when the fluid rushes under the nearly closed disc the flat seat is flushed or washed clean, allowing the disc to be seated without danger of being held up by scale or mud.

The Y valve shown by Fig. 14 is made by the Lunkenheim Company, and possesses several peculiarities. It is a brass to brass seat and disc, and is made regrinding in the manner described in a preceding paper on globe valves. It will be noted that the ends of the valve are male and female, and are always sent thus unless otherwise specified. All the benefits of solid seat valves are to be derived from this, as described for globe valves, and by

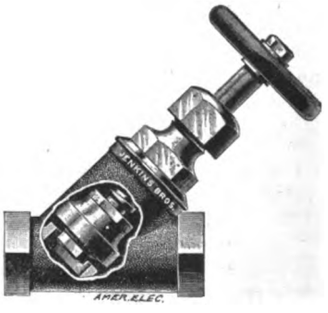

FIG. 12.—JENKINS Y VALVE.

occasional regrinding the blow-off may always be maintained tight and in good condition.

The elaborate form of Y blow-off valve shown by Fig. 15 is made by the Enyon-Evans Manufacturing Company, and the design of the body allows a clear passage when the disc is raised up, thus overcoming any tendency to clog. A hand-hole is provided with a quick acting lock and cover, which makes it easy to get into

Digitized by Google

the valve in case of necessity. The valve seat is renewable and exchangeable and the disc is so made that the part thereof which comes in contact with the valve

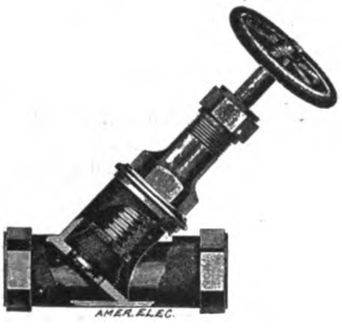

FIG. 13.—ADAMS Y VALVE.

seat can be renewed at will. It is claimed that the capacity of these valves is from 60 to 100 per cent. greater than other forms of Y valves of the same size.

A large number of special valves have been designed to meet peculiar conditions, and among such is the automatic stop

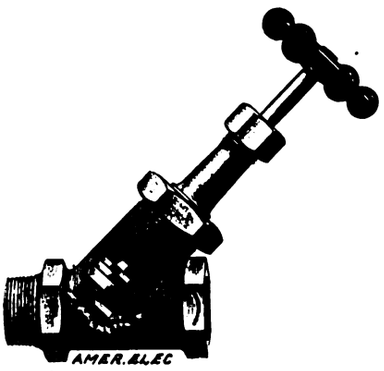

FIG. 14.—LUNKENHEIMER REGRINDING Y VALVE.

safety valve, shown by Fig. 16. This valve is made by the Riter-Barclay Manufacturing Company and is used for the purpose of stopping automatically the flow of steam from a broken main or pipe. A sudden increase in velocity of the steam carries the valve upward to its seat, where

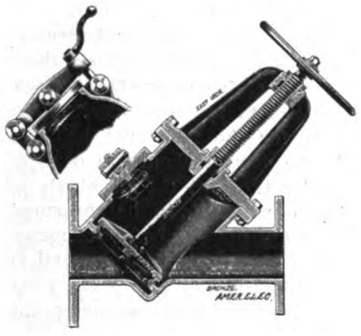

FIG. 15.—EYNON-EVANS Y VALVE.

it is retained by the pressure below it, thus preventing the further escape of steam. The degree of sensitiveness depends upon the weight of valve and size of flange. The threaded stem is to push the disc down from its seat when the valve is to be opened. By putting a disc upon this stem it can be made to serve as an ordinary stop valve, with the advantage that the stem cannot be left

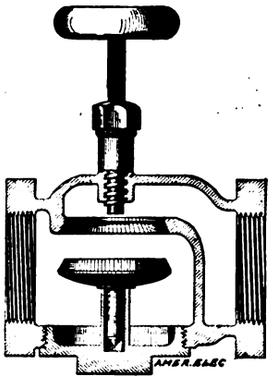

FIG. 16.—AUTOMATIC STOP SAFETY VALVE.

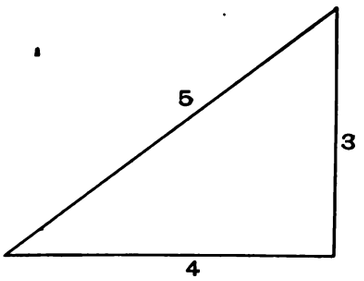
screwed down far enough to render the automatic valve inoperative without shutting off steam entirely.

## *Lessons in Practical Electricity*

### IDLE CURRENT AND POWER FACTOR.



A somewhat unfortunate term which has been introduced into alternating-current nomenclature is "idle current." If the meaning of the phenomenon to which it applies is well understood, the term is a convenient one to use, but otherwise it is apt to lead to misapprehension. The term is actually a misnomer, for the apparent excessive current in an alternating current is not in all senses idle, the excess in fact being due to idle e. m. f.

To illustrate by an analogy, suppose that we have six storage batteries in a circuit, running a 12-volt motor, taking, under normal load, 10 amperes. Suppose now, that one of the cells is reversed, it would result in neutralizing a second cell, thus reducing the free e. m. f. to 8 volts. If now we substitute for the former 12-volt motor an 8-volt motor, the latter, if it does the same work as that in the first case equivalent to 120 watts, will require 15 amperes. Leaving aside the internal resistance and what actions may occur in the two neutralized cells, the battery will give forth the same energy in both cases and the motor will do the same amount of work. In the one case, however, 10 amperes will flow over the line, and in the other, owing to four volts being rendered idle, 15 amperes will flow. Therefore, the second arrangement will result in an additional line loss due to the larger current, though the work is the same in both instances.

Let us now take the cause of an alternating-current induction motor, which, if non-inductive, would use 10 amperes at 12 volts to perform its normal work. There is, of course, no induction motor that is non-inductive, but by placing in series or parallel with such a motor a condenser of proper capacity, the circuit as a whole will act as if non-inductive, for the reason that the capacity e. m. f. will neutralize the inductive e. m. f. Now suppose in such a circuit the condenser is withdrawn, and that the product of the volts and amperes becomes 180 instead of 120 when the motor is performing the same work as before.

We thus have a difference of 60 volt-amperes or apparent watts, as registered by instruments. Yet we know that, leaving aside any difference in motor losses, an equal amount of energy has been consumed in both cases. This discrepancy is due to the additional voltage required to overcome the inductive e. m. f. of the motor, which, in the first mentioned case, was neutralized by the capacity e. m. f.

Wherever current passes through a resistance, however, it will waste energy proportionate to the square of its strength, so that any increase of current in the second case is due to a decrease in the effect of the other factor of energy or

RELATIVE DIMENSIONS AND PHASE ANGLES OF IMPRESSED E.M.F. AND OHMIC AND INDUCTIVE DROPS.

e. m. f., which decrease is in turn due to the neutralizing effect of an inductive or back e. m. f.

In the two cases cited, the useful energy, as stated before, is 120 watts, while the volt-amperes, as recorded by the measuring instruments or apparent watts, are 180. The power factor is the ratio of these two, and in this case would therefore be 2/3 or 0.66.

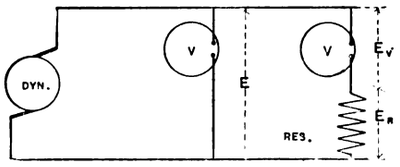
Referring now to the accompanying cut, suppose that the impressed e. m. f. in an alternating-current circuit, as, for example, at the terminals of a choke coil, is 5 volts, and that the ohmic drop in the coil is 3 volts and the inductive drop 4 volts. The only e. m. f. usefully applied is that to overcome the ohmic drop, or 3 volts, the inductive drop acting as a counter e. m. f., and merely neutralizing a portion of the impressed e. m. f. The ratio, therefore, of the useful e. m. f. to the e. m. f. applied to the coil is as 3.5, and the power factor of the coil therefore is 3/5 or 0.6. That is to say, if 1 ampere is passed through the coil, though the product of the volts and amperes is 5 watts, but D 0.6x5 or 3 watts of energy will actually be used.

If we were to consider this case and use the idea of idle currents, the reasoning would be somewhat as follows: Since the e. m. f. measured is 5 volts, and the energy in the circuit but 3 watts, the energy current is 0.6 ampere and the idle current 0.4 ampere. By some, however,

Digitized by Google

the idle current is assumed to be in phase with the inductive e. m. f., in which case its value would be to the entire current as the inductive e. m. f. is to the impressed e. m. f., or, in this case, 0.8 ampere.

In either case it will be seen that the idea of a portion of the current being idle is a false one. The true conception is that the greater the inductance in a translating device the more current is required to be delivered to it to do a given work, since part of the e. m. f. component of work is neutralized by the induction e. m. f. This additional current, while requiring no additional power at the machine, loads the line and increases both its drop and $C^2 R$ loss.



## Electrical Catechism

*293. What instruments are necessary for measuring resistance?*

High resistances may be measured by a voltmeter, by a bridge or by an ohmmeter. Low resistances may be measured by an ammeter and a voltmeter, or by a voltmeter and standard resistance. There are other methods suitable for laboratories with fine apparatus and skilled operators, but most measurements of resistance for practical purposes can be made with the apparatus mentioned.

*294. How can resistance be measured with a voltmeter?*

For this purpose a voltmeter of known resistance and a dynamo or battery giving constant voltage are necessary. First connect the voltmeter directly to the terminals of the dynamo, as suggested at A in the figure, or to some circuit connected with it, on which the current is

MEASUREMENT OF RESISTANCE WITH A VOLTMETER.

not changing. Carefully measure the voltage between the lines, and then connect in series with it the resistance which is to be measured, as shown at B in the figure, and again read carefully the voltage indicated on the voltmeter. This reading will be smaller than the first, because the resistance of the circuit is greater and less current goes through the voltmeter than before. Ohm's law, that current equals voltage divided by resistance, is equally true if turned around to read that resistance equals voltage divided by current. Now, when the same current flows through two resistances, the voltage or fall of potential through each is proportional to the number of ohms resistance in each. In the case above, the drop through the voltmeter is evidently the reading of the voltmeter, while the difference between that reading and the first one taken when the voltmeter was connected directly across the circuit, is the voltage drop through the resistance being measured. This may be expressed as follows: The resistance being measured equals the resistance of the voltmeter multiplied by the difference between the two readings and divided by the smaller reading.

*295. Give an example of measuring resistance by a voltmeter.*

Suppose we wish to measure the resistance of the field coil of a one-half kilowatt, 125-volt motor. The voltmeter has a resistance of 18,000 ohms. When connected directly to the circuit, it indicates 125 volts; when connected in series with the field coil of the motor, it reads 121 volts. (Of course in this measurement, it is necessary to place the voltmeter a sufficient distance from the motor so that its magnetic field will not influence the voltmeter.) The resistance of the motor field is then $18{,}000 \times (125 - 121) \div 121 = 595$ ohms.

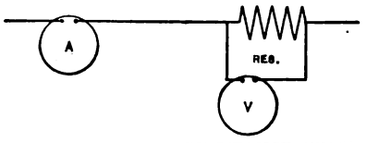
*296. How can a voltmeter be used to measure insulation resistance?*

By connecting one side of the circuit with one side of the dynamo and connecting the other to it through the voltmeter. For example, suppose it is desired to test the insulation between the frame and the windings of the motor. Connect the frame of the motor to one side of the dynamo circuit; connect the other side of the dynamo circuit to one terminal of the voltmeter, and connect the other terminal of the voltmeter to the armature or field coil of the motor. Suppose, as before, that the voltage across the dynamo is 125 volts; when the voltmeter is connected to the motor as just described, it reads 2 volts. Then the resistance of the insulation is $18{,}000 \times (125 - 2) \div 2 = 18{,}000 \times 123 \div 2 = 1{,}107{,}000$ ohms.

*297. How can the resistance of the voltmeter be determined?*

The best instruments have the resistance marked on the case or on the box. If this is not found, it can be determined easily if one can get some high resistance of known value. As before, first measure the voltage across the line, and then connect the high resistance of known value in series with the voltmeter. The resistance of the voltmeter equals that of the other multiplied by the second reading and divided by the difference between the two.

*298. Give an example of determining the resistance of a voltmeter by means of a known resistance.*



Suppose that the voltmeter reads 125 volts when connected directly across the line, but only 75 volts when in series with a resistance of 10,000 ohms. The resistance of the voltmeter is then: $10{,}000 \times 75 \div (125 - 75) = 750{,}000 \div 50 = 15{,}000$ ohms.

*299. What range of resistances can be measured satisfactorily with a voltmeter?*

It depends largely upon the range and the resistance of the voltmeter. With a Weston 150-volt instrument one can measure from about 100 to 2,500,000 ohms, the greatest sensitiveness and accuracy being for resistances about equal to that of the voltmeter. With one having a range from 0 to 5 volts, one can measure resistances from about 3 to 85,000 ohms.

*300. How can one measure resistance with an ammeter and a voltmeter?*

Connect the ammeter in series with the resistance to be measured and connect the

MEASUREMENT OF RESISTANCE WITH AMMETER AND VOLTMETER.

voltmeter in shunt around it, as shown in the figure. By Ohm's law, the resistance equals the current divided by the voltage.

*301. Give an example of measuring resistance by an ammeter and a voltmeter.*

Suppose the current through one of the field coils of an arc dynamo is 10 amperes, while the voltmeter shows 20 volts when connected around the coil. The resistance of the coil is then: $20 \div 10 = 2$ ohms.

The voltmeter connected around an arc lamp in the same circuit shows 45 volts. The apparent resistance of the arc lamp (including the arc) is: $45 \div 10 = 4.5$ ohms.

*302. What precautions are necessary to insure accuracy when measuring resistance with a voltmeter?*

Be careful that the voltage of the dynamo or battery does not change between the two readings; this can usually be checked by taking a second reading across the line with the voltmeter alone. Be sure also that the voltmeter is not affected by any magnetic field from the circuit being measured. Also be sure that the wires and connections used do not have any appreciable resistance, or that must be considered.

*303. What precaution should be taken when measuring with ammeter and voltmeter?*

Be careful that neither instrument is affected by magnetic field from the other instrument or from any other source. Be careful not to use more current than is suitable for the resistance being measured. Be careful about the connections, especially those at the terminals of the resistance which is to be measured, for if these are not good the voltmeter will read too high. There is a small source of error in the fact that if the voltmeter is connected inside the ammeter, the ammeter measures the current through the voltmeter as well as that taken by the resistance; on the other hand, if the voltmeter is connected behind the ammeter it measures not only the drop through the resistance, but also that through the ammeter, and through the connections. It is usually better to neglect the current in the voltmeter and connect it directly to the terminals of the resistance.

# Queries and Answers

Can 125 cycle transformers be run with new machines giving 60 cycles? H. T.

Yes, with equal satisfaction. See editorial pages for further details.

How can the negative and positive terminals of a battery or dynamo be distinguished by placing a wire from each in a glass of water? W. H. D.

The negative terminal gives off hydrogen and bubbles more freely than does the positive.

Does it make any difference in the case of a constant potential arc lamp whether the resistance is between the positive wire and the lamp or between the lamp and the negative wire? R. D. C.

No difference whatever.

A small motor with a pole armature will turn half way and then stand still. What is the probable trouble? C. E. K.

In all probability the connections of the coil on one of the poles of the armature are reversed.

How many cells of type "A" Edison-Lalande battery will I require to run motor described in the American Electrician of February, 1897, wound for 6 volts? G. J.

The Edison-Lalande battery gives about 7/10 of one volt with a normal load. Nine such cells connected in series will give 6 volts.

What is the formula for computing the c. p. of incandescent lamps at increased voltages above the normal? S. B. S.

The c. p. varies approximately as the sixth power of the voltage supplied, although this law depends somewhat upon the initial efficiency of the lamp; thus a 110 volt, 16 c. p. lamp would give roughly 17 c. p. on 111 volts, about 18 on 112 volts and so on for a short distance.

I would like to know how to construct a machine that will wind a solid iron ring, such as that in the regulating coils on the back of the G. E. alternating fan motors, taking the wire from a spool without winding it upon a shuttle. W. M. N.

No machine can be built that will do this work, as the spool cannot be slipped through the ring, making it a physical impossibility.

Please state the best way to make a counting machine for counting turns of wire for armature, field coils, etc., when wound upon a lathe. W. M. W.

The simplest method is to use a bicycle cyclometer with a piece of wire fastened to the head stock of the lathe in such a way as to advance the cyclometer one notch each revolution. A few trials will determine the number of hundred turns per mile indicated on the cyclometer.

Can telephone and telegraph messages be sent upon the same wire with a ground return? A. H.

Yes, by connecting in series with each telepgraph instrument, at the terminals between the line and ground, a choke coil, and by shunting around this choke coil and telegraph apparatus a telephone set in series with a condenser. Further information will be given on this subject later.

Given 6 cells of a voltage 1.05 each and an internal resistance of 0.5 ohms each, joined in series and placed on a circuit containing resistance in parallel of 3 and 30 and 300 ohms each, what will the current flowing in the circuit be? W. R.

The current will be almost exactly 1/100 of an ampere in the 300-ohm shunt, 1/10 of an ampere in the 30-ohm, and 1 ampere in the 3-ohm branch, as the e. m. f. of the battery will be pulled down by the internal drop to about 3 volts.

Given a compound-wound dynamo of 50 k. w. capacity, voltage at full load 115, armature resistance hot 1/1000 ohm, shunt resistance hot 25 ohms, drop in series coil 5/10, volt, watts loss in friction 1250, hysteresis loss 300, what is the efficiency of full load? H. S.

The losses at full load are as follows: Armature copper loss 190 watts, series field loss 220 watts, shunt field loss 530 watts, friction loss 1250, hysteresis loss 300 watts, making a total of 2490 watts loss. If the output is 50,000 watts the imput must be 52,490 watts and the efficiency about 95 per cent.

Please inform me as to the cost of running a 15 h. p., 220 volt motor for 10 hours at 10 cents per kw. hour. Would it be 7 1/3 cents per h. p. hour? J. J. M.

Ten cents per kw. hour amounts theoretically to 7½ cents per h. p. hour, but owing to the losses in the motor 10 cents per kw. hour input would amount to about 9 or 10 cents per h. p. output. The cost of running the motor will depend largely upon the load placed upon it. If run continuously at full load for 10 hours at this rate it would amount to $12 for 10 hours.

What form of dynamo should be used in charging a storage battery and why? A. E. C.

A shunt machine only should be used as a series or even a compound machine is apt to have its field magnetization reversed in case it slows down and the storage battery tends to discharge back through the machine. In this case the machine would act as a dead short circuit upon the battery, tending to help its discharge. With a shunt field this cannot occur, as the battery tends to keep the field constantly excited in the proper direction.

In a G. E. 4 ring, 3 phase alternator is there the same voltage between any two of the rings and how should lamps and motors be connected? J. W.

On testing it will be found that there is the same voltage between any two of three of the rings, but that the fourth gives a lower voltage between itself and any one of the other three. Three phase motors should be connected invariably to the three terminals and not at all to the fourth. Lamps should be divided in three different loads connected respectively between one of the three terminals and the fourth, the latter becomes then a common return for three different groups of lamps.

What is the simplest form of incandescent lamp ground detector for 110 volt circuits? W. A. H.

Two 110 volt lamps connected in series across the lines, the middle wire between them being tapped off to ground. In case there is no ground in the system each lamp gets half the voltage, the current passing in series through the two. In case one of the mains becomes grounded the lamp connected to that main is obviously connected between ground and ground and gets no e. m. f., the other one getting 110 volts; thus one goes out and the other shines at full c. p. when there is a ground upon the system. The one which goes out is connected to the grounded side.

Is street lighting a practical success on a 2080-104 volt, 125 cycle, single-phase system using lamps connected with transformers already supplying incandescent lights to private houses? L. B. P.

Arc lights are often run on consumers' premises from the transformers which run the incandescent lights, and with success when the lines and transformers give close regulation. Arc lights drop the voltage badly on poorly regulating transformers. Street lights would probably, as a rule, be too far removed from private transformers for this work, although considerable drop in the leads from the transformer to the light might be allowed to take the place of the resistance usually used in series with the light.

Does it make any difference whether the equalizer is on the positive or negative side of compound-wound machines? Is it necessary to have the equalizer on the negative side of the machines in order to connect them with storage batteries? A. V. S.

It makes no difference which side of the machine the equalizer is connected to except that, of course, it must be connected to the same side the series field is joined to. Many railroad companies connect the series field and equalizer on the negative side of their machines, so as to give a low voltage between equalizer bus and ground. In connection with storage batteries it is only necessary to connect the battery between the equalizer and the opposite pole rather than across the outside terminals, so that in case the dynamo slows down and the storage battery discharges back through it, the current will not pass through the series field and reverse the magnetization of the machine.

Have dynamo machines been built so as to be self-exciting, series, shunt or compound-wound and give direct currents and also alternating currents of any frequency desired? R. C. J.

Yes, an ordinary direct current dynamo can have its winding tapped to collector rings, which will give alternating currents of a frequency dependent upon the speed and number of poles, and of any desired number of phases. Such a machine can, of course be shunt or compound wound on its direct current end, and if desirable, fitted with a rectifier and compound winding for its alternating end. Some railroad companies having long distance lines now use such machines, giving 500 volts direct current for sections of the line near their stations and alternating currents which are stepped up to high pressure and transmitted out to rotary converters in substations for the feeding of the distant sections.

## THE SAFETY THIRD-RAIL SECTIONAL CONDUCTOR SYSTEM.

On April 12th the first public test was made of a full sized sectional conductor railway installation worked out on the plans of the Safety Third-Rail Electric Company of New York City. The track on which the showing was made is a short section of the Long Island Railroad at Manhattan Beach connecting the Manhattan and Oriental Hotels, with a length of about 2,000 feet; this has hitherto been operated with a steam locomotive and car, connecting with all the trains arriving from New York City, but during the coming summer the traffic will be carried by the new system.

The equipment consists of a "Duplex" convertible car, mounted on Peckham maximum traction trucks fitted with General Electric motors. The third rail is a 65-lb. tee, in sections about 18 feet long, placed midway between the track rails. It is surrounded by a wooden trough placed directly on the sleepers, the rail being supported inside the trough by granite blocks and the trough afterwards filled with asphaltic cement. The sections of the third rail are insulated from each other by artificial granite blocks about 12 inches long. The current is picked up from this rail by two shoes, one under each truck of the car. The automatic switches which connect the sections under the car with the main feeder and again disconnect them when the car runs away from them are of the electromagnetic type, operated by currents sent to them by the car, and may, therefore, be located at any convenient point, or grouped in neighboring structures or vaults.

The general design of the switch is shown in one of the accompanying illustrations. The winding is enclosed in a cast-iron cylinder with a central plunger, which lifts up the main contacts at the bottom of the switch; these consist essentially of a primary contact of laminated copper leaves and secondary contact or following break of carbon to render harmless any arc that may occur. At the top of the switch is an auxiliary break, the purpose of which is described below.

The general method of operation is best shown in the accompanying drawing, where WW represent the wheels of a car running on a track, T, and driven by the motor, M. The third rail is indicated at R, midway between the track rails, and is divided at I and $I_1$ by insulating sections. Every other section of this third

ONE OF THE AUTOMATIC SWITCHES.

rail is blank, that is, it has no connection at any time with the main feeder, the alternate or intermediate sections being connected at proper times through the automatic switches with the source of power. In the illustration the central piece between the insulating joints I and $I_1$ is such a blank section, while that to the left may be connected through the switch, S, with the main feeder, F, and that to the right through the switch $S_1$. with the same feeder. The car takes current from the third rail through the contacts, C and C .

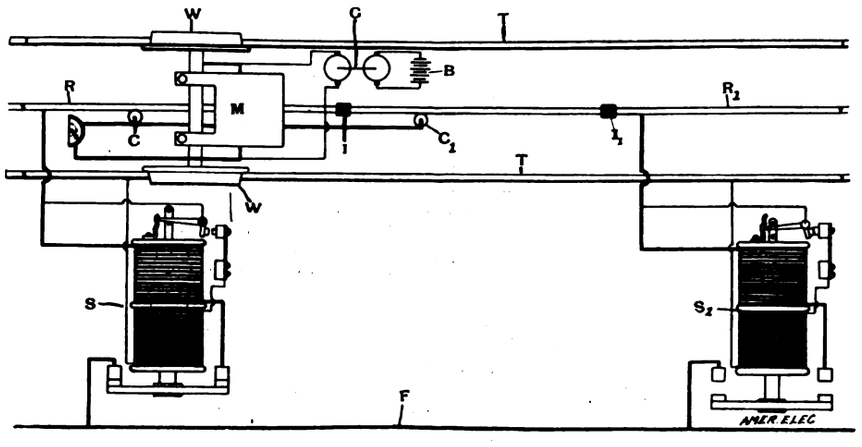

DIAGRAM SHOWING SCHEME OF OPERATION.

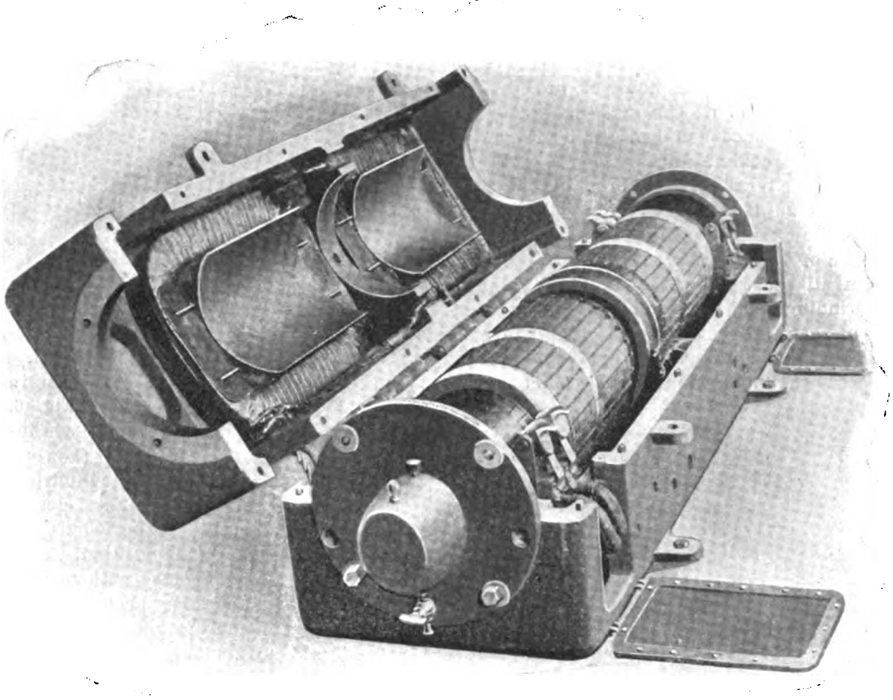

The distinguishing peculiarity of this system is the fact that power house current is used to operate the switches and, although a local source of current exists at the car for picking up the switch in case at any time there is no connection with the main feeder, yet no fourth rail or set of contacts is necessary for transmitting this local current to the switches. This necessitates that the local source of current shall be applied between the third rail and the track rails and therefore that it shall have the full pressure of the current supplied, namely 500 volts. This is ingeniously obtained upon the car by means of a small storage battery working a motor generator, which transforms the low pressure of the battery to 500 volts.

The operation of the system is as follows: Supposing that the car indicated in the diagram is moving to the right, as indicated by the arrow, it is in the position shown taking current from the main feeder through the switch, S, and holding the plunger of this switch in the up or closed position by virtue of the series winding indicated on the upper part of the switch magnet. When the car advances so that the contact, $C_1$, passes beyond the insulating joint, $I_1$, on to the section of the third rail, $R_1$, it introduces into this section current derived from contact, C, which is still on the last live section, R. This current passes through the fine wire or shunt winding on the lower half of the coil of switch, $S_1$, and instantly pulls up the plunger, closing the lower contacts of the switch. The current then has two paths to the car, one through each of the switches, and divides between them in approximate equality. The raising of the plunger of switch, $S_1$, also breaks a small auxiliary contact shown at the top of the switch and connected in the fine wire circuit, but the plunger is held up by the current flowing through the coarse wire or series coil. When the contact, C, passes the insulating joint, I, in the third rail, current no longer comes in through the switch, S, and, both its shunt and series coils being de-energized, the switch drops open by gravity and is ready for the next car, the same cycle of operations being repeated at all the switches as the car passes them.

It is clear that at any time when the current is turned off in the controller from the car motors it will no longer hold up the switches by means of the series coil, and the car will be cut off from the main feeder. In order to again get connection with the power house the storage battery indicated at B, and the motor generator indicated at G, are installed on each car. While the car is running and taking current this little motor generator continuously charges the battery from the main line. When the controller is turned to the off position the motor generator is cut out of circuit, and when it is desired to again take power the first notch of the controller connects the 500-volt side of the motor generator across the third rail contacts and the ground thus giving sufficient current to energize the fine wire winding of the switch or switches connected to the sections on which C and $C_1$ bear and to pull their contacts into the up or closed position. Immediately thereafter the controller is advanced another

Digitized by Google

notch, throwing current into the motors, which current comes through the coarse wire windings of the same switches and holds them in the up position, the car running on as explained above. If the

THE MOTOR GENERATOR.

controller is moved to the second notch too quickly before the electromagnetic switch has time to act, the car motors will obviously act as a short circuit upon the motor dynamo, and if moved too slowly from the first to the second notch the switch will obviously vibrate up and down like the make and break device of an induction coil, as it breaks its own shunt winding every time it rises, but it is found that the switch may be made to keep good time with controllers as ordinarily operated.

In the equipment at Manhattan Beach the storage battery consists of ten cells of the 7 V type of chloride accumulator, and from them 20 volt lamps are operated in multiple to light the car. The motor generator is a two-field machine, illustrated in the accompanying figure, ingeniously designed to occupy a limited space, so that it may be placed under the ordinary car seat. The machine weighs about 500 pounds, and is designed for high armature reaction, so that it may withstand the occasional short circuit above mentioned without injury to itself or the battery. The two-field feature is necessitated by the fact that the ratio of transformation should vary from about 500 to 25 volts while the battery is being charged, to 18 to 500 volts while the battery is discharging. This is accomplished by special field windings connected with a contact in the main controller.

The patents on the system have been taken out by Captain John McLeod Murphy, the electrical and mechanical engineer-in-chief of the Company, of which the well known banker, Emerson McMillin, is president. These patents cover broadly the motor generator principle by which 500 volts can be generated on the car without a large number of storage cells and by which a fourth rail or set of contact studs can be done away with as well as several other valuable features.

## THE WAGNER SINGLE PHASE MOTOR.

It is becoming more and more obvious to the central station manager that profits depend on the uniformity of the load, making it necessary for lighting plants to obtain day loads, if possible. The only day load of any consequence is the distribution of power by means of motors, which has proven difficult in the case of single-phase alternating current plants owing to the backwardness of the development of the single-phase motor as compared with direct current or even multiphase alternating current motors.

Although there are many different principles under which small alternating current motors may be built, those of any commercial size may be divided into two general classes—the synchronous and the induction types. The first is practically an alternating current dynamo without rectifier or composite winding. It must be brought up to speed by some auxiliary starting device, such as another motor, and thrown into circuit only when in synchronism and with the proper phase relation, just as one dynamo is thrown in multiple with another. When circuits are changed it is liable to lose synchronism and stop, it always requires an exciter and its field strength affects greatly the regulation. For these reasons it is not adapted for general power distribution in small units from lighting circuits.

The other type is the induction motor with a rotary field analagous to that of the multiphase motor. While a single-phase alternating current will not alone give such a rotary field, the currents induced in the rotating part of an induction motor give a magnetizing force lagging behind that impressed by the winding of the field or primary circuit, to which the single-phase circuit is supplied. When the motor is running, this lagging magnetizing force is carried by the motion of the rotating part to a position at an angle with the main magnetizing force with which it is out of phase, thus giving to a motor with a correctly proportioned stator a true rotating field which makes the induction motor as satisfactory a machine upon single phase as upon multiphase circuits.

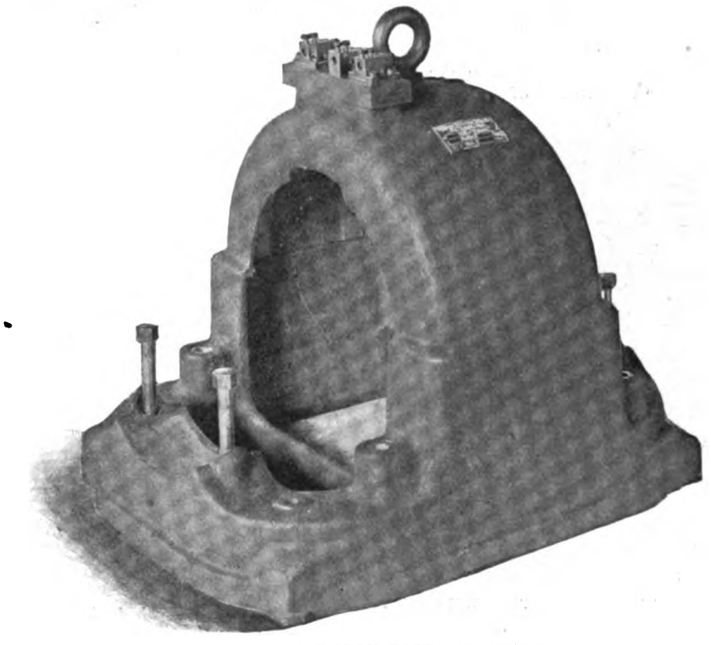

FIG. 1.—THE CAST IRON BASE AND SHELL.

Digitized by Google

The only essential difference is the fact that there is in the induction motor fed with single-phase current no rotating field until the motor is running, and hence there is no tendency to start from standstill unless some auxiliary arrangement is supplied to give torque up to a speed at which the rotary field effect will carry the load.

The accompanying figures and the description given below apply to the line of motors made to meet these requirements by the Wagner Electric Manufacturing Company of St. Louis, Mo.

Structurally each machine consists of an enclosing shell of cast-iron, Fig. 1, forming the base and the semi-cylindrical cover; slipped upward into this from below is the field ring, with its winding, shown in Fig. 2, and this is fastened in place by a cast-iron follower, Fig. 3, bolted to the shell. While the field has poles in a magnetic sense, it has no yoke ring with internally projecting polar extensions, such as are found in direct current machines, but consists of a ring of laminated plates slotted on their inner periphery to receive the winding, which is uniformly distributed in these slots. The coils, one for each pole, are hand-wound and laid up spirally, i. e., the two middle slots on each side of the center tooth of a pole are first wound, and from them the wire is carried into the two adjacent slots, one to either side, and so on out until all the slots of a pole are filled, giving what is called the "pancake" winding.

In the field of which the illustration, Fig. 2, was made there are 4 poles, and therefore 4 such spiral coils. The armature of this motor is shown in Fig. 4, from which it may be seen that it closely resembles the armatures of direct-current machines. The laminated core is slotted, the slots, however, running not parallel with the shaft, but at a slight angle, in order that the passage of the armature teeth past the field teeth shall not set up high frequency variations of the magnetization, which would cause screaming. The inclination of the armature teeth allows them to pass gradually across the field teeth much as the rotating blade of a lawn mower crosses the stationary blade. The armature is wound just as is a direct-current armature for the same number of poles, and the coils are connected to a commutator, which, however, in the Wagner motor is of the disk or radial flat type. Two carbon brushes bear against this flat commutator

Three terminals are brought out from the windings of this motor and one side of the circuit may be connected to either one of two of them. One connection cuts in all the turns of the field or primary windings and the other cuts out about 25 per cent. of the turns of each pair of field coils, being termed by the Wagner Company the "loop connection." This throws the whole voltage of the supply circuit across a smaller number of turns, so that the back e. m. f. per turn of wire of the motor must be greater; in other words, the alternating density of magnetism in the iron of the motor must be greater. With this connection the motor will stand heavier overloads and build up its speed against a greater starting torque, but it increases the magnetizing or lagging currents and thereby reduces the power factor. The iron losses are also increased.

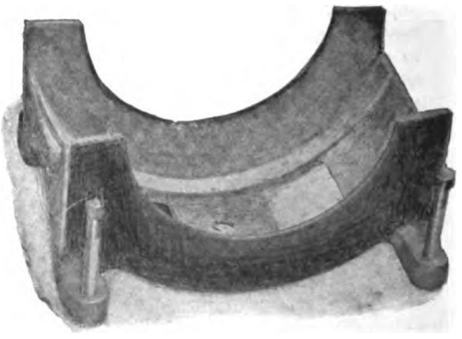

FIG. 3.—THE FOLLOWER.

FIG. 4.—THE ARMATURE.

The starting device is best shown in the cross section, Fig. 6. Here there may be seen inside the spider of the rotor a pair of semi-cylindrical centrifugal weights, closely encircling the shaft in their inner position. They are connected with rods by which they push a sleeve inside the commutator axially along the shaft, the push being resisted by a coiled spring inside the sleeve. When the weights fly out by centrifugal force they move the carbon brushes away from the commutator and slip into contact with the commutator segments a ring of metal which short circuits all the armature or rotor coils.

FIG. 2.—THE FIELD RING AND WINDINGS.

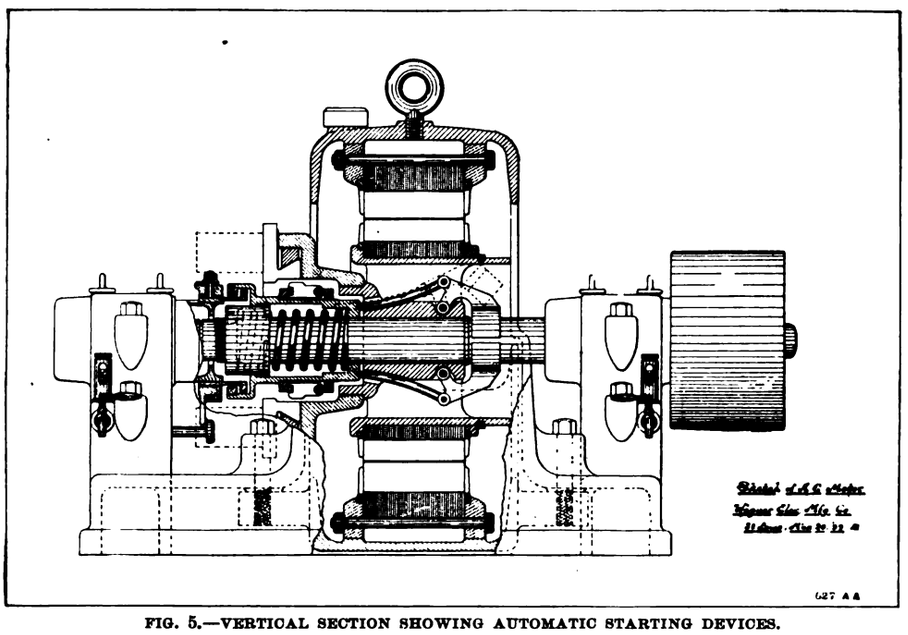

FIG. 5.—VERTICAL SECTION SHOWING AUTOMATIC STARTING DEVICES.

When the motor is started the weights are in their inner position, the commutator is not short circuited and the brushes are bearing upon it. The two

Digitized by Google

brushes are connected by a resistance and act to short circuit a part of the commutator. The currents set up in the short circuited windings by the alternating magnetism of the field or stator are repelled by the field itself, giving a torque which sets the motor in motion. When it approaches full speed the centrifugal weights fly out, the brushes are removed from the commutator, the short circuiting collar is brought into contact with the segments and the machine run as a pure induction motor as explained above. By moving the position of the brushes by hand the direction of this initial or starting torque may be reversed and the motor may thus be brought up to speed and run in either direction equally well without any change of the connections.

The number of poles in such motors is directly dependent upon the speed desired. With 60 cycle current, giving 72 alternations per minute, a 4-pole motor will tend to run at about 1800 r. p. m., falling off from this slightly with increased load. A 6-pole motor would similarly run at about 1200 r. p., an 8-pole at 900 r. p. m., etc. With 120 cycles the number of poles must be doubled to give the same speeds.

## INCANDESCENT LAMPS—A DETAILED DESCRIPTION OF THEIR MANUFACTURE.

Although incandescent electric lamps are a very common commodity and have been in use for a number of years, they are still a very delicate and somewhat complicated device requiring the greatest skill in all the mechanical details, an end that can only be obtained by constant watchfulness by experts, and users and buyers have generally little idea how much attention and expense is required in this direction to meet their demands for high grade articles. As there are few factories that give more attention to careful inspection than the one operated under the direction of the Shelby Electric Co. at Shelby, Ohio, the processes here followed furnish the particulars for this story.

The bulbs are purchased by all lamp manufacturers from the glass makers and are all practically bell-shaped, but differ in size, depending upon the candle-power of the lamp. Those for the ordinary 16 c. p. lamp are made with a long, straight neck or tube about ¾-in. in diameter. The transparency is an important factor in the bulb, and for this reason they are all made of the first pourings from the pots of molten glass. The remaining portions, which contain more or less dross, are made into dishes, bottles and other glassware, where transparency is not a necessity. For this reason lamp factories do not make their own bulbs, as there would be too much waste material. The form of the bulb as it reaches the lamp maker is shown in Figure 1. It is first washed and dried by means of rapid circulation of air, so that no spots are left on the bulb. It is then "tubulated" by having a small glass tube fused to the base at one side of the neck, Fig. 2. In some factories the bulbs are tubulated at the large end, but as by this process a tip is left when the tube is removed, the Shelby Company prefers to tubulate at the base, so that one line of their lamps is known as the "tipless bulbs." The company also manufactures on an extensive scale the ordinary tipped lamps.

The next most important element is the filament. The material for this is usually some form of cellulose, but in this factory the particular material is kept a secret, known only to the chemists of the company. In the process of manufacture a fine white thread of the material is formed by squirting it through a die and when dried it has the appearance of an ordinary fine fiddle string. This material is then carbonized by being wound in threads of fifty upon forming blocks which

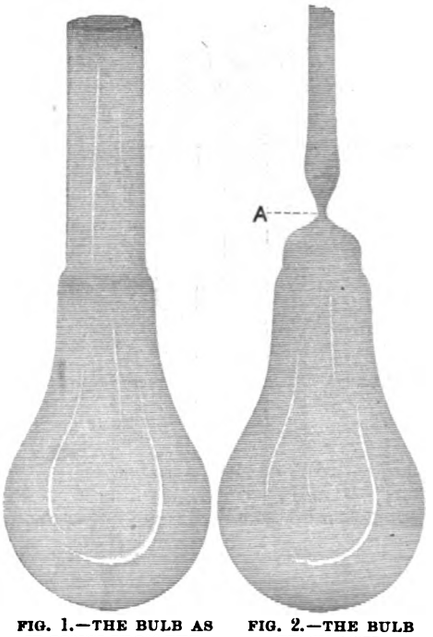

FIG. 1.—THE BULB AS IT COMES FROM THE GLASS WORKS.

FIG. 2.—THE BULB TUBULATED.

are made from carbon. In the Shelby lamp the filament is usually made with three helical coils, and when properly placed upon the carbon forms, the ends of the filaments are fastened by means of paraffine, when the forms, with their contents, are packed in large crucibles and surrounded with pulverized graphite. The crucibles are then covered and sealed and placed in specially designed furnaces, where the temperature is gradually raised by even stages until a high degree is reached, when they are cooled off by the same gradual process until the crucibles can be removed. By this process the filaments are thoroughly carbonized, and when removed from the form they have the appearance of fine steel wire, and the loops maintain their shape. The filaments are now assorted in four or five different grades by means of micrometers which measure to one three thousandth of an inch, and are trimmed to accurate length and made ready for the platinum wire attachments.

The sections of platinum wire are usually about half an inch in length and one end of each is formed into a little tube, first having been flattened and then drawn by means of pliers through a ruby die. The opposite end of the platinum section is then fused to silvered wire, which ultimately forms the leading-in wire to the lamp. Silvered wire is employed by this company in preference to copper, to obviate any liability of oxidation, and is one of the features of the Shelby lamp. The stem, which is another special feature of these lamps, is made by joining the ends of two small glass tubes by a glass bar, making a U shape section. The sections of the silvered wire together with their platinum terminals are now fused within this stem, when they are ready to receive the filaments, and these are attached in the mounting room by inserting the ends of the filaments in the little tubes previously formed on the free ends of the platinum wire. These tubes are then pressed firmly against the filaments by means of pliers, when the stems with the filaments attached are taken to the plating room, where a perfect contact is made between the filaments and the platinum wires by an electric welding or plating process. For this purpose a specially designed machine is operated into which the terminals are carefully clamped, when a current controlled by an automatic regulating device is directed through the section, welding or depositing the plating product. For this operation a small generator is provided and there is a very curious current regulator which controls the current by steps until the contact is perfectly formed.

The stem with this filament goes next to the treating room, where the filament is subjected to a process which is known as plating and which makes it uniform in resistance throughout its entire length. To acomplish this, the filaments are placed, a number at a time, within receivers from which the air is exhausted, and the lamp is lighted by current and allowed to burn for a while in a gaseous carbon compound. In this process, when the proper condition is secured, the current is automatically cut off and directed to the next filament, being controlled by delicate instruments depending on the resistance of the filament. Being thus prepared, the filament with its stem is sealed in the bulb, care being taken that in the process of fusing the stem to the base of the bulb the stems are straight and are attached to the bulb at the proper point. As this process goes on, dents or cavities are formed in the neck of the bulb, which are designed to assist in holding the base, which is attached by means of plaster to the lamp.

As preparatory for the vacuum process the lamps in groups of twelve are attached by means of the tubes, fused to the bulbs as above described, to the forks or prongs of the exhaust pipe of the pumps. As soon as the air is exhausted the lamps are lighted, first by a weak current, which is gradually increased, and as the lamps continue to burn the product of combustion is pumped out, a process which re-

Digitized by Google

quires about one hour and three-quarters. In this process a circular hood is dropped over each group of lamps designed to retain the heat generated by the burning, which raises the temperature of the bulbs and assists in expelling the particles of air and gas that have a tendency to adhere to the inner walls of the bulbs.

The vacuum test follows and consists in placing the lamps on the terminal of an induction coil of high potential, which is located in a dark room and which causes the bulb to emit a peculiar glow, showing the condition or degree of the vacuum. If in the test the glow does not show that the vacuum is a "dead black," the lamps are returned to be re-exhausted. Being finished, the lamps are measured to determine their candle-power, volts and watts. For this photometric process a storage battery current is employed.

Following this process the lamps go to the selecting room, where they are sorted as to voltage, candle-power and economy. When ordered they are again tested for vacuum, after which the required base is attached by means of cement, and in this process the terminal wires are soldered in. When dry the lamps are placed upon racks and burned for an hour before they are packed for shipment, and while being burned undergo their final inspection as to appearance when burning with the current required. From this test the lamps go to the shipping room, were they are washed and carefully wiped and dried, after which they are packed in pasteboard compartments in substantial wooden cases. The employees are mostly girls and the average wages are about $1.35 a day, the number of employees being about 180 and the output averaging 5,000 lamps daily. The output includes lamps of every candle-power between four and fifty, in every voltage from forty to two hundred and fifty volts. The entire equipment of the works is up to date and every department seems permeated with the spirit of progress which enables them to claim that the Shelby lamp is the "best on earth."

## TESTS OF CLING-SURFACE.

Some instructive tests of the transmission of power by means of leather belting, with and without treatment with cling-surface, have recently been made under the direction of Prof. R. C. Carpenter, by the laboratory force of Sibley College, Cornell University. The results of the test are shown in the two diagrams represented herewith, in which the abscissae or horizontal distances of both, represent the same tests; in other words, the slip shown for a given initial tension in one diagram corresponds to the horse power for the same tension in the other. An analysis of the results of these tests is best given in the words of Prof. Carpenter, the following being quoted from a letter written by him on this subject:

"The general result of the test with cling-surface shows an increased transmitting power as compared with the same belt in an untreated condition; it also shows an increased arc of contact, and very much less slip. It shows a very high transmitting power when the belt is run extremely loose or with very little tension on the pulleys, the reverse of which is true with the untreated belt. It will be seen from the diagrams that the greatest transmission capacity for the belt treated with cling-surface was found when there was the least possible tension on the belt, and when the belt was running so slack that the sides nearly touched.

"In the test of the same belt not treated with cling-surface the results were quite different, inasmuch as the capacity with very light tensions was practically nothing, and the capacity increased as the tension increased; at no point, however, did the untreated belt have even approximately the same capacity as the treated belt, with the same tension; and, moreover, the treated belt transmitted much more power with a very light tension than the untreated belt with a heavy tension. The test with the belts, treated and untreated, running on wooden pulleys, showed essentially the same characteristics.

"The general results of the tests of the untreated and treated belts when running on iron pulleys is shown in the accompanying diagram, Figs. 1 and 2. In Fig. 1 the horizontal distance show the tension on the belt in pounds per inch of width, the vertical distances show the horse power transmitted per inch of width of belt for a speed of 4500 ft. per minute. The lower line represents the results obtained with the untreated belt; the upper line the results obtained with the treated belt. It will be noted that the lower line continually rises, showing an increase in capacity with an increase in tension; the upper line descends at first, showing a decrease in capacity with increase in tension, and later rises. In no place does the transmitting capacity of the treated belt fall below that of the untreated belt. In comparing the respective results it will be noted that the treated belt has a carrying capacity of 13.8 horse power when the tension per inch of width is 5 pounds, while for the same conditions the untreated belt has no carrying capacity; furthermore, it is noted that the carrying capacity of the treated belt, even at this low tension, is nearly 40 per cent. higher than that of the untreated belt, even when the tension has been increased to 80 pounds per inch of width of belt. The diagram in Fig. 2 shows the arc of contact and the maximum percentage of slip for bolts run both in the treated and untreated condition with different tensions and on iron pulleys.

"In regard to the questions raised as to the preservative qualities of Cling-Surface and to the permanency of the effect produced by its application, the writer would say that our tests have of necessity been of too short duration to give conclusive answers. The general effect of the Cling-Surface is to soften the belt and to put it apparently in the best condition for transmitting power and retaining its good qualities. The surface produced by the Cling-Surface remains apparently unchanged after several weeks of use, and the inference to be drawn is that the material has an effect which continues permanent for some time at least."

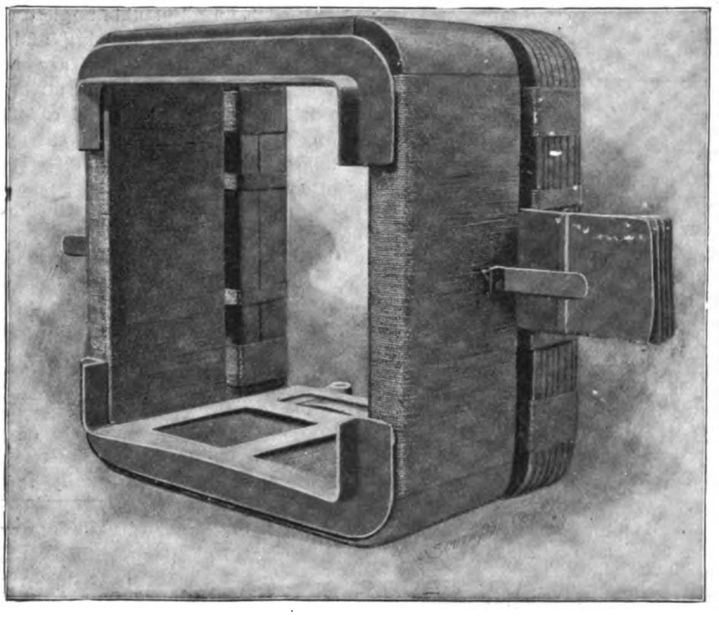
# New Apparatus and Appliances

### A RELAY CIRCUIT BREAKER.

It has become universally customary to open loaded dynamo or feeder circuits by means of the circuit breakers instead of switches wherever the former instruments are in the lines. While this practice was primarily dictated by laziness, the tripping of the circuit breaker being easier than the opening of the switch, it is commendable, as the circuit breaker is always fitted with following breaks, which are not injured by the arc as are the blades of knife switches.

A CIRCUIT BREAKER WITH RELAY OR OVER VOLTAGE COIL.



It is often found desirable to open circuits from points distant from the switchboard, either in case of emergency or to save walking to and fro. Several types of electro-magnetic switches have been built for this purpose. A happy combination of the two principles above mentioned is effected in the circuit breaker illustrated in the accompanying engraving, which is made by the Ward-Leonard Electric Co., Bronxville, N. Y. The breaker is supplied with two independent coils or magnets, one connected as usual in series with the line to act on overload, and the other with a finer winding connected across the lines through one or more push buttons at any desired location. Both magnets operate the same latch on a single pole breaker in the middle of the instrument.

The equipment shown is single pole, but can be made double pole by placing another switch at the right of the right-hand magnet, the latches of both switches being tripped by the plunger of the magnet between them. Obviously the fine wire magnet may be kept on permanently closed circuit and adjusted so that it will only pull up its plunger when the voltage exceeds a certain maximum safe limit, thus making the circuit breaker an over-voltage as well as an overload instrument.

---

### THE FIELDS OF WESTINGHOUSE GENERATORS.

One of the characteristics of Westinghouse engine type dynamos is the arrangement of the field coils. The field castings are divided vertically and set upon a guide plate, over which they may be moved laterally away from the shaft to allow the removal of the armature or field coils without the necessity of disturbing the outboard bearing or dismantling the engine. This opening of the fields in a horizontal direction is of particular convenience where head room is limited or cranes for lifting heavy weights are not available.

THE SHUNT AND SERIES COILS OF A RAILWAY GENERATOR FIELD.

The shunt and series coils are always separately wound, the series coils, as a rule, being nearer the yoke and the shunt coils nearer the pole. The series conductors are composed of forged copper straps of rectangular section laid up edgewise and kept together by binding ropes at intervals. The shunt and series coils for a 500-kw. direct-coupled railway generator are shown in the accompanying engraving, which clearly indicates the multiple straps by which a good clamped contact can be obtained between coils on adjacent poles and the single straps carrying the shunt current. The coils are, as is there indicated, mounted on two brass skeleton plates, which are secured in place by being bolted to the laminated poles, no extended pole pieces being used.

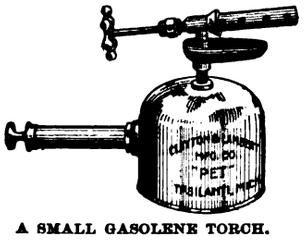
Any slight inequality of the field strength of these generators which might have serious consequences in parallel wound machines, is automatically corrected by an ingenious invention of Mr. B. G. Lamme. It is obvious that in a parallel wound machine the current may not distribute itself equally between the different paths, one under each pole, from the positive to the negative brushes, but may, if one pole is a little stronger than the others, flow mostly under the strong poles and little, or none at all, under the weaker one. If one pole is considerably weaker than all the others, the current may even be reversed in it and exert a reaction on the field which will further weaken it and cause the path under that pole to act as a short circuit to the rest of the machine. This is particularly likely to occur when the bearings become worn, or from any other reason the armature gets out of alignment, increasing the air gap on one side and diminishing it on the other.

Digitized by Google

In the Westinghouse machines the windings are cross connected at points of equal potential, there being two or three such cross connections per pole. The winding under each pole is virtually a synchronous alternating current motor, and these are all connected in multiple by the cross connections above mentioned, thus allowing magnetizing currents to flow from pole to pole to mutually adjust the field strength just as occurs when synchronous alternating current machines are connected in multiple. This prevents the excessive heating which occurs when the current is unequally distributed, as well as the enormous mechanical strains which ensue from unbalanced fields.

A TELEPHONE INDUCTION COIL.

The Varley Duplex Magnet Company, Jersey City, N. J., has brought out a



A BOX COIL FOR TELEPHONE TRANSMITTERS.

new box coil possessing several points of superiority over the style brought out over a year ago. It permits the use of a secondary wire one gage number heavier without increasing the external dimensions of the coil, thus diminishing the resistance and improving the efficiency. The screw holes are both in the cover of the box, insuring accurate alignment and a fixed distance between them, one screw passing through the head of the inner bobbin.

A CONVENIENT TORCH FOR SMALL WORK.

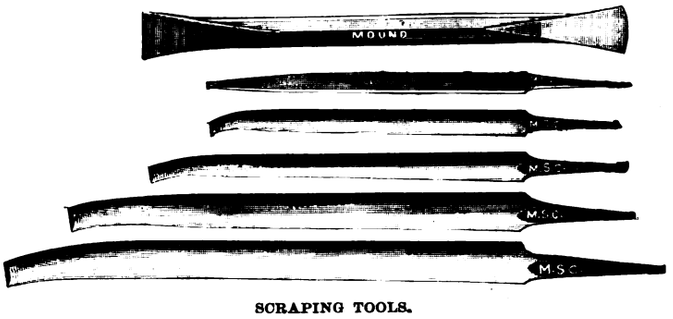
The Clayton & Lambert Manufacturing Company, Ypsilanti, Michigan, has put

A SMALL GASOLENE TORCH.

on the market a simple and handy torch shown in the accompanying cut. It is particularly convenient for inside wiring or any small work needing a needle flame strong enough to do light brazing. The tank is spun in one piece of number 18 brass and is fitted with a horizontal air pump, which also serves as a convenient handle. The burner is round and fitted with cleaning out plug.

A DEVICE FOR REMOVING AND CLEANING INACCESSIBLE INCANDESCENT LAMPS.

In theatres, churches, high ceiled hotels, depots, etc., the incandescent lights are, as a rule, very difficult to get at, involving



AN INCANDESCENT LAMP MANIPULATOR.

the use of step ladders, which are hard to handle in such places without injury to the furniture. A device for grasping the incandescent lights and removing, replacing or cleaning them from a position on the floor, is made by the Incandescent Electric Light Manipulator Company of Boston, Mass., and consists of a long telescoped pole carrying rubber lined nippers with an adjustable angle and proper arrangements for gripping and turning the lamp. Special tools are made for Westinghouse bases and string lamps. With a little practice and careful handling this device saves a great amount of labor in the moving of step ladders or other apparatus for getting the operator up near to the lamp.

SCRAPING TOOLS.

A convenient set of fine scraping tools for scraping engine bearings, valves, journals, etc., is made by the Mound Tool & Scraper Company, St. Louis, Mo., in sets of six tools of various shapes and sizes, from 8 to 14 inches long, carefully tempered, neatly polished and packed in a substantial and suitably arranged oak case.

SCRAPING TOOLS.

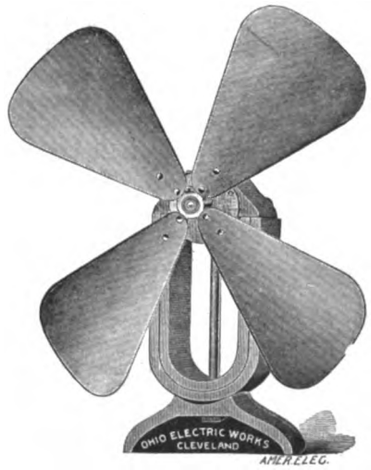
A MONITOR ELECTRIC BELL.

The internal construction of a bell in which the armature is not attached to the hammer lever but is separately pivoted from it, is represented in the cut shown

A MONITOR ELECTRIC BELL.

herewith. A compound lever effect is obtained in this way which swings the hammer through a long arc, giving a quick blow and a very quick return of the hammer from the metal of the bell, producing an unusually clear tone. The bell is struck on its side and not on the edge, as in other makes of this type, this improvement being claimed as giving a better ringing effect. The contact points are so arranged that they slide upon each other for a distance not less than 3/16 of an inch, insuring clean surfaces and reducing the burning. The bell is now made in the 3-inch size, the gongs being of heavy brass, either polished or nickeled. It is listed as the type "Q" sliding contact electric bell by the makers, Rousseau's Electrical Works, New York City.

NON-MAGNETIC WATCHES.



In these days of increasing use of structural steel and of powerful electric currents which give it a permanent magnetization, the owners of watches with steel hair springs constantly find their timepieces disturbed by influences which they cannot account for. The difficulties may not be great, requiring resetting perhaps once a week, but they are annoying and can easily be overcome by using a non-magnetic metal for this delicate part.

Digitized by Google

Carl A. Paillard, a watch adjuster of Geneva, Switzerland, has invented a palladium hair spring and compensation balance that is entirely unaffected by magnetic influences. Watches with this improvement are made in all grades and sizes by A. C. Becken, Chicago, Ill. The palladium has other advantages over steel in that it is not rusted even by salt water, and the balance is so perfectly compensated that it is not affected by the heat obtained by placing it on a stove.

### A MAGNETO BATTERY FAN.

It is well known that very small dynamos require a large percentage of their output for the excitation of their fields, but that the same is true of motors of equivalent sizes does not seem to be appreciated. A fan designed to run without waste of energy in exciting the fields of a

A MAGNETO FAN MOTOR.

motor with electromagnets is shown herewith. The field in this case is a double horseshoe permanent magnet cutting down the current consumption for a 10-in. fan running at 1000 r.p.m. to about 1 ampere at seven volts, according to the claims of the makers, the Ohio Electric Works of Cleveland, Ohio.

### INSULATION AND CABLE TESTING GALVANOMETERS.

Messrs. Willyoung & Company, Philadelphia, have recently brought out the new design of D'Arsonval galvanometer shown in Fig. 1. The field is of laminated special magnet steel and the coil proper is contained in a tube which is removable from the magnet in the manner first suggested by Prof. Ayrton and Mr. Mather. Fig. 2 shows tube and coil in section, while in Fig. 3 we have the tube with sheath removed.

The D'Arsonval galvanometer (as opposed to the Thompson type) is probably one of the best instruments for practical use. As now made, it can be extremely sensitive, stable as regards disturbance by mechanical causes, and totally unaffected by all currents except the one passing through it. Magnetic changes in the neighborhood do not worry it.

As shown, the tube, using the word in its largest sense, consists of a rib, R, (Fig. 3), by which are supported the top and bottom torsion heads. A straight fibre above, and helical spring fibre below, furnish torsion and carry the current in and out at the same time. Over the whole slips the sheath, T, which, when in place, is secured against withdrawal by the screw, D (Fig. 3). In case of an accidentally broken suspension one needs but remove the screw D and slip off the sheath, T, to have the entire system, suspensions,

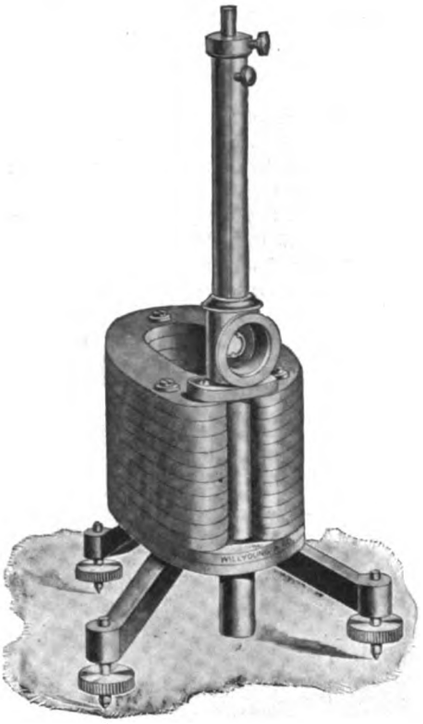


FIG. 1.—AN INSULATION TESTING GALVANOMETER.

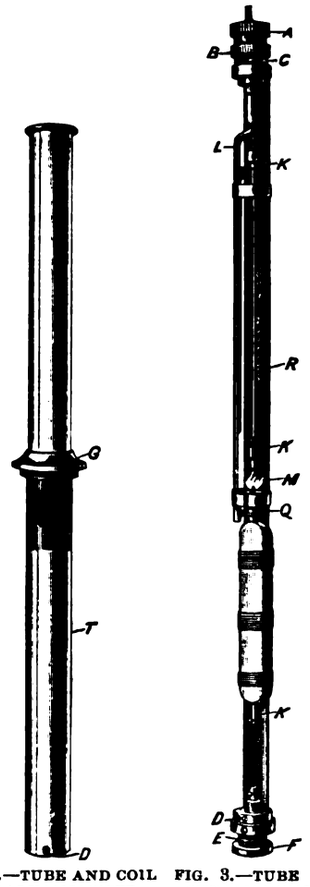
etc., absolutely free and accessible. The suspensions themselves are all of standard length and end with bits of No. 22 copper wire, while the torsion heads, as also the top and bottom of coil, are tipped with special connectors, K, so made as to just contain the No. 22 wire; a small set screw is then tightened and holds them securely.

Another feature is the clamp for locking the system against accident and taking strain from the suspension. Through the center of the upper torsion head runs a spindle, or wire, L, at the top of which is a milled head, A. This spindle (Fig. 3), is bent out as shown and finally terminates below in a little fork just under the disc, Q. The head, A, will therefore raise L, and hence the coil by the disc, Q, until jammed tightly against the holed out stop above.

These D'Arsonval galvanometers are furnished with tubes, either dead-beat or ballistic, and as the tubes may be interchanged very quickly and without interference with connections, it follows that an instrument with two tubes is adequate for all the necessities of both insulation and capacity work. The sensitiveness of the tubes may be varied up to 1500 or 2000 megohms, i. e., one scale revision for 100 volts through 150,000 to 200,000 megohms.

Besides supplying these instruments as parts of laboratory outfits, Messrs. Willyoung & Co. are also putting them into portable cable testing sets for street service; in this form they are equipped with a telescope and scale permanently at-



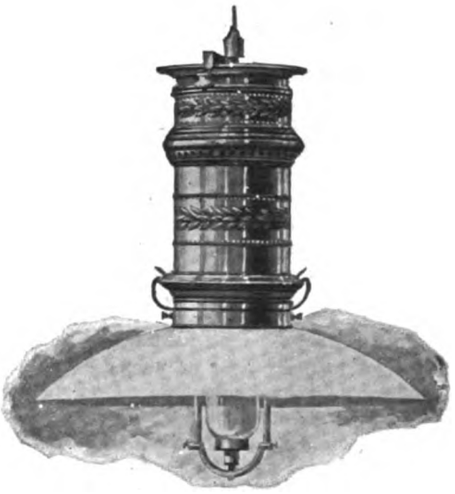


FIG. 2.—TUBE AND COIL OF GALVANOMETER. FIG. 3.—TUBE WITH SHEATH REMOVED.

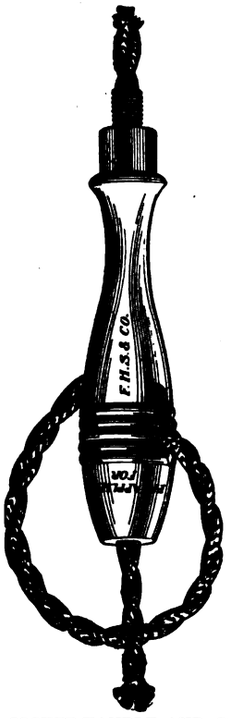
tached and are mounted in oak or cherry boxes, with sling straps, etc. Mr. James G. Biddle, Drexel Building, Philadelphia, is selling agent for the Willyoung apparatus and will be glad to furnish further particulars to interested parties.

### THE MORRIS ARC LAMP.

The enclosed arc for constant potential direct-current circuits, shown in the ac-

A CONSTANT POTENTIAL ARC LAMP.



companying cut, is made by the Morris Arc Lamp Company, Chester, Pa. This

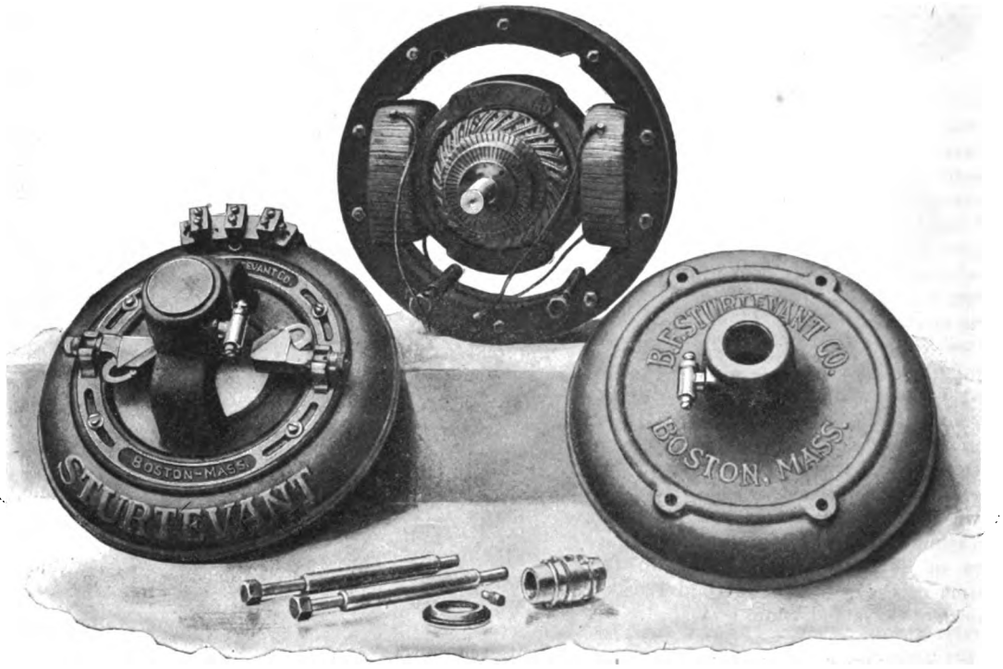
Digitized by Google

lamp is made in two lengths, one 30 inches over all, giving 100 hours' service with 5 amperes, the other 24 inches over all, giving 60 hours' service with 3 or 5 amperes. The carbon-feeding mechanism consists of a single solenoid concentric with the carbon holder, the plunger lifting the holder by means of a simple washer clutch. Sudden movements are prevented by a dash pot with a graphite piston. Besides the lamps designed to run singly on 110-volt circuits, with 80 volts across the arc, lamps are made to run singly across 220-volt mains, or 2 in series with the same voltage, or 5 in series on railroad circuits.

### A COMBINED SOCKET HANDLE AND CORD ADJUSTER.

The most convenient place for adjusting the cord of a hanging incandescent lamp is naturally at the lamp itself, and the

A SOCKET HANDLE AND CORD ADJUSTER.



socket handle shown in the accompanying illustration is fitted to perform this function, as well as to give a convenient means of handling the lamp. It also serves to prevent the fraying of the insulation of the wires near the metal parts where a short circuit might occur. This convenient implement is made by Frank H. Stewart and Company, Philadelphia, Pa.

### THE STURTEVANT VENTILATING FAN MOTORS.

The bipolar type of enclosed motor shown in the accompanying engraving is used for direct coupling to propeller fans in all sizes up to and including the 48-inch. For larger sizes 4 and 8-pole types are employed. The motors are entirely enclosed and thereby protected from dust, a valuable point in locations where dust is constantly drawn through them, and are carefully designed for the low losses which are essential in motors without ventilation. The machine is capable of continuous operation for 10 hours with a temperature rise not exceeding 30 degrees F.

The arrangement for supporting the brush holders is a departure from existing methods. The leads to the brushes are brought through from the rear, doing away with any dangling wires. The brushes are of hard carbon and the holders are of a modified reaction type, allowing immediate adjustment when it becomes necessary to reverse the direction of rotation of the motor.

The design of the propeller wheel is the result of an extended series of comparative experiments with different types. The delivery edge is helical, and the form is such that the air is picked up at the inlet edge of the blade at low velocity, and when well under the influence of the blade is accelerated to its maximum velocity with the least amount of slip. As a result, the efficiency is extremely high. The wheel is partially enclosed within a conoidal inlet ring, which decreases the frictional resistance to the entering air. By means of a tripod support the motor is rigidly held in place, and the entire apparatus may be bolted directly to the wall through which the air is to be discharged.

THE PARTS OF A VENTILATING FAN MOTOR.

### INTERCOMMUNICATING TELEPHONE.

There are illustrated in this issue two companion instruments that have been on the market for a number of years, although the designs in which they now appear are a radical departure from all forms and makes of instruments of this class.

The principal change has been made in the wall telephone, as will be noticed by reference to the cut thereof. These instruments are constructed entirely of metal, the base being a jappanned and gold striped iron casting, on which are mounted the other parts. The directory card frame, gong, transmitter top and circular case containing the signal keys are all highly polished and nickeled. All binding posts are avoided. All insulated bushings are specially made of hard rubber. The entire interior mechanism is polished and nickel-plated, insuring ease and continuity of action. The contacts are designed so that a sharp rubbing connection is made in every case.

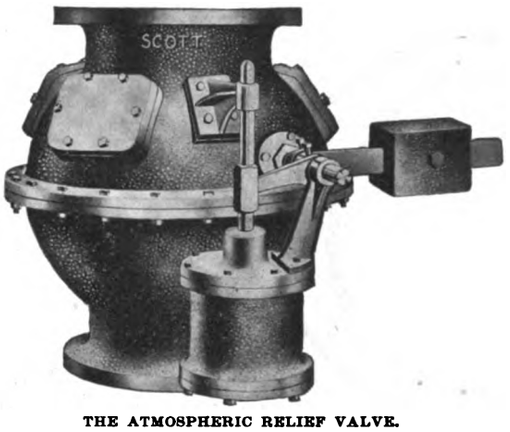
Special attention has been given to connecting these instruments to the main wires rapidly and securely. Too much attention cannot be given to this point in inter-communicating telephone systems, especially owing to the large number of wires that require attention. A loose or otherwise poorly made connection in any one of the instruments will invariably make itself known after the instruments have been in operation for awhile; therefore provision must be made to substantially and correctly connect the main wires to their respective points. In the instrument illustrated, this is accomplished in a manner that experience covering a good many years has shown to be the best. First, the back of the instrument is placed and fastened in position directly over the main cable. Second, the ends of the wires are brought directly to the proper contact pieces. Third: the front of the instrument, containing transmitter, receiver and all the signal keys, is placed in position, all connections being made automatically by this operation.

The desk instrument illustrated is the well known type manufactured by this company. Some of the more recent improvements in the construction of this

Digitized by Google

instrument are the following: First: the entire interior mechanism is polished and plated, giving a smoothness and freedom to the several parts that could not be obtained otherwise. Second: the instrument is not grounded, as is common practice in the Bell Telephone Co.'s apparatus, and other similar instruments. The transmitter is entirely insulated from the outside case in every way. Special provision is made to carry the two wires by the adjustable joint without having any loose wires exposed. All the instruments shown are equipped with the company's new transmitter, in which no wood or other substance that deteriorates is used. The transmitters are of special design and are made by special machinery, insuring uniformity.

THE DESK SET.



THE WALL INSTRUMENT.

The foregoing instruments are manufactured by the Allen-Hussey Company, having its main offices in Chicago and New York, which makes a specialty of interior and inter-communicating telephone systems.

---

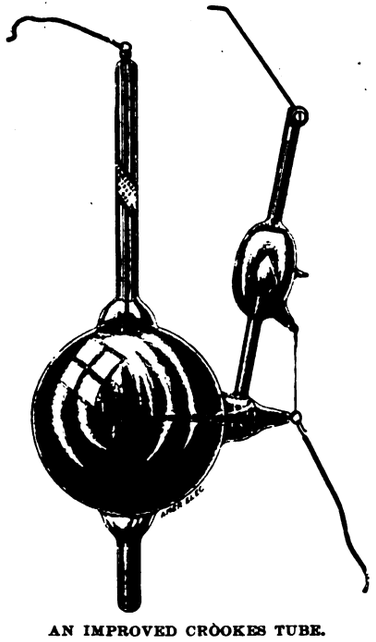
TWO SCOTT VALVES.

The accompanying cuts illustrate two of the valves shown in the new catalogue of the Roe Stephens Manufacturing Company of Detroit. Some of the important features claimed for the Scott "pop" safety valves are: The adjustable screw threaded ring, with angular face, by which the valve is adjusted to loose any desired pounds, or fraction of a pound pressure of steam, and by which there is a constant pressure of steam held on the valve seats while blowing off, thereby preventing all abrasion and wear of seats and consequent leakage; the device by which the inequality of pressure of spring is overcome; and transmitted to the axis of the valve, thereby preventing all friction and liability of valve to cock or tilt, and consequent leakage and cutting of seats; the construction of the lock-up, which is simple and effective, and precludes any possibility of the valve being tampered with.

THE ATMOSPHERIC RELIEF VALVE.

The second illustration shows the Scott water sealed exhaust relief, or back-pressure valve. This valve is constructed to operate in exhaust mains between the low pressure cylinder and the condenser, and is so designed that should the condenser fail to operate and a back pressure form, the valve will automatically open, allowing the steam to escape into the atmosphere. All possible leaking of air which would tend to destroy the vacuum in the condenser is obviated by the water seal. This valve can be regulated to open at any desired pressure, and is noiseless under all circumstances while in operation, when weight is properly adjusted and air cushion regulated. It can also be used in connection with exhaust steam heating, and is so constructed that any amount of back pressure can be carried for this purpose. It is made in all sizes from 4 inches to 16 inches.

Special attention is also called in this catalogue to the Scott extreme high pressure gate valves. These valves will stand a working pressure of 300 pounds, and are tested to 1000 pounds hydraulic pressure. They are made of the best material. The seats in the iron body are screwed in and are interchangeable. The disks are wedge shaped, solid, or double cylindrical wedge, as desired. They have a ground joint under end of stuffing box, so they can be packed when full open. They are furnished with flanged or screwed ends with by pass and gearing, when so ordered.

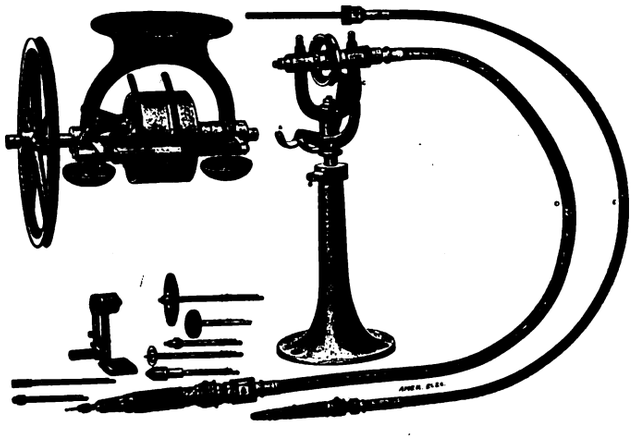


A SELF-REGULATING X-RAY TUBE.

All who have used Crookes' tubes know the general effect which continued use exerts whereby the vacuum is increased until it finally becomes such a high insulator that no more current can be forced through the tube without a strain that punctures or breaks down the glass. Several devices have been gotten up to overcome this difficulty, generally involving the use of an auxiliary or branch tube containing a metal which will give off vapors and reduce the vacuum when heated.

THE "POP" SAFETY VALVE.

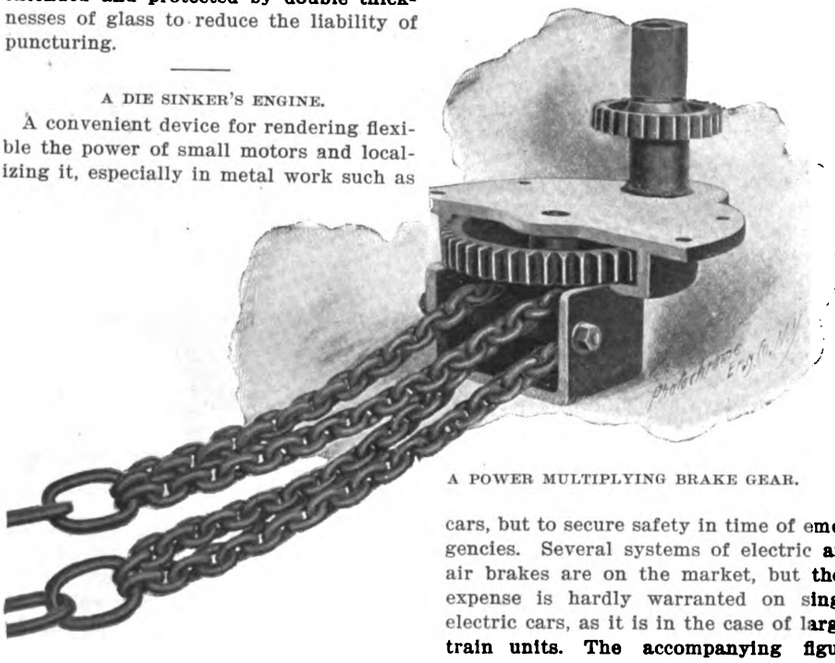
The accompanying figure shows a tube arranged so that the heating is automatically effected as soon as the resistance rises too high, so that the tube automatically restores its own proper vacuum. This is accomplished by means of a branch tube containing a small bulb, which, in turn, contains potash, which will give off suitable vapors when heated. The bulb is exposed to a cathode in the auxiliary tube which is exhausted to a low Crookes' vacuum, the corresponding annode being in a shunt circuit around the main tube.



AN IMPROVED CROOKES TUBE.

When the resistance of the latter becomes too high, the discharge passes

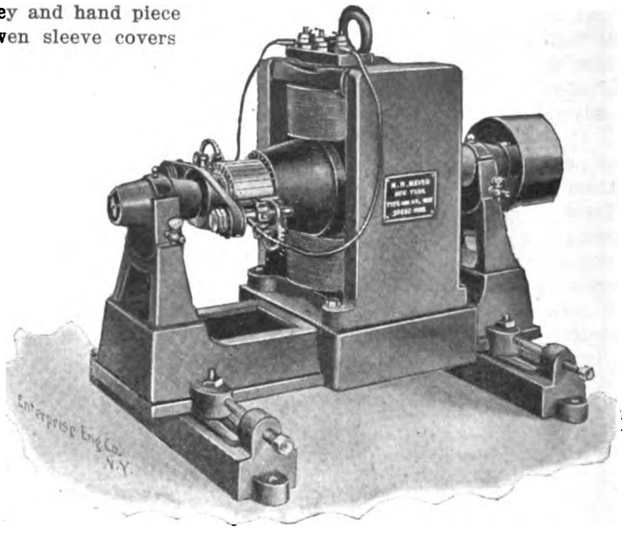
Digitized by Google



through this shunt circuit, bombarding the bulb with cathode rays, heating the potash within it and thereby reducing the vacuum in the main bulb. By adjusting the spark gap of the shunt circuit the resistance of the main bulb at which the current will take the shunt circuit can be changed and the degree of exhaustion changed with it, so that the tube can be readily changed for X-ray penetrations of different substances. The main bulb is about 4½ inches in diameter, and bears a crushing pressure of over 700 pounds, in spite of which it is less than 1/64 in. thick, an important factor, as glass is partially opaque to X-rays. The larger diameter gives a low heating of the glass and provides a larger surface for the deposit of the aluminum which is torn off from the cathode. The cathode terminals of both the main tube and regulator are extended and protected by double thicknesses of glass to reduce the liability of puncturing.

A FLEXIBLE SHAFT ENGINE.

### A DIE SINKER'S ENGINE.



A convenient device for rendering flexible the power of small motors and localizing it, especially in metal work such as that of die sinkers and mould cutters, is shown in an adjacent figure. As the reader will instantly see, it is an adaptation of the principle employed in that terror of the dentist's patient, viz., the dental engine; and is made by the S. S. White Dental Manufacturing Company of Philadelphia. The flexible arm, which is the main feature of the engine, consists of a tempered steel wire cable, so arranged that it maintains its tension without straining or uncoiling, with rigid ends for the attachment of pulley and hand piece or tool carrier. A woven sleeve covers and protects it throughout its length. It gives great freedom and extreme delicacy of manipulation with absolute control of the power and of its direction of operation, factors almost as valuable in fine metal work as in the dental office.

A POWER MULTIPLYING BRAKE GEAR.

### THE STERLING SAFETY BRAKE.

With the constantly increasing weights and speeds of electric cars, improved methods of braking are necessary, not only to reduce the labor of handling the cars, but to secure safety in time of emergencies. Several systems of electric and air brakes are on the market, but their expense is hardly warranted on single electric cars, as it is in the case of larger train units. The accompanying figure shows an improved hand brake made by the Sterling Supply and Manufacturing Company of New York City. The device consists of a spindle shaft socketed to the handle staff and geared to a double sprocket wheel in the ratio of 5 to 2, thus multiplying the motorman's power. The double sprocket wheel carries two continuous chains, so that should one break the other takes up its work instantly and the wear is distributed, increasing the life of the chains. With this device it is not necessary for the motorman to use the foot dog except in case of emergency, as the leverage secured by the gearing enables him to easily hold the brake by hand.

A BIPOLAR IRONCLAD DYNAMO.

### THE MAYER DYNAMOS AND MOTORS.

The illustration above shows a view of an improved direct-current dynamo or motor, made by the Maxwell M. Mayer Electric Company, New York. The machines are of the bipolar, ironclad type, the whole magnetic circuit being a single, open-hearth steel casting. This is bolted to a cast-iron base, to which are cast the pillow-block supports. These are bored at the same time as the pole-pieces, securing in this way the correct alignment of the bearings and armature. The field coils are wound on metal spools. In the armature mica insulation is employed throughout. Tempered copper commutators of large size and bearing surface and carbon brushes are used. These machines are built in sizes of one, two, three and five horse-power, and are constructed for hard and heavy service.

## NEW BOOKS.

Electricity in Town and Country Houses, by Percy E. Scrutton. Second Edition. London. Archibald Constable & Co. 148 pages. Illustrated. Price $1.00.

This is an elementary work of value more to the owner of town and country houses, who is in doubt as to what system of lighting to install than to the engineer who is, as a rule, acquainted with the general propositions the book contains. It is, however, of some interest owing to its description and illustration of English details, which differ from those on this side of the water.

Digitized by Google

The Universal Electrical Directory. London. H. Alabaster, Gatehouse & Co. 1182 pages. Price, 6 shillings.

The 1889 annual issue of this valuable directory contains a total of 25,464 names, approximately 16,070 more than were contained in the directory of 1898. Much financial information is given, and telegraphic addresses and local telephone numbers have been added, the various new features in creasing the size of the directory by 64 pages.

Small Accumulators, How Made and How Used. By Percival Marshall. New York, Spon & Chamberlain; 80 pages, illustrated. Price 50 cents.

This small manual is an elementary hand book for the use of amateurs and students, and the first of a series of popular scientific works for electricians and engineers. This book is particularly adapted for those seeking the first rudiments of information on this subject, rather than for experts in storage battery work, owing to the fact that it is made up largely of the answers to questions written to the author as the editor of the "Model Engineer and Amateur Electrician."

## LEGAL NOTES.

ELECTRIC SNAP SWITCHES. — The United States Circuit Court of Appeals at Boston has reversed the decree of the Circuit Court in the case of the Hart & Hegeman Manufacturing Company of Hartford, Conn., vs. the Anchor Electric Company et al., alleging the infringement of a patent granted to Gerald W. Hart. The Court of Appeals sustains the Hart patent and orders the case remanded to the Circuit Court for further proceedings.

## PERSONALS.

DR. S. S. WHEELER, president of the Crocker-Wheeler Electric Company, recently returned to New York City from a visit to Havana.

MR. GEO. J. JACKSON, secretary of the National Conduit and Cable Company, has returned to New York City after a short absence in Europe.

MR. F. A. LARKIN, New York manager for the E. P. Allis Company, of Milwaukee, Wis., has returned from a short business trip in Europe.

MR. W. A. STADELMAN, New York manager for the Brown Hoisting and Conveying Machine Company, of Cleveland, Ohio, has returned from Yucatan, after a month's trip in the tropics.

W. J. CLARK, general manager of the General Electric Company's foreign department, sailed on the Etruria for Liverpool recently. He will remain abroad four months, to complete the organization of his department and to look after the installation of General Electric apparatus in London, Bristol and Dublin.

Mr. C. S. KNIGHT, formerly of the Fort Wayne Electric Corporation, has been elected vice-president and general manager of the Siemens & Halske Electric Company of America. It is understood that a number of other former members of the Fort Wayne Company's staff will join forces with Mr. Knight. The appointment of Mr. Knight is by many taken to indicate the inauguration of a more vigorous business policy on the part of the company, which has the use in America of all the data, patents and designs of the parent company in Berlin. The latter owns the most extensive electrical works in the world and does a more comprehensive electrical business than perhaps any other establishment the world over, as it manufactures a complete line of power and lighting apparatus as well as telephone, telegraph, submarine cable and other signaling equipments and supplies. The American company has hitherto but touched upon this wide field. Mr. Knight was connected with the Pennsylvania Railroad until 1881, joining the Fort Wayne Electric Company in 1886. He has been since 1894 a director of the Fort Wayne Electric Corporation, which has handled the business under contract with the receiver of the original company.

## TRADE PUBLICATIONS.

THE ELECTRIC APPLIANCE COMPANY, Chicago, Ill., has issued a revised price list of pole fittings, telephone wire, lamp cord, speaking tubes and cut outs.

THE METROPOLITAN STEAM BOILER COMPOUND MANUFACTURING COMPANY has issued a circular of testimonial letters from users of the Metropolitan compound for cleaning steam boilers.

THE UNITED CORRESPONDENCE SCHOOLS of New York City has published a book of testimonials entitled, "What Students Say," showing the appreciation of those who have taken its courses.

THE GARTON-DANIELS ELECTRIC COMPANY, Keokuk, Ia., has distributed a number of slips pointing out the necessity for lightning arresters on railway cars and railway overhead lines, and calling attention to the good points of Garton-Daniels' arresters in these locations.

THE NOVELTY ELECTRIC COMPANY, of 50 North Fourth Street, Philadelphia, Pa., has issued a catalogue No. 16 of house material, listing practically all the interior fittings for bells, gas burners, telephone instruments, etc., and also a special catalogue covering the fan motors which it carries.

JAS. M'CREA & COMPANY, of 1113 South Canal Street, Chicago, Ill., report that they have received more unsolicited testimonials of their climax steam joint clamp for repairing leaks where pipes are screwed into fittings from electric light and street railroad power plants than from any other one industry.

"THE AMERICAN TELEPHONE" is the name of a publication of which number 1 of Vol. 1 is dated April, 1899. Although nominally a monthly periodical devoted to the interests in general of independent telephone associations, it is evidently published in the interest of the American Electric Telephone Company of Chicago.

THE SPRAGUE ELECTRIC COMPANY has circulated a folding picture of a yachting scene made up after the style of the old-fashioned valentine, representing several yachts in full sail and intended to convey the idea that a Lundell motor never gets becalmed. The illustration should certainly appeal to the children.

THE ELECTRIC STORAGE BATTERY COMPANY has issued a circular abstracting some of the vaulable information given in the paper on "Latest Progress in the Application of Storage Batteries," read by Mr. Joseph Appleton before the meeting of the New York Electrical Society in January.

THE ELECTRIC GAS LIGHTING COMPANY, 195 Devonshire Street, Boston, has issued a small catalogue entitled, "A Few Specialties in the Line of Electrical House Goods." Among them are the star electro-mechanical gong, as well as various types of switches, push buttons, indicators, bells, etc., suitable for interior work.

THE LYNN INCANDESCENT LAMP COMPANY, of Lynn, Mass., has published a neat little pamphlet pointing out the fact that about $20,000 every month is simply thrown away in the United States by breaking up incandescent lamps and throwing away the glass, the metal base and the platinum wire, simply because the carbon filament is broken, and mentions the fact that 3 cents per lamp means $7.50 per barrel.

THE NATIONAL INDIA RUBBER COMPANY, Bristol, R. I., has issued a new catalogue of the N. I. R. & Paracore wares and cables made by its electrical department. The catalogue contains the proceedings of the special committee of the Underwriters' National Electric Association, constituting the improvements in the national code, which will make it of particular value to wire users who have not as yet become acquainted with all the details of these changes in the code.

"THE WILKINSON STOKER" is the title of a handsome catalogue published by the Wilkinson Manufacturing Company, of Philadelphia, Pa., describing the Wilkinson automatic mechanical stokers and smoke preventors, as well as several other specialties manufactured by the same company, notably the Wilkinson patent condenser and valveless pump, the Wilkinson trunk engine, the vertical archimedean-screw coal lift, the Wilkinson "land engine" ejector condensor and Wilkinson's paragon metallic packing.

THE PETITE ARC LAMP has been handsomely illustrated in a recent catalogue issued by the Western Electric Company. The Petite Arc Lamp is made in a number of different styles, so that it is suitable for use under different conditions. In the catalogue can be found some valuable information regarding the care and operation of enclosed arc lamps. As the Petite Arc Lamp is suitable for street railway plants, power circuits and isolated plants, these catalogues are valuable to those connected with installations of this kind.

DIRECT CONNECTED RAILWAY GENERATORS is the subject of a bulletin issued by the Westinghouse Electric and Manufacturing Company, superseding an older bulletin on the same subject, with the latest up-to-date descriptive matter and illustrations. The bulletin illustrates one of four 800-k.w. engine type generators in the power house of the South Side Elevated in Chicago, as well as an 800 k.w. machine used by the Consolidated Traction Company in Pittsburg. It also describes the method used by the Westinghouse Company for balancing the magnetic circuits of parallel wound machines.

THE CUTLER-HAMMER MANUFACTURING COMPANY, of Chicago, Ill., has issued a perpetual catalogue on rheostats, consisting of a convenient binder in which may be fastened properly punched sheets listing the various types of motor starters made by the company whenever these sheets are printed and sent to its customers. Among the devices of recent design listed in these sheets is the C. & H. pressure regulator, which consists of a diaphragm supporting a weighted lever, which in turn opens or closes with a snap the circuit of the solenoid of the C. & H. self-starter. Sheet No. 72 also shows the reversing switch for electric elevators designed for use in connection with the same self-starter.

THE RACINE HARDWARE COMPANY, of Racine, Wis., has issued a catalogue describing the Racine Automatic Engines. This company's specialty in steam engine work consists of vertical, high-speed, single-valve, shaft governing engines, made in sizes from 2 to 37 H.-P. The valve is a simple form of piston valve. The governor is of the Rites inertia type. All engines are fitted with an outbearing beyond the fly wheel secured to an extended base, giving additional support

Digitized by Google

and stiffness to the crank shaft. The machines are well adapted to the running of isolated electric light plants, particularly in cramped locations, where their high speed of about 400 r. p. m. fits them for direct coupling to small generators of standard design.

THE WESTERN ELECTRIC COMPANY, of Chicago, Ill., has published a bulletin under date of March, 1899, on the Stanley lighting transformers which it carries as western agents. One of the good features of these transformers as there pointed out is the fact that all sizes are made for the same regulation, so as to maintain an evenly distributed e. m. f. in all installations and to facilitate the running of transformers in multiple, as where two or more transformers of different drop with increased load are operated in parallel the one having the best regulation will tend to take more than its share of the load. The Western Electric Company also carries in stock Stanley alternating current motors for any standard voltage and frequently from ¼ h. p up to 10 h. p.

THE SHAW ELECTRIC CRANE COMPANY, Muskeegon, Mich., has issued an illustrated catalogue of electrically operated cranes that on account of the beauty of its illustrations and the completeness of its descriptions deserves a place in scientific libraries. The catalogue illustrates and describes various types of bridge cranes, from the mammoth 80-ton double trolley equipments of some steel works and the 70-ton single trolley of the Watervliet Arsenal down to the comparatively small types used in central stations. A crane of particular interest to those owning power stations is that built for extra slow speed and therefore fitted with small motors, high speeds and large motors being unnecessary where the crane is not in constant use. This crane is also fitted with wire rope instead of chains, which reduces the size and weight of the trolley.

THE SPRAGUE ELECTRIC COMPANY, New York City, has issued another of its characteristic catalogues, this one describing the 1899 Lundell fan motors. As usual the catalogue is a striking and attractive piece of work, the general scheme of its finish being white and gold on green. Some interesting anecdotes are given of the use of Lundell fan motors, one of them being as follows:

An officer of the "Amphitrite" states that had it not been for the Lundell fans on board of his ship, as well as on board of the "Terror," "Miantonomah" and "Puritan," during the cruise in the Carribean Sea, the mortality among the men would have been distressingly increased. The thermometer in the ward rooms and steerage more times than not registered above 115 degrees. In the engine room the temperature was usually above 135 degrees and in the fire room 140 to 150 degrees. Fans were distributed in these various locations, as well as in the ward rooms and officers' staterooms.

THE ELECTRIC STORAGE BATTERY COMPANY, of Philadelphia, Pa., has issued circular No. 49, dated April 3, describing and illustrating the Hartford battery station of the New York, New Haven & Hartford Railroad. As traction engineers will remember, the third rail line of the New York, New Haven & Hartford Railroad, running from Berlin to Hartford, is supplied from a power station at the former end and current is taken from it at Hartford to light the railway station and adjacent buildings. The railway voltage varies all the way from 200 to 550 volts and these extreme fluctuations, of course, tend to transmit themselves through the motor generator to the lighting mains. To keep a regulation sufficiently accurate for incandescent lamps in the latter service a storage battery of 62 cells is installed. In order to prevent the fluctuations of the third rail circuit from affecting the storage battery too severely the motor of the motor generator set is wound with special compound coils so connected that when the third rail voltage falls and the battery tends to discharge power back through the motor generator, it weakens the field of the motor and tends to maintain the set at constant speed and vice versa.

## BUSINESS NEWS.

THE FISCHER EQUIPMENT CO. of Chicago has built an electrically driven ambulance for the Michael Reese hospital of that city.

OUTDOOR SUMMER LIGHTING.—In order to meet the demand for decorative lighting the Western Electric Company has placed on hand a large supply of weatherproof sockets.

THE ELECTRICAL ENGINEERING PUBLISHING CO., publishers of "Electrical Engineering and Telephone Magazine," has removed its offices from the Monadnock block to the Marquette building in Chicago.

MANNING, MAXWELL & MOORE, the well-known dealers in railway machinists' supplies, move on May 1st to far more commodious quarters in the new Singer Building, 85 Liberty Street, New York City.

J. JONES & SON, New York City, sell fans for use on both lighting and battery circuits, the latter complete with battery outfits. Few, if any, makers carry both styles, but users and local dealers can obtain both from one source by giving their orders to this house

LARGE ISOLATED PLANT GENERATORS.—The Great Northern Hotel, of Chicago, Ill., which for many years has been supplied with current from the central station mains, has recently transferred its load to its own plant, which consists of three 150-k.w. Western Electric generators.

A LARGE PUMPING ENGINE of the crank and fly wheel type has been ordered by the Water Commissioners of Dunkirk, N. Y., from the Snow Steam Pump Works of Buffalo, N. Y. The engine will have a capacity of four million gallons, and will be fitted with Corliss valve gear, controlled by a new design of governor.

THE WESTERN ELECTRIC COMPANY, in its manufacture of fan motors, not only looks after the balancing of the armatures, but also weighs the fan blades and inspects and balances the fans independently of the motors before assembling. This careful attention to detail is one of the reasons why the Western Electric fan motors are so quiet and satisfactory.

THE CONTINENTAL IRON WORKS of Brooklyn advocates the use of internally fired boilers for land as well as marine purposes, and is pushing the Morison suspension furnaces for use in electric light and power plants. The works recently issued an illustrated catalogue of boilers fitted with these furnaces, giving complete drawings showing details of construction.

THE STROMBERG-CARLSON TELEPHONE MANUFACTURING COMPANY announces that it has not, as has been reported, been a party to the proposed amalgamation of the independent telephone interests. Having a complete public exchange apparatus, a multiple switchboard, a central energy system, an inter-communicating system and a combined police signal and telephone system, the company naturally feels that it can safely remain independent of the proposed independent consolidation and profit thereby.

THE STAR BRASS WORKS, Kalamazoo, Michigan, have recently received some testimonial letters which speak most highly of the hard brass trolley wheel made by them. The Mt. Clemens Fast Line of Detroit, Michigan, reports that it has run one 29 days on a car drawing 100 amperq and running at 48 miles per hour, the car mileage being about 250 miles per day, with the bushing still as good as new. In another case the wheel ran through sleet and ice that burned out the harps and bushings of other wheels constantly.

A CASE OF SAVING BY MEANS OF MECHANICAL DRAUGHT.—The United States Cotton Company, of Central Falls, R. I., has made a remarkable record in the way of low fuel cost which for one year amounted to $5.80 per i. h. p., the average output being about 1500 h. p. This low figure was primarily due to the use of a low grade mixture, costing only $2.29 per ton, the burning of which was rendered possible by the introduction of mechanical draught. The fan, costing less than $600, built by the B. F. Sturtevant Company, of Boston, Mass., effects an annual saving of no less than $6500 in the fuel bill.

# A COMMUTATOR NECESSITY.

**For Sale by all Supply Houses.**

**Upon receipt of this coupon we will send FREE, sample stick.**

THE ERICSSON TELEPHONE COMPANY announces that its offices are being moved from 20 Warren Street to 296 Broadway, New York City.

THE BELKNAP MOTOR COMPANY, Portland, Me., has appointed Mr. A. W. Koenig as its representative for the middle and southern states after May 1st, 1899.

THE ONONDAGA DYNAMO COMPANY and THE S. E. I COMPANY, of Syracuse, N. Y., have placed the general agency for their goods in New York City and the territory contiguous thereto in the hands of Mr. Jay Holmes at 39 Cortlandt Street, New York City.

THE COMMERCIAL ELECTRICAL SUPPLY COMPANY, of St. Louis, Mo., has passed out of the hands of its former owners and into the control of Mr. Wm. F. Nolker, sons and associates, who hope to make the company one of the foremost supply houses of the West.

THE AMERICAN SILK MANUFACTURING COMPANY, of Philadelphia, Pa., announces that it is meeting with remarkable success with its engine and dynamo wiper, made out of pure raw silk to take the place of the ordinary cotton waste generally used for this purpose.

THE SHAWMUT FUSE WIRE COMPANY, of 93 Federal Street, Boston, Mass., was burned out of both office and factory at this location on March 27. The company has secured permanent quarters at 161 High Street, Boston, where it will be pleased to receive customers and friends.

THE WESTON ELECTRICAL INSTRUMENT COMPANY is preparing for the construction of its new factory at Waverly, N. J., a suburb of Newark. Ground will be broken in a few days for the erection of what will probably be one of the most complete manufacturing establishments in the country.

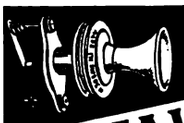
THE ELECTRICAL BUREAU OF THE NATIONAL BOARD OF FIRE UNDERWRITERS has removed its Chicago office and Laboratory to No. 67 E. Twenty-first Street, where all communications to the Western office of the bureau, or to Mr. W. H. Merrill, Jr., the electrician of the bureau, should be addressed.

THE CLAYTON & LAMBERT MANUFACTURING COMPANY, of Ypsilanti, Mich., maker of gasoline fire pots, etc., has recently contracted for a new factory adapted to its increasing needs. The new works will be located in Detroit, the structure being of brick and stone 40 x 75 feet and three stories high.

THE STANDARD UNDERGROUND CABLE COMPANY of Pittsburg, Pa., is now furnishing a 2 conductor cable 2500 ft. long for the Tennessee and Arkansas Telephone Company, to be placed under the Mississippi River at Richardsons' Landing, Tenn. The company has been using an overhead wire for a year, but it gave too much trouble.

THE CUTLER-HAMMER MANUFACTURING COMPANY, of Philadelphia, has recently certified to an increase in its capital stock from $50,000 to $100,000, the fourth increase in the six years of its existence, the original capitalization being $10,000. The increase was, as were the others, necessary for carrying on its rapidly increasing business.

THE ABILITY TO MAKE OR EVEN READ an elaborate drawing with all the conventions and refinements of modern drafting is a most valuable and rather rare attainment among electrical engineers who have not seen active drafting room service. The International Correspondence Schools of Scranton, Pa., offers short courses in mechanical drawings with complete drawing outfits, which make the acquisition of this attainment comparatively easy.



THE HARRISBURG FOUNDRY AND MACHINE WORKS have been awarded the contract for engines of a capacity of over 4000 h. p. for the immense new plant of the Great Northern Paper Company, which will be the largest paper producing plant in the world. There are ten engines in the order.

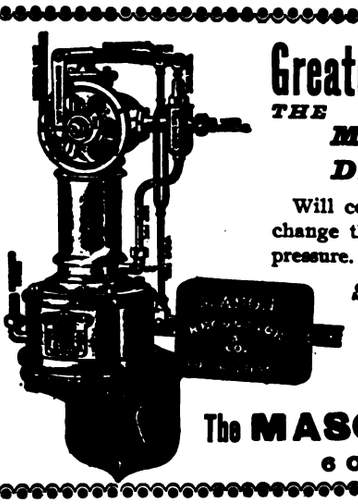
Digitized by Google

each engine weighing 60,000 pounds, which will develop 350 h. p., maximum capacity 400. This order is just one-half of the entire order, the aggregate of which will be nearly ten thousand horse power. This is the largest order for engines of the wheel governing type ever placed in this country.

THE ANNUAL MEETING of the stockholders of the Joseph Dixon Crucible Company was held at the company's main office, Jersey City, N. J., Monday, April 17, and out of a possible vote of 7,345 shares, there were 7,069 shares voted for the re-election of the old board, consisting of Edward F. C. Young, John A. Walker, Daniel T. Hoag, Richard Butler, William Murray, Alexander T. McGill and Joseph D. Bedle. President E. F. C. Young, Vice-President and Treasurer John A. Walker, Secretary Geo. E. Long were re-elected by the directors. Judge Joseph D. Bedle was also re-elected as counsel.

THE WARD LEONARD ELECTRIC COMPANY has put on the market the "TR" type of motor speed regulator suitable for machines from 1/16 to 1 h.p. inclusive. The resistance material in this regulator consists of wire wound around pottery tubes, which are then covered with two or more coats of specially prepared porcelain enamel, completely covering and hermetically sealing the resistance. These tubes are made up in three standard sizes, rated according to their power dissipating capacity, viz., 36 watts, 72 watts and 144 watts, continuous duty, there being 26 different graded resistances for each capacity unit.

THE MONTAUK MULTIPHASE CABLE COMPANY has recently received a large additional order from Melbourne, Australia for its fire detective cable. It is quite remarkable that an American product of such recent production has created a demand for itself at such a great distance. A noted fire department engineer has recently stated that if he could have five minutes' notice of any fire he could suppress the same in the next five minutes. The Montauk Multiphase Cable gives instant notice of dangerous heat. The company has recently opened a branch office in the Brazer Building, 27-29 State Street, Boston, Mass., at which place the various electrical adaptations of the cable are shown with sections of the dangerous parts of buildings and the way in which they may be wired for detecting fire.



THE WATERTOWN STEAM ENGINE COMPANY announces that the New York State Hospital at Ogdensburg has just installed a new plant, including four Watertown high-speed engines. The new four-valve Watertown high speed is making a very satisfactory record for economy. Results are especially satisfactory when the engine is running (as must sometimes happen) at much less than its rated horse-power. For example: An engine whose normal load is 180 H.-P. has at times been put to do the work of only 75 H.-P., and this it has done with less steam consumption than a standard high-speed engine of good make of 80 H.-P. In other words, the four-valve Watertown engine at less than 50 per cent. of its rated load has shown better economy than the standard high-speed engine at nearly or quite its full load.

**HAUNTS IN THE WILD WOODS**

AND

**GAY PLACES FOR SUMMER OUTINGS.**

Either or both, can be found along the lines of the Chicago, Milwaukee & St. Paul R'y in Wisconsin, Minnesota, Northern Michigan, Iowa and the Dakotas. Among the many delightful summer resorts are Delavan, Waukesha, Oconomowoc, Elkhart Lake, Marquette, Madison, Kilbourn, Minocqua, Star Lake, Lakes Okoboji, Spirit Lake, Clear Lake, Big Stone, Frontenac, White Bear and Lake Minnetonka. In the north woods of Wisconsin, in the forests of Northern Michigan and Minnesota, and in the far stretches of the Dakotas true sportsmen can fish and hunt to their heart's content. For pamphlet of "Summer Tours," and "Fishing and Hunting," apply to nearest ticket agent, or address with two cent stamp, Geo. H. Heafford, Gen'l. Pass Agt., 555 Old Colony Building, Chicago, Ill.

# American Electrician.

Vol. XI | New York, June, 1899. | No. 6.

## SOME ENGLISH CENTRAL STATIONS.

### ILLUSTRATING FEATURES OF CENTRAL STATION ENGINEERING DIFFERING FROM AMERICAN PRACTICE.

The development of central stations, or as the English call them, "electricity works," has proceeded in England apace with that in America, so that unlike electric traction, which has copied and therefore closely resembles American practice. English central stations have many details and even main features quite strange to American eyes. As a rule the English stations are small as compared with the general run of central stations on this side of the water, owing perhaps to the fact that the English towns were already as a rule equiped with gas plants before electric lighting was perfected; while American towns have largely grown up since the development of electric lighting, so that the central station has often preceded the gas works.

There is this striking difference, however, between these small English central stations and those of the same size here, viz., that the English plants are invariably worked out on the plan of low depreciation and a permanent investment, with the highest class of direct coupled machinery, high grade switchboards, underground distributing systems, etc., thoroughly studied to allow for future extension and to remain in service—barring revolutionary changes in practice—for 50 to 100 years to come. Taking the average run of plants of the same size throughout the rural towns of this country and especially of the West, it will be found that they are generally equipped with wooden buildings, belted machines of various types arranged and erected in any way that came handy, skeleton switchboards, slipshod overhead pole distribution, etc. This comparison is not intended as a severe criticism of American practice, as the rapid growth of American cities makes any intelligent provision for the needs of a score of years hence impossible at the present time, so that an expensive plant would prove an unwise investment, while the comparative stability of the English population makes a predetermination of the needs of the future more accurate.

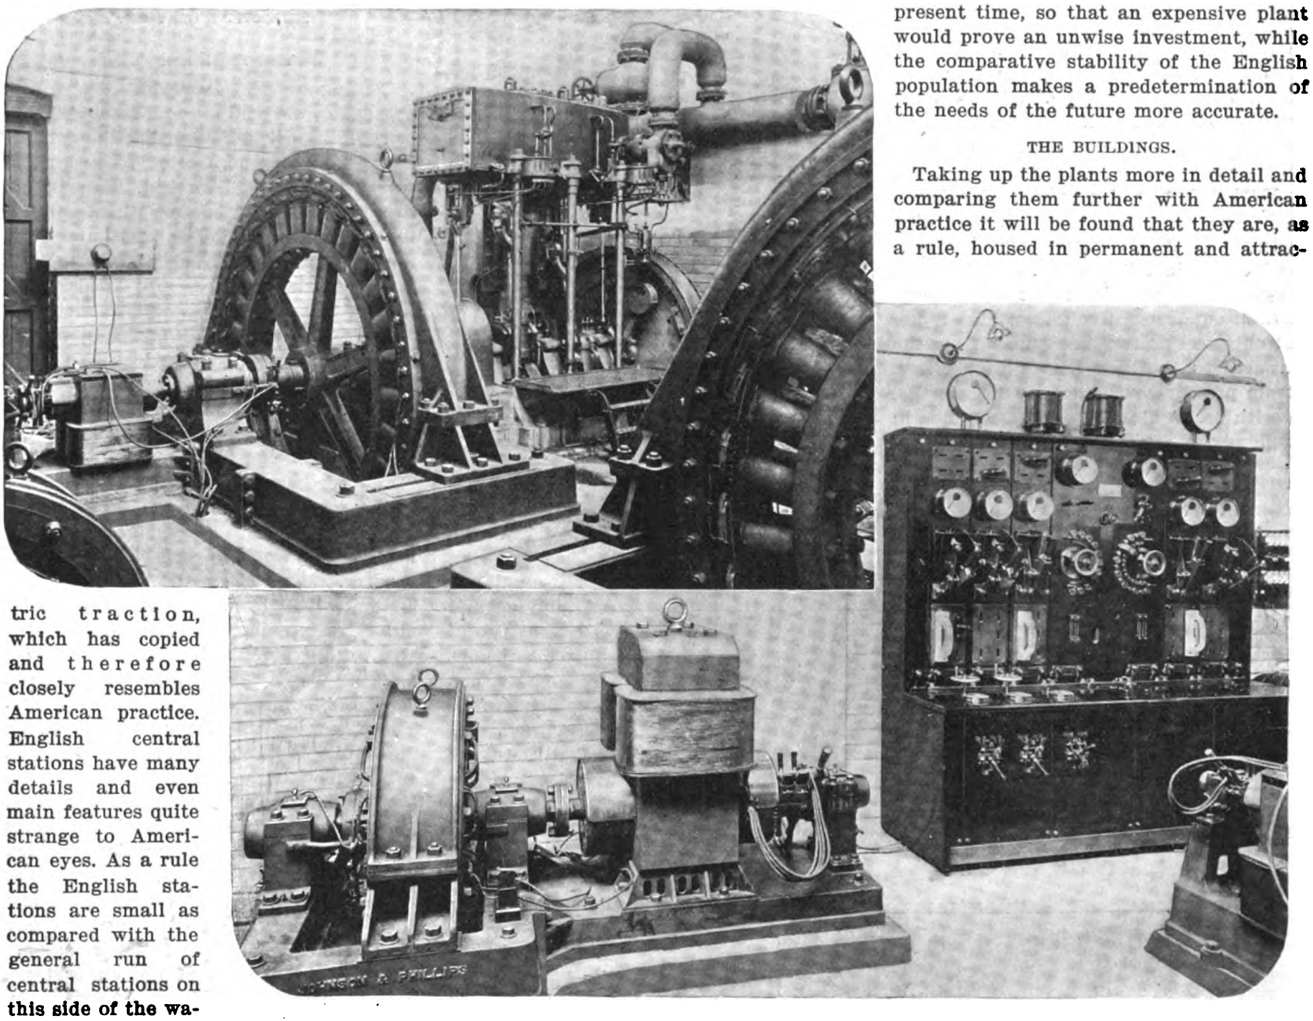

FIG. 1.—TWO VIEWS OF THE ALTERNATING CURRENT STATION AT ECCLES.

#### THE BUILDINGS.

Taking up the plants more in detail and comparing them further with American practice it will be found that they are, as a rule, housed in permanent and attractive appearing brick structures, generally designed with considerable architectural taste, resembling more than anything else municipal waterworks and similar public structures in this country. High brick stacks are customarily used, forced or induced draught being apparently almost

Digitized by Google

unknown. The exterior of a typical structure for this purpose is shown in Fig. 1. The general lay out of the plants also resembles that now approved in this country, viz., a pair of main bays parallel with each other, one containing a row of boilers backed up against the division wall between the two bays, just the other side of which is a corresponding row of engines and generators. In the plant shown in the illustration referred to there are two such main bays, which are arranged with a row of coal bunkers in a separate structure running alongside the boiler house and a battery room adjacent to the engine room. This particular plant follows also the general custom now favored in this country of using steel truss roofs and an overhead crane spanning the engine room.

### THE BOILER EQUIPMENTS.

Coal conveying apparatus is comparatively rarely used, while on the other hand mechanical stokers are quite common. Fig. 3 shows a view of three boilers, two of which are fitted with automatic stokers, the appearance of which is strange to American eyes, as is the use of such stokers fed by hand. Although the water tube boiler is finding its way into English central stations, most of them still prefer the comparatively old and well-tried Lancashire and similar internally fired types, such as are represented in Fig. 3. Nothing resembling these boilers is found in this country, containing as they do no small fire tubes such as we have in our locomotive and marine types, but only one or two main tubes from the furnaces to the rear end of the boilers. Steam pressures vary around 150 pounds, as with us. A steam specialty common in England, but unknown here, is a special safetly valve attached to a float inside of the boiler, which opens the valve in case of low water. Such a valve is shown in the section of a Lancashire boiler—Fig. 5.

Economizers are found in England much more frequently than in this country and the general layout of the steam piping closely resembles that known here, the only difference being perhaps the more general use in England of duplicate headers, ring mains, duplicate feed piping, and the liberal use of copper bends, branches, etc. Motor driven feed pumps, etc., are gradually taking the place of direct acting steam pumps in England, as well as in this country. An ingenious arrangement of pump valves and by-passes for grouping together on one valve board the complete controlling arrangements of two pumps with either hot and cold feed or suction to either or both pumps is shown in Fig. 6.

FIG. 2.—EXTERIOR OF THE FOLKESTONE MUNICIPAL PLANT.

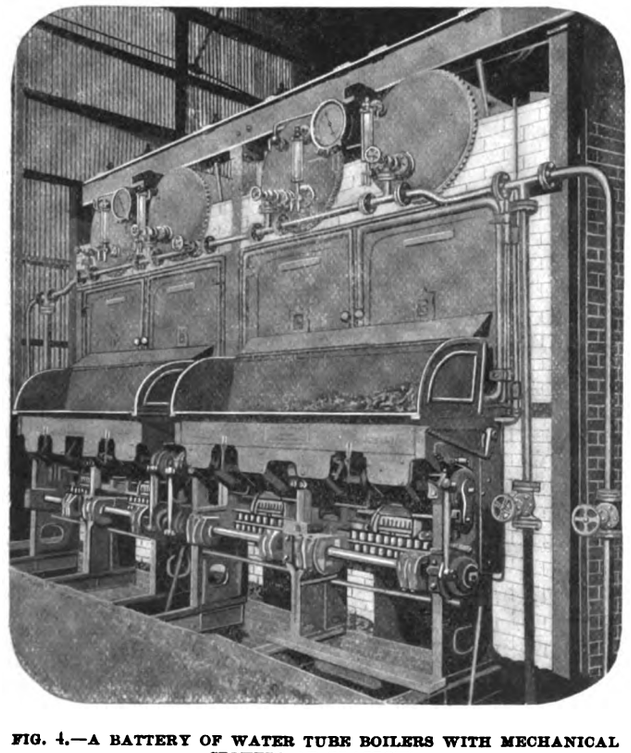

FIG. 4.—A BATTERY OF WATER TUBE BOILERS WITH MECHANICAL STOKERS AT GLASGOW.

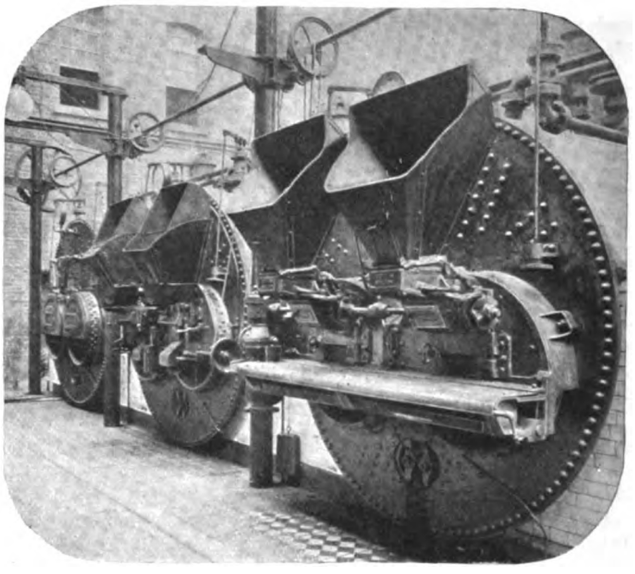

FIG. 3.—THE BOILERS OF THE BELFAST MUNICIPAL STATION.

### THE ENGINE ROOM.

Coming to the other side of the wall separating the engine room from the boiler room it will be found that the average English plant generates only one kind of current and uses vertical, high speed, two or three crank engines direct coupled to the generators. The horizontal high speed engine so often used in central stations and almost universally used in isolated plants in this country is practically unknown in England. The Willans engine is apparently the greatest favorite in English work, Fig. 9 showing an equipment of this kind, using both 2 crank and 3 crank Willans engine, each of the steeple compound type.

Another peculiarity of English practice is the continued use of the throttle governor, which has almost gone out of existence for work of this kind in this country. Very often the throttle valve is controlled by a shaft governor by means of a collar transmitting the motion to the valve, and is often fitted with a spring which can be adjusted while the engine is running, for varying the speed. The writer knows of one plant in which the voltage is regulated in this way, as well as the distribution of the load between the dynamos running in parallel with each other, the field rheostats being rarely disturbed. In direct-current plants, which preponderate in England, these engines are mounted with their crank shafts low down between two girders cast in one piece, which, extended, forms a support for bipolar dynamos of the under type, i. e., with the fields above the armature. Fig. 7 shows such an arrangement. The generator field magnets are as massive as those of the now obsolete Edison bipolar type, so widely used at one time in this country, and give good regulation, without compound windings, owing to the stiffness of the fields.

The favorite system of distribution is the 3-wire, the English patents on which have already expired, and in all new

Digitized by Google

plants the voltage adopted is 400 to 450 volts between the outers using 200 to 220 volt lamps between each outside main and the neutral. The current is often generated by three wire sets, consisting of two of these bipolar dynamos coupled to opposite ends of the engine shaft as the lower illustration of Fig. 10 shows, but in many plants single generators, giving 450 volts, are connected straight across the outer conductors, these generators taking the main part of the load, any difference between the loads in the positive and negative sides being taken up by the balancing sets. In some plants 3 wire balancing generators are not used at all, all of the generators giving the full voltage between the positive and negative mains, the proper voltage of the neutral being maintained midway between that of the outers by means of balancing transformers consisting simply of two 225-volt machines coupled together and connected in series across the outer mains with the neutral connected between them. In case this balancing set fails for any reason, the storage battery, which is an invariable accompaniment of these plants, can be depended upon to maintain the balance, the neutral being connected in to the middle of the battery.

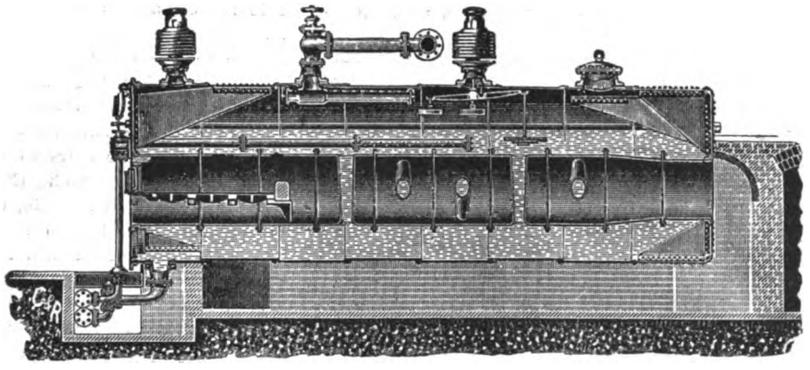

FIG. 5.—CROSS SECTION OF A TYPICAL LANCASHIRE BOILER.

Another method of direct current generation quite well known in this country is what is known as the "Oxford" system, in which the power station generates direct current at a voltage much higher than that at which it is used, and may, therefore, be situated some distance from the district supplied. A notable plant of this kind is that at Shoreditch, which has become quite famous owing to its use of refuse for fuel, the dynamos there generating direct current at 1100 volts constant potential, which is transmitted to sub stations and then transformed down by means of motor dynamos, or what have been termed in this country, dynamotors, i. e., direct-current machines with two windings and two commutators on one armature and with one set of fields. A notable feature of some machines of this kind is the use of a grounded metallic shield between the high and low-tension windings to prevent the high-pressure current from getting into the distribution system.

Fig. 8 illustrates part of a sub station of this kind where the power is transformed from the pressure of 2200 volts at which it is generated, to 450 volts, at which pressure it is distributed in a 3 wire system. A storage battery across the low-tension mains constitutes a part of the equipment of a part of this sub station. In such cases the power station is also, as a rule, equipped with low-tension dynamos to supply loads in its neighborhood, with storage batteries and motor generators to transform from the low to the high pressure or vice versa. The fields of the high-pressure machines are in that case supplied with current from the low-tension mains to avoid the use of very fine wire. Fig. 9 illustrates such a plant, the two larger machines giving 2250 volts and the two smaller machines in the background the low-tension, the motor generating set in the foreground serving as a link between the two.

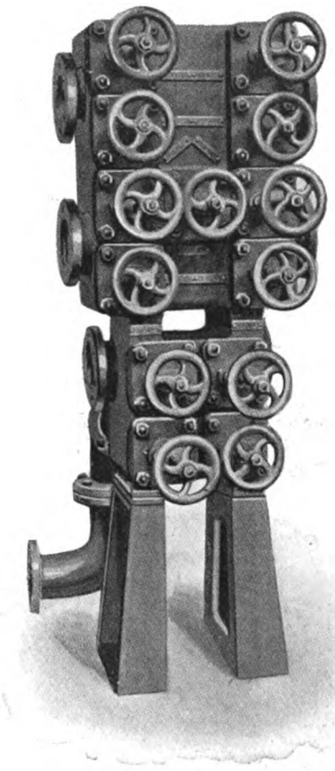

FIG. 6.—A PUMP VALVE BOARD.

Owing to the use on 3 wire systems of pressures double as high as are used in this country, the stations are enabled to supply the scattered loads of the smaller cities without recourse to alternating currents, so that alternating current plants are not as frequently found as in America.

ALTERNATING CURRENT PLANTS.

A few facts about one representative plant, however, and another that stands alone, there being nothing like it the world over, are given below.

The first is illustrated in Fig. 1, being, like many of those illustrated and described above, a municipal undertaking. The engines are cross-compound, of a vertical marine type, open front and direct coupled to revolving field fly wheel alternators, which generate 120 kw. each with a frequency of 50 cycles per second. The engine governors are of what is known in England as the "Begtrup" type, utilizing a single weight, and corresponding to the Rites inertia governor familiar here. The exciters are bipolar machines direct coupled to the ends of the alternator shafts. In this plant there is also what is known as a motor alternator, which is shown in the illustration. It consists of a bipolar direct-current machine coupled to a synchronous alternator, with a capacity of 25 kw. The direct-current end of this machine is run with a 56-cell

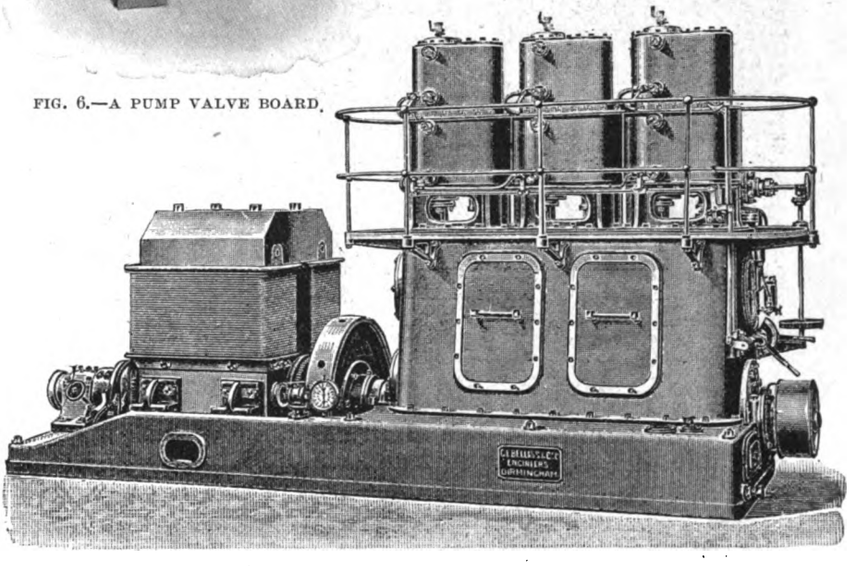

FIG. 7.—A TYPICAL GENERATING SET.

Digitized by Google

storage battery, which it charges at convenient times, the storage battery carrying the whole alternating current load by means of the transformer action of the motor alternator, at times of light load, as after midnight. This machine also helps to smooth out the load curves of the station and to avoid running the two alternators when the load is somewhat too large for one but not sufficient to run both with a good economy. A peculiarity of this battery is the fact that its cells, which contain 55 plates each having a capacity of over 1500 ampere hours at a 2-hour discharge rate, are enclosed in lead boxes mounted on oil insulators.

The other alternating plant referred to as forming a class by itself is the world-famous Deptford installation of the London Electricity Supply Corporation, to which a new machine has recently been added which is shown in section in Fig. 11. This, like its predecessors, is a Ferranti single phase alternator of the disc type, i. e., with a thin, ironless armature revolving between the field poles. The flat, thin armature coils form a disc outside the rim of the fly wheel, to which they are bound by bolts, as the illustration shows. This machine generates 10,000 volts direct in its own coils. The windings of the coils cannot very well be insulated against this high voltage from the frames in which they are held owing to lack of space, so each individual frame is carefully insulated from the fly wheel rim by bedding the bolt deeply in an insulating substance and surrounding it by a deeply corrugated insulating sleeve, which gives a long surface distance between the coils and the fly wheel. These corrugated covers of the bolts can be seen in the upper part of the machine, the lower ones not requiring them, as the winding is simply grounded at one end to the fly wheel. For this reason only one collector ring is necessary, and that is shown at the right hand side of the machine with similar bolts fastening it to the hub. To prevent the current from jumping from the coils to the poles which approach them very closely on either side, the latter are covered with micanite caps. The wheel, which is of cast iron and split, runs at a very high speed for a fly wheel of this size, viz., 156 r. p. m., giving great centrifugal strains, which are resisted by means of 6-in. tie bolts fastening its rim to a ring shrunk on to the shaft inside the hub, there being 8 of these tie bolts spaced around the wheel between the spokes.

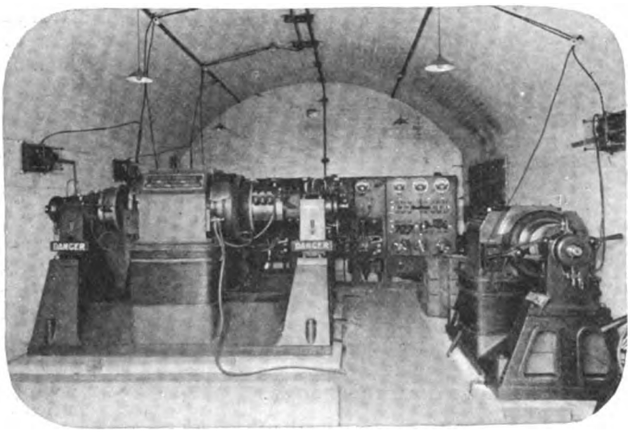

FIG. 8.—A MOTOR GENERATOR SUBSTITUTION AT HULL.

The speed gives the armature coils, which have a pitch diameter of some 20 ft., the enormous peripheral velocity of about 10,000 ft., or almost two miles per minute. There being 64 poles on each side of the armature, the frequency is about 83 cycles per second. This machine, with others of the same type in the same station, undoubtedly generates a

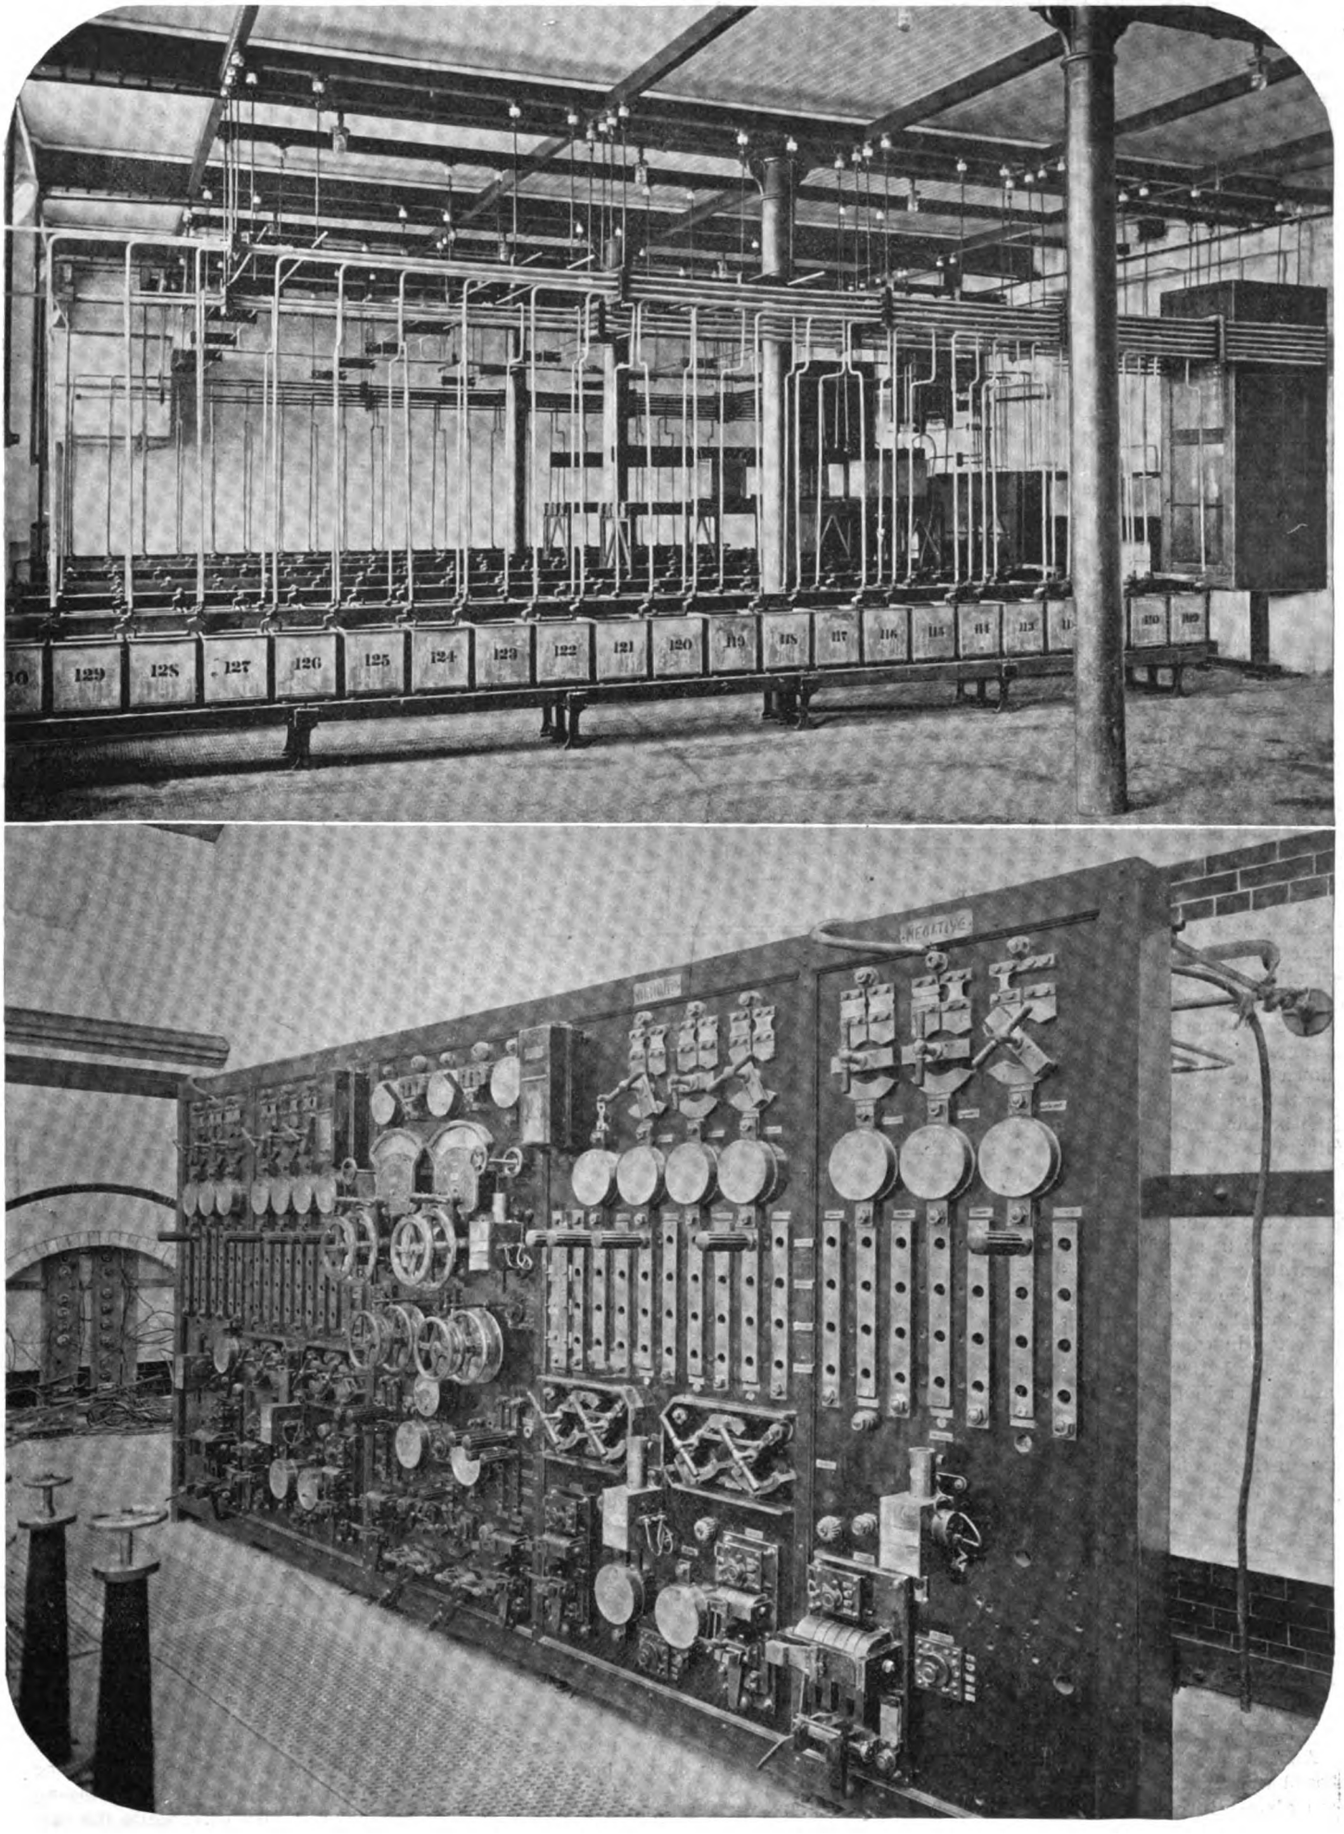

FIG. 10.—THE STORAGE BATTERY AND SWITCHBOARD OF THE MUNICIPAL CENTRAL STATION AT BELFAST.

Digitized by Google

voltage higher than any other machine with a revolving armature, and probably enjoys, also, the distinction of having a much higher linear speed at the air gap than any other dynamo machine the world over. The engine which drives it consists of a 3-crank, 6-cylinder, steeple compound set, rated at 2200 h. p. It is governed by three ordinary fly ball throttle governors, one for each high pressure cylinder, and the steam is controlled by piston valves in the high pressure and slide valves in the low pressure cylinders, driven by single eccentrics, the whole machine being of the simplest character.

SWITCHBOARDS.

Switchboards and switchboard details differ, of course, from American practice much more than do larger machines, owing to the greater chances for many different and equally satisfactory designs of each part. Slate seems to be the accepted material for switchboard panels, marble being rarely, if ever, used. The lower half of the illustration, Fig. 10, shows a board in which the connections between the dynamos and the several bus bars are made by means of plugs similar in principle to the early types of telegraph plug boards. Across the back of the board the bus bars run horizontally, while the dynamo terminals are connected to vertical strips on the front of the board, so that by proper plugging, various combinations of circuits can be made.

English generators are, as a rule, connected through automatic circuit breakers, which are almost invariably fitted with underload release, i. e., so arranged that when the load falls off to a certain small value, such as 10 per cent. of the rated output of the machine, the breaker opens automatically. With such an arrangement all that is necessary to shut down a dynamo is to turn off the steam. As the speed falls the load falls off until the breaker opens when the dynamo delivers but little or no more current. Sometimes the breakers are also fitted with overload release and sometimes fuses are used. Circuit breakers of this type may be seen in the lower part of the board shown in Fig. 10. The fuses at the top of the same board have rotating switches by which another fuse may be inserted in case one burns out.

Storage batteries on the 3 wire system are as a rule fitted with end cells connected not between the main battery and the outer mains, but in the middle, between the two halves of the battery proper and the neutral, thus all the end cells of both sides of the system are brought together in series with each other, where they may, if desirable, be separately charged by one low voltage machine. Boosters are often used also for charging the batteries, and as a rule are driven by being simply coupled to the balancing motors described above, Fig. 13, showing such a set, consisting of two balancers and two boosters.

Another peculiarity of English switchboard work is the fact that the dynamos are almost invariably controlled at one polarity; thus in the case of the 3 wire system the connection from the machine to the neutral is left permanently in and the switches, fuses, circuit breakers, ammeters, etc., are all connected between the machines and the outer bus bars. Even in the case of alternating plants the same principle is carried out, the big Deptford machine described above being grounded at one polarity, the other polarity only being carried to the switchboard. This practice probably originated from the fact that it is quite customary in England to permanently ground 2 wire systems, which practice may be traced further to the prevailing use there of concentric feeders, the outer conductor of the feeder being the grounded one to reduce the strain on the insulation surrounding it, and in fact to practically do away with the need of any such insulation.

Another detail of switchboard work strange to American eyes is the arrangement of the panels on the board, shown in Fig. 1. Here all the six panels are hinged at the bottom in such a way that they may be swung forward to examine the connections behind them, in which position all the contacts to the panel are broken, leaving the switches and all instruments upon them dead.

DISTRIBUTING SYSTEMS.

Practically all electric wires are carried underground in England in lead-covered cables, which are not always, as in this country, drawn into conduits. Several vitrified conduit systems are in use,

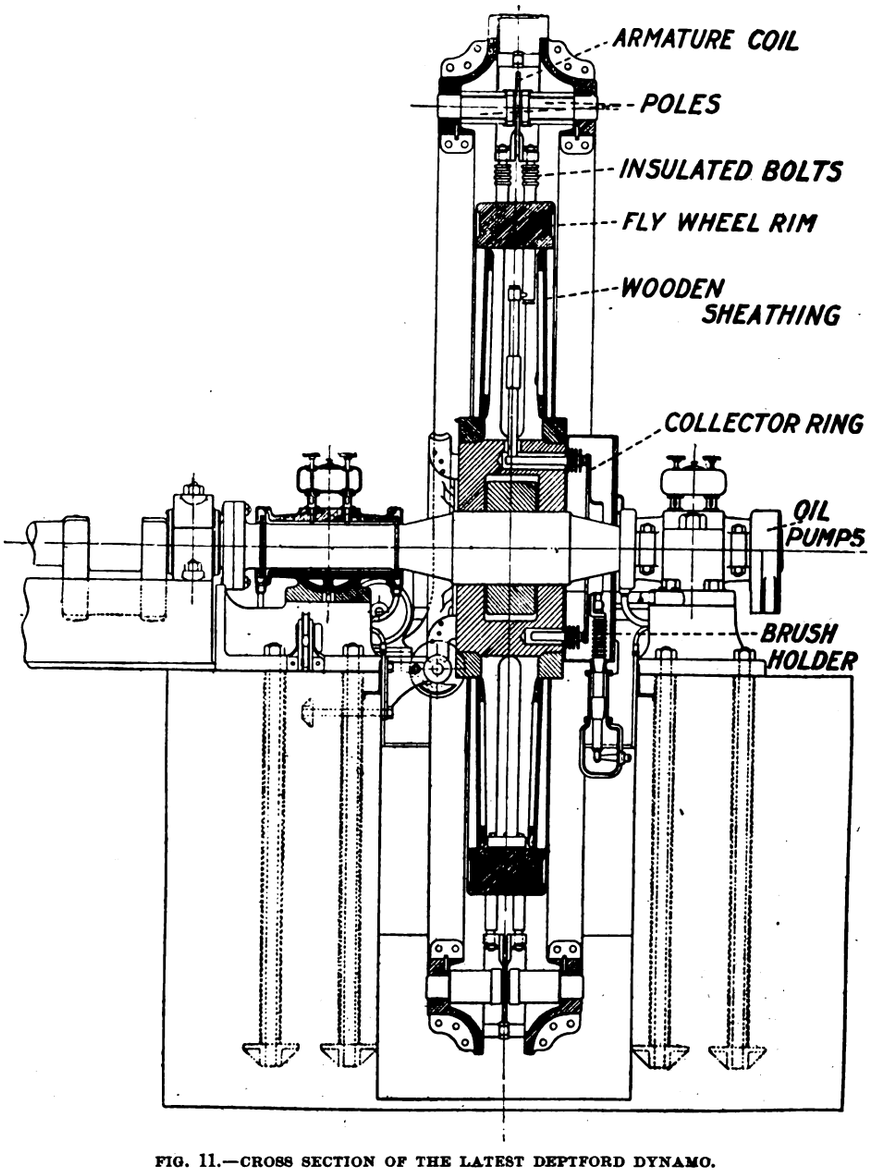

FIG. 11.—CROSS SECTION OF THE LATEST DEPTFORD DYNAMO.

but often the cables are yarned and armored by means of steel tape or wire and simply laid in a trench. Sometimes they are laid in a wooden box or trough, with pitch or bitumen run around them, while in other cases they are simply covered with boards to prevent workmen from striking them with picks. The feeders are almost universally concentric cables, in the case of three wire or three phase systems triple concentric, the outer conductor being the neutral or grounded one of the three. The central core or conductor is, as a rule, a cable made up of ordinary stranded wire, while the sur-

Digitized by Google

rounding conductors are often made up of copper straps interlocked. These concentric cables were also used for distributing mains in the past, but the latest practice seems to favor 3-core cables, not concentric, but somewhat similar to the cables used in this country. These are lead covered and are often joined by means of cast-iron coupling boxes, filled with an insulating cement, similar to the coupling boxes used on the Edison tubes under American streets.

ARC LIGHTING.

Very few series arc machines are used in England, the majority of direct current plants running the arc lights from the constant potential mains just as is done in this country by the Edison companies, but with a greater number of arcs in series on account of the higher voltage. The plants working on the "Oxford" system described above, with constant potential direct current machines giving 1100 or 2200 volts, work arcs on multiple series 20 or 40 lamp circuits across these high voltage constant potential mains, connected up just as series incandescent circuits are in this country.

One peculiarity of English street lighting is the fact that the arc lights are rarely run after midnight, the arc light poles being fitted with incandescent lights, generally two per pole, which are switched on when the arc lights are turned off, very frequently by automatic switching devices. Alternating current plants supply their arc lights by means of rectifyers, which transform the alternating current to a direct current and automatically regulate so as to keep the current constant on a series circuit, no matter how many lamps are burning. A view of one of the most recent machines of this class is shown in Fig. 14, this being designed for a 50-light circuit supplied from sin-

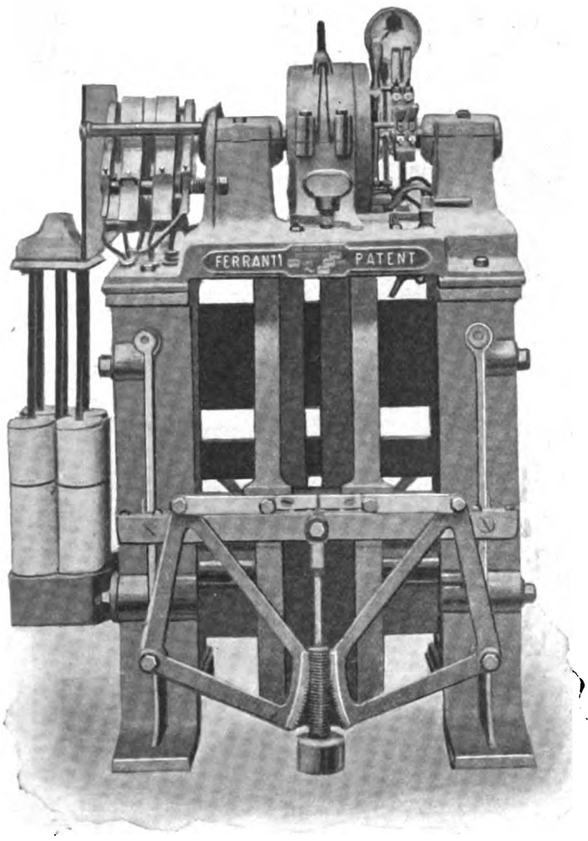

FIG. 14.—A RECTIFIER FOR ARC LIGHTING.

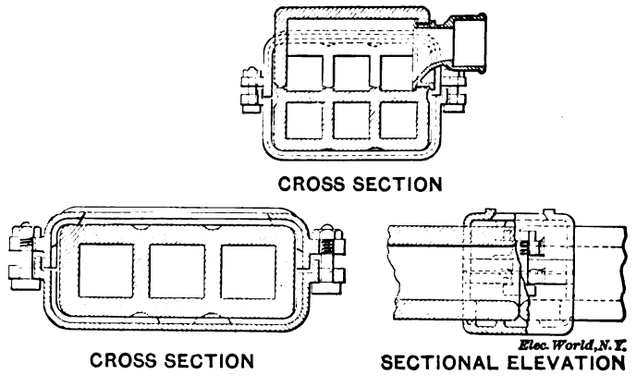

FIG. 15.—CROSS SECTION OF CONDUIT SHOWING METHOD OF JOINTING AND OF ENTERING A SERVICE.

FIG. 16.—THE IMPRESSED E.M.F. FROM A RECTIFIER.

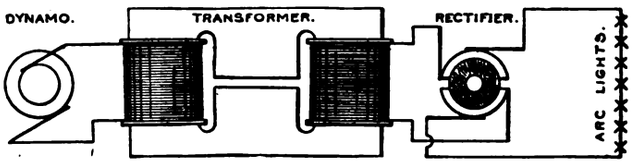

FIG. 17.—GENERAL SCHEME OF CONNECTIONS OF RECTIFIER.

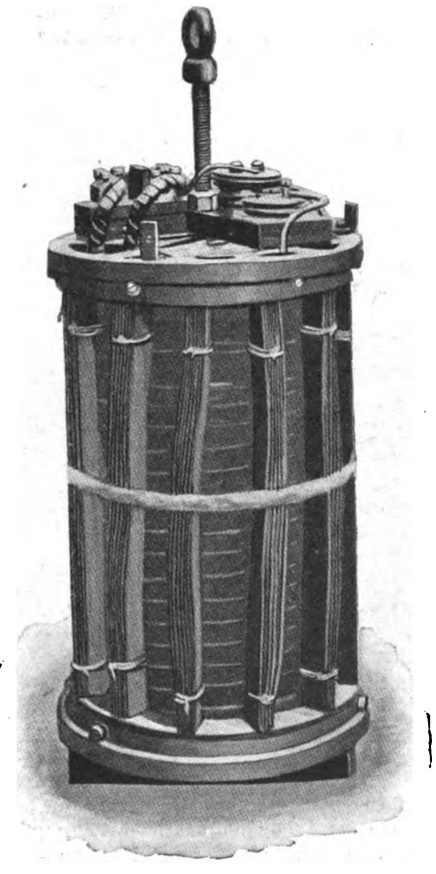
gle phase currents of the usual frequency in England, viz., 50 cycles, multiphase alternators, by the way, being a great rarity in English central stations.

The general principle of the rectifier consists in the rotation of a commutator through which the arc light circuit is fed from a special transformer. By this means one-half (let us say all the negative) waves of current are reversed in the arc light circuit, which gets, therefore, a current which is unidirectional. This current, coming as it does from single phase supply, is pulsatory in character and has a wave form which may be represented roughly by the diagram, Fig. 16. The general scheme of the connections of a rectifier is clearly indicated in Fig. 17. Here the alternating current dynamo is shown feeding a transformer of peculiar shape, having considerable magnetic leakage. In such a transformer the regulation for constant potential is very poor, in fact the machine gives almost constant current. In the English machine referred to above this regulation is accomplished in another way.

The general design of the machine shown in Fig. 14 comprises a synchronous alternating current motor mounted on the top of the machine and driving the commutator, which appears at the left hand end of the shaft. Below this is the transformer, which is designed to automatically regulate in such a way as to give constant current through the rectifier to the arc lamps from the constant potential of the alternating current mains. The transformer consists, as may be seen, of two horizontal cores, one above the other, and connected at their ends by vertical yokes embedded in the frame of the machine. Surrounding these cores are the primary and secondary windings, which are free to slide horizontally, or rather to swing horizontally, being mounted on frames hung from the body of the machine. In the position shown, the primary and secondary windings are quite close to each other and are held there by means of the weight and peculiar segmental gear arrangement in the lower foreground. When, however, the load is applied, the two sets of coils repel each other and tend to push away, this push being resisted by the weight above mentioned, which tends to force them together. If the current strength becomes greater than that needed by the arc lamps the coils push apart until the magnetic leakage becomes so great that the current is reduced to the proper amount, and vice versa. When more lamps are switched in to the series circuit the current falls, reducing the repulsion, the weight pulls the two coils together, diminishing the magnetic leakage and keeping the current nearly constant. At the left hand side of the machine is shown a group of four porcelain jars filled with water and constituting, with the carbon rods, a water switch, which is used to open the arc light circuit; the high self-induction of the transformer making this opening by any ordinary switch a dangerous proceeding.



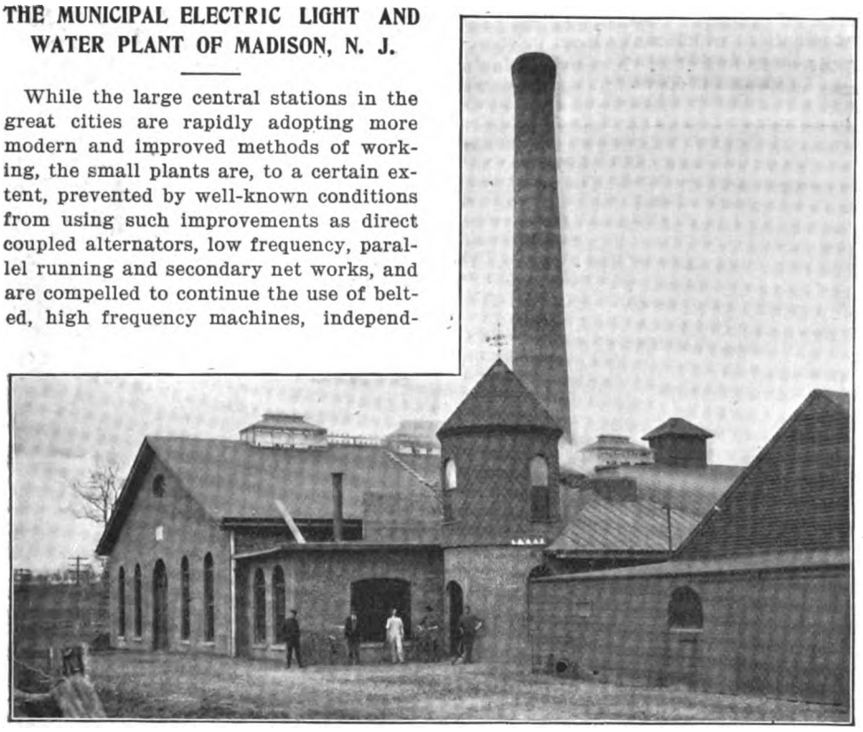


FIG. 18.—A MANHOLE TRANSFORMER.

Small house to house transformers are looked upon with disfavor in England owing to their low all day efficiency. Secondary mains, generally 3-wire, are favored, fed at intervals by large transformers. One of the latter, as designed for manhole service, is shown in Fig. 18.

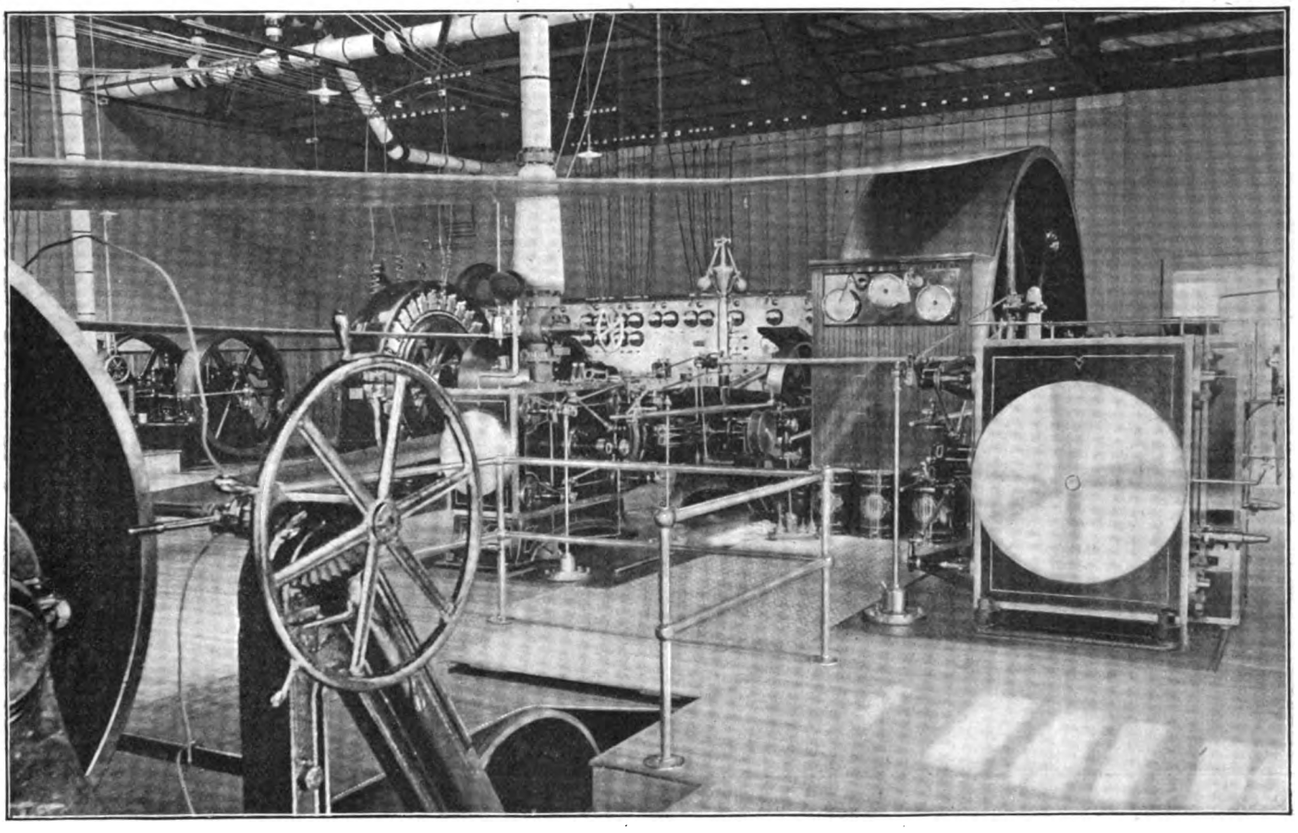
## THE MUNICIPAL ELECTRIC LIGHT AND WATER PLANT OF MADISON, N. J.



While the large central stations in the great cities are rapidly adopting more modern and improved methods of working, the small plants are, to a certain extent, prevented by well-known conditions from using such improvements as direct coupled alternators, low frequency, parallel running and secondary net works, and are compelled to continue the use of belted, high frequency machines, independently run with house to house transformers. That careful attention to details will allow such plants to depart from the general slip-shod characteristics of the old-fashioned central station and approach the trim appearance and economical working of a metropolitan plant—even when old machinery is kept in use as additions are made—is illustrated by an attractive, though small, municipal station in Madison, N. J.

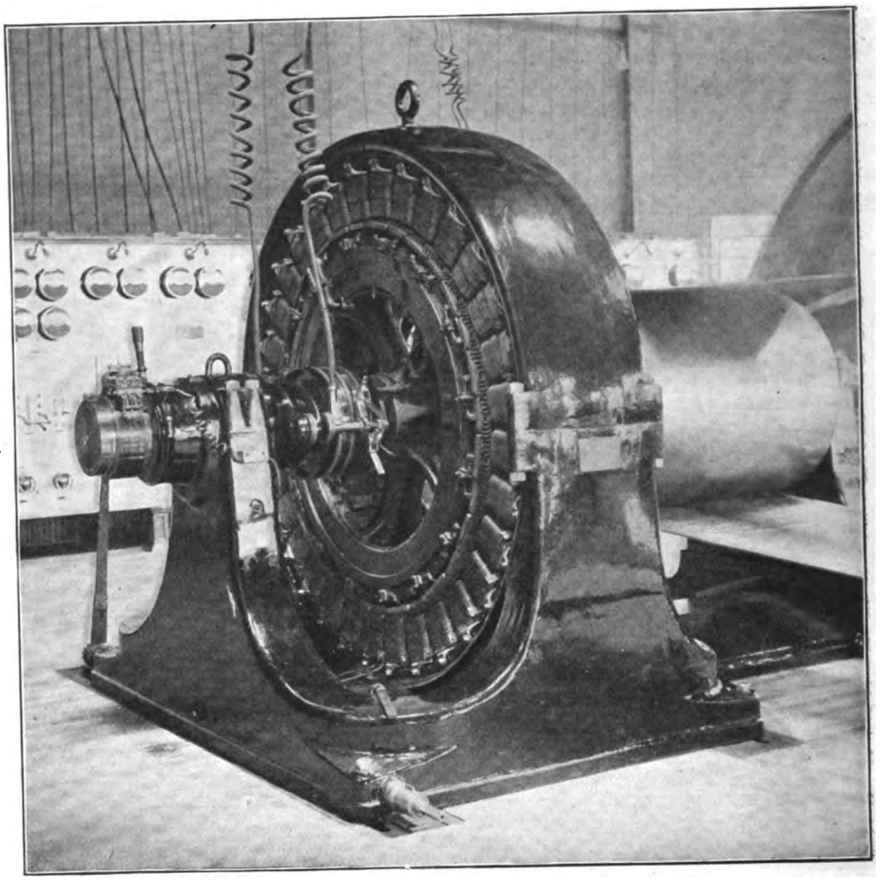
THE EXTERIOR OF THE MADISON MUNICIPAL STATION.

The Borough of Madison has a population of about 4000, the heads of families being largely "commuters" from New York and Newark, and as a rule of the wealthier classes. The one little lighting plant has no competition, there being even no gas system within the city limits. It therefore carries all the residence and street lighting, the former entirely on alternating house to house transformer circuits and the latter on series alternating incandescent circuits fed by the same generators.

The plant was first built about 10 years ago and has been so successful that the load has outgrown the equipment twice since, the present outfit being the third installation. The different steps represent well the evolution of central station engineering in the last decade; the first plant consisting of a 16x16 Ball & Wood high speed engine, direct belted to a 60 kw. T. H. alternator, and supplied with steam at moderate pressure. This was outgrown in two years' time and was enlarged by the addition of a Ball & Wood cross-compound belted to a 120 kw. alternator. Condensing appeared to be desirable at that time and the consulting engineer of the plant, Mr. C. O. Mailloux—who has served the borough in the same capacity from the time it started this municipal plant until the present—decided to make use of a small stream which, however, did not have a sufficient flow for condensing purposes. For probably the first time in this country in central station work, a cooling pond was used, the cooled water being taken to the condens-

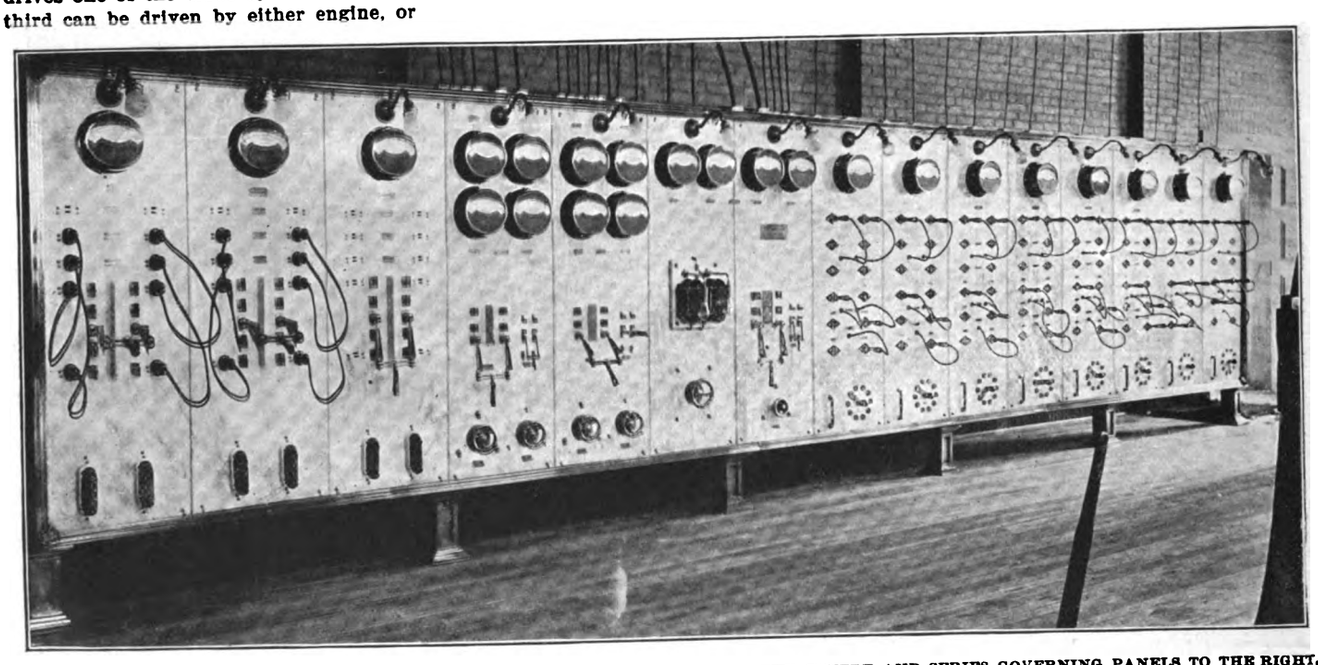
AN INTERIOR VIEW SHOWING COUNTERSHAFT TO THE LEFT, SWITCHBOARD IN THE BACKGROUND AND CORLISS ENGINE TO THE RIGHT.

Digitized by Google



ers from one end of it and returned to the other, radiation and vaporization being depended upon to dissipate the heat given to the pond by the hot discharge of the condensers.

A few years later this plant was outgrown and the building was enlarged, new apparatus was bought and combined with the old to make the existing arrangement. The cross-compound engine was retained and belted to one end of a countershaft, to the other end of which was belted a new cross-compound Corliss engine made by Hewes & Phillips.



This engine has several details which particularly fit it for successful operation in a plant of this kind. The governor controls the cut-off on both the high and low-pressure cylinders, the connection from the governor to the low-pressure tripping mechanism being fitted with an attachment so that the relative percentage of cut-off in the two cylinders may be varied at any time by hand, even when the engine is running. The engine is also piped so that it may be run as two simple engines instead of one compound, increasing the capacity and doing away with the need of a larger engine to carry occasional overloads, which would reduce the efficiency at normal loads.

A new dynamo of twice the capacity of the larger one already in service was purchased and the three generators were belted to a countershaft with two friction clutches, made by the Hill Clutch Company, dividing the shaft into three sections, each end section respectively carrying the pulleys of one engine and dynamo, the middle section carrying the third dynamo, so that each engine always drives one of the three dynamos and the third can be driven by either engine, or all three sections can be coupled together and the load thereby distributed between the two engines.

The generators consist of two old T. H. alternators and one new Westinghouse machine with several improvements of recent adoption, which make it an interesting piece of apparatus. It delivers single phase current at 1100 volts with 16,000 alternations per minute and is rated at 250 kw. The armature winding is not of the unitooth or pole wound type buried in large slots, one to each pole, customary in such machines, but is distributed in a large number of slots, eight per pole. These slots are almost uniformly spaced on the surface of the armature, one tooth of each eight being, however, wider than the others. The slots are parallel sided and the armature windings are slipped into them and fastened by wooden strips in a way similar to that used on the windings of direct current machines made by

THE 250 KW. GENERATOR WITH DISTRIBUTED WINDING AND ROTATING SERIES TRANSFORMER

THE SWITCHBOARD, SHOWING FEEDER PANELS TO THE LEFT, MACHINE PANELS IN THE CENTRE AND SERIES GOVERNING PANELS TO THE RIGHT.

Digitized by Google

the same manufacturers. The conductors are form wound into a sort of spiral or "pan cake" coil, which is slipped into the eight slots, four on each side of the central wide tooth.

Another peculiarity of this machine is the fact that the armature current itself does not pass through the rectifying commutator and series coils of the composite wound field. Rotating with the armature is a series transformer which supplies the commutator and series field with a derived current proportional to the armature current going to the collector rings. This series transformer, in order to balance the armature, is divided in two parts placed diametrically opposite to each other.

The switchboard is unusually complete, compact and flexible for a plant of this kind. It consists of 15 marble panels, four for the machines, three for feeders and eight for the series circuits and was built by Sheehan & Hewitt of Newburgh, N. Y. Each machine has four instruments consisting of the usual alternating current voltmeter and ammeter and a direct current voltmeter and ammeter for the exciter. Six bus bars are carried the length of the board, a pair for each of the three machines, and the feeder panels, which appear at the left hand end of the accompanying illustration, are fitted with double throw switches and flexible cords by which the clips of either the top or bottom of the switch may be connected to any desired one of the three pairs of bus bars. Thus the commercial feeders may be thrown from one dynamo to another without interrupting the circuit for more than a fraction of a second. If the switch is in the upper position, it is only necessary to connect the cables from the lower clips to the sockets of the desired bus bars and then throw the switch down. It is impossible to accidentally multiple the dynamos, as the plug on the end of the cable connecting to the switch clips is larger than that connecting to the bus bar.

It was aimed in the construction of the board to place all of the lightning arresters, the ground detector, the meters, station transformers, etc., which are objectionable on the face of the board, to the back of the board. For this purpose there was provided a slate slab for each one of the panels, which is held in position by suitable iron brackets and on these slate slabs are mounted the instruments and transformers named above. Thus the face of the board is kept free from those instruments, transformers, etc., which render the same unsightly.

The series circuit panels at the right hand end of the board are fitted with flexible cords and plugs by which each circuit can be connected to any one of the three machines, each panel also containing Messrs. Sheehan & Hewitt's series governing device, by means of which the current in the series circuits can be closely adjusted to the desired 5½ amperes over a wide range of resistance variations. This is acomplished by means of a transformer on the back of the panel by which the voltage delivered to the series circuit may be boosted up or down in large steps and a dial switch in the lower right hand corner of the panel, by which small inductive resistances can be cut into the circuit to compensate for the single lamps.

## ECONONY OF MULTIPLE EXPANSION ENGINES.

BY WM. S. ALDRICH.

The influence of accessories upon the economy of multi-expansion engines may be such as to entirely offset the advantages to be derived from using such a type of engine in electric power plants. Boilers, fuel economizers, feed-water heaters, have each their characteristic features and introduce variable elements in the economical working of any power plant under variable loads. Steam pumps and condensers, on the one hand, and steam jackets and re-heating receivers, on the other, introduce alike indeterminate elements under variable loads. It is impossible to do more than merely call attention to the influence of these accessories upon the economical working of the plant. It is quite improbable, however, that their varying economy under varying loads would amount to more than a small percentage of the total variation in economy of the boiler, engine and dynamo units under similar conditions.

The type and setting, methods of feeding and of firing boilers are of scarcely less importance, especially the latter. Whether hand firing or automatic stoking is adopted, the greatest care must be observed to conserve the coal pile under the varying steam supply called for by the variable demands of the electrical supply. Variations in steam quality, in storage capacity, and in efficiency are not very marked for the common types of boilers used in central stations at the present day. Whether fire or water tubular boilers are to be adapted for multi-expansion engines, the practice appears to be following closely marine precedents, as the steam pressures keep going up higher. But departures must be made to suit the new conditions and these, of course, are chiefly in the direction of larger steam spaces to adapt the boiler plant to the rapidly varying demand made upon it in electrical work, all in marked contrast to the steady loads on boilers and engines in marine service and pumping plants.

Steam jackets have not come into favor in multi-expansion engines for either electric light or railway service. From the steadier loads of the former supply it might appear that steam jackets would improve the economy, but much depends upon the skillful handling of the jackets by the engineer in charge. In railway service, the varying quantities of steam used in the cylinders cannot be accompanied by an adaptation of the steam jacket to meet these changes, producing quite variable cylinder condensation. The highly efficient jacket at one load may prove a positive loss at another load, unless so operated as to maintain such a source of heat supply for the cylinder walls as to fully make good the losses by cylinder condensation under the variable load and cutoff in any given cylinder. Altogether, the steam jacket is not an unmixed good when variable loads are considered. Its economical considerations are apparent and its reputation has been well established by more or less conclusive tests under old conditions, as in marine service and pumping plants.

Receivers for multi-expansion engines have fallen somewhat into disuse in marine service, where every effort is made to reduce weight of motive power machinery, and where it has been found that the usual piping and connections between cylinders furnish sufficient volume to prevent irregular changes in pressure from greatly influencing the economy of working. In mill engines and those for pumping plants, working as they do with very slight variations throughout the day, the practice is about equally divided, as to whether receivers shall be used or not. In electrical supply service and more especially in railway work, some provision must be made for meeting the frequent changes in volume of steam used and especially to provide that the expansion shall not be carried below the back pressure. At the same time, receivers offer every facility for re-heating the steam in its passage from one cylinder to the other. The advantages of this have been so frequently pointed out that it is only necessary here to notice this feature as one now quite essential to the economical working of steam in multi-expansion engines and especially in those of the two-cylinder type coming into extensive use directly connected to electric generators. By thus re-heating the steam, the moisture from its previous use in a high-pressure cylinder is converted into dry steam, and the whole quantity of steam may even be slightly superheated to compensate for cylinder condensation losses in the next cylinder.

The manner of working steam is of the most vital importance in determining the economy of multiple expansion engines under variable loads. As far as American practice is concerned it is primarily a question of how to obtain economic working of the steam with variable cutoffs in the use of high ratios of expansion. In general, it may be said that the conditions which insure a final release of the steam as dry steam will be conducive to economy. Therefore, if by any means we can work the steam from initial admission to final release so as always to insure the condition of final dryness of the cylinder walls at exhaust, we should secure the main point at issue in the operation of all steam power electric plants; namely, a more or less uniform economy for wide ranges of load variation. Initial superheating and the use of re-heating receivers conduce alike to bring about this result.

The influence of the number of cylinders upon the economy of multi-expansion engines is still open to discussion; that is, whether steam shall be worked from a given initial pressure through a given range of expansions to the condensing plant in two or three cylinders, by compound or triple expansion. It is altogether a timely topic for electrical supply. The present tendency is toward reducing the number of cylinders to effect any given wide range of expansion for two principal reasons, which are especially applicable to electric power plants; namely, the structural advantages of the two-cylinder compound type over the three-cylinder triple expansion type and the remarkably uniform economy of the compound type throughout wide ranges of load variations.

The two-cylinder type in practice admits of mounting the generator between the cylinders. The three-cylinder type requires an outboard mounting of the generators on an extension of the crank shaft, usually one generator on each end, subjecting the crank shaft to enormous bending moments sometimes brought on by the sudden and great load changes. Moreover, the greater the number of cylinders the greater the complication in mechanism, the greater care needed in operation and the consequent liability to derangement or to be thrown out of service altogether.

It is quite possible to obtain by compound working the same economy as in triple working, under the same conditions of pressure and number of expansions. Moreover, the variations in number of expansions due to variable cutoff incident to the load changes, can be more economically met in a case of compound than in triple working. Added to this are the additional advantages arising from a judicious use of reheating receivers, with more or less of the so-called "drop" in pressure between the high and the low pressure cylinders to meet the variations in terminal pressures due to changes in cutoff. Two-cylinder compounds with expansion of the steam from 20 to 30 times are now built and are working with a satisfactory economy. In earlier days the high ratios of expansion would have called for three or four cylinders.

Non-condensing compound engines that are not now economical may be made to yield better results by the use of superheated steam, and to such an extent as to offset the gain that would arise from changing them to the condensing type. In other words, there may be less expense in some plants attached to superheating the steam than in the introduction of a condensing plant. The improvement, however, in evaporative surface condensers and roof condensers have recently been so marked that it would be a close question to decide.

The quality of the steam used in multi-expansion engines throughout the whole range of its working is, of course, a far more important consideration that in simple engines. It is none the less so when the uncertain elements of variable load changes are introduced. These, no doubt, produce changes in the quality of the steam, from admission to final release, which, though not now fully determined, will in time show that the economy is greatly affected thereby. Aside from the considerations of variable economy due to greater or less number of expansions incident to load changes, it is quite probable that the other and most important factor is the quality of the steam throughout the cycle of its expansive working.

Superheated steam will bring about great improvement in any case. For each type of multi-expansion engine operating under a given set of conditions, or within certain limitations as to loads, it will be found that superheated steam will insure more uniform economy when carried to the extent best suited to the given set of conditions. In other words, practical experience and a few engine trials with various degrees of superheating will furnish such coefficient of superheat as will be applicable to new installations. While a slight degree of superheat is to be obtained by throttling, or the use of pressure-reducing valves, or by the American type of construction of water tubular boilers, it is not at all sufficient to realize from this source alone the full improvement in economy under variable loads, that is possible in multi-expansion engines. The higher the ratio of expansion the greater is the improvement in economy arising from this feature alone, as well as from the additional economy due to using superheated steam.

The degree of superheat best adapted to any engine cannot be fully predetermined, as the evil effects which it is expected to counteract in part cannot themselves be fully predetermined. This is entirely apart from any thermodynamic consideration of the improved economy due to superheating as such, and relates more to the making up of losses due to cylinder condensation. These latter losses have been found to vary with the cutoff of the ratio of expansion, and the kind of surface exposed to the steam by the cylinder walls. In any given engine these elements are very nearly constant, so that the best degree of superheat to compensate for these losses may be determined at once upon the installation being turned over for service.

It is not possible to separate this question entirely from that of the influence of type of engine upon economy. More especially, since the type of engine is largely determined by the way in which the steam is worked in multiple expansion; that is, whether with or without intermediate receivers between the cylinders, intermittent, or with continuous expansion. The non-receiver type of multi-expansion engine has certain meritorious features for driving electric generators, whether it is constructed in the form of a tandem or cross compound unit. In either case it is an adaptation of the so-called "Woolf" compound engine, in which the expansion line of the low-pressure cylinder follows very closely or may even coincide with the exhaust line of the high-pressure cylinder. In this way of working steam it has been found that remarkably uniform economy may be obtained throughout wide ranges of load variations without great structural complications, on the one hand, or the undesirable feature of negative power, due to looped indicator cards, on the other hand.

The high-pressure cylinder works against a variable back pressure, according to the cutoff, to suit the load changes; the low-pressure cylinder has, therefore, a variable initial pressure, as in the case of an engine controlled by a throttling governor. The lighter the load the earlier the cutoff in the high-pressure cylinder and the lower the initial pressure in the low-pressure cylinder. This type of compound engine has been made successful. Controlled either by throttling governor or by automatic cutoff regulation, it is a type of multi-expansion unit admirably adapted to isolated plants with high-speed direct-connected generators.

The plant economy as determined by the pounds of steam per kilowatt-hour, is the controlling factor in the final analysis of this question. The most economical multi-expansion engines may be very uneconomically operated, accompanied with like negligence in other portions of the installation. The highest attainable efficiency in the individual units that make up the installation of an electric power plant is no guarantee that the best economy of operation will be secured. Certain of these units will have a desirable range of economic working which may not exactly coincide with similar ranges for other units. Certain efficiencies will reach toward a maximum, while the efficiencies of another portion of the installation will be far from a maximum. Whatever the efficiencies of the individual units, it will still be found, in many instances, that the final result of operating all of them in combination under variable loads will be to give a maximum economic range at some proportional part of the full load of the plant, which point it would be scarcely possible to predetermine without working through all of the steps in the several transformations of energy.

However, a multi-expansion engine with quite a uniform rate of water consumption for a given range of load changes, directly coupled to a generator having a high maintained efficiency from about one-third load to its safe maximum overload, will in general produce the most satisfactory results when examined from the standpoint of economy of installation and operation. The pounds of water per kilowatt-hour in large generating units of this type may be kept within a range of ten per cent. variation over a range load from one-third to maximum output. Moreover, the operating expenses become more nearly uniform and quite irrespective of transient load variations in generating units of about 1000 kilowatts and over.

# THE CANDLE POWER OF ARC AND INCANDESCENT LAMPS.

## THE APPROPRIATE LIGHT UNIT.

BY PROF. WILBUR M. STINE.

The action of the American Institute of Electrical Engineers and of the National Electric Light Association in giving official indorsement to the opinion of scientists who have carefully investigated the subject, legalizing the amyl acetate lamp as the standard of illuminating power, renders all forms of candles obsolete for light standards. Relinquishing the candle as the concrete light standard, should the term candle-power be given up or retained?

For illustration, suppose the meter were the legalized standard of length, and that this action was generally accepted and measurements were made with meter-sticks instead of foot-rules, would it be advisable to employ the ratio of the meter to the foot, and having made the measurements with the meter unit, to express the measured dimensions in feet?
